19 **Abstract**

20 In recent years, ammonia emissions have been continuously increasing being almost four
21 times higher than in the 20th century. Although an important species as its use as a fertilized
22 sustains human living, ammonia has major consequences both for humans and the environment,
23 because of its reactive gas phase chemistry that makes it easily convertible to particles. Despite
24 its pronounced importance, yet, ammonia emissions are highly uncertain in most emission
25 inventories. However, the great development of satellite remote sensing nowadays provides the
26 opportunity for more targeting research in constraining ammonia emissions. Here, we used
27 satellite measurements to calculate global ammonia emissions over the period 2008–2017.
28 Then, the calculated ammonia emissions were fed to a chemistry transport model and ammonia
29 concentrations were simulated for the period 2008–2017.

30 The simulated concentrations of ammonia were compared with ground measurements
31 from Europe, North America and Southeastern Asia, as well as with satellite measurements.
32 The satellite-constrained ammonia emissions represent global concentrations more accurately
33 than state-of-the-art emissions. Calculated fluxes in the North China Plain were seen more
34 increased after 2015, not due to emission changes, but due to changes in sulfate emissions that
35 resulted in less ammonia neutralization and hence in larger atmospheric loads. Emissions over
36 Europe were also twice as much as those in traditional datasets with dominant sources to be
37 industrial and agricultural applications. Four hot-spot regions of high ammonia emissions were
38 seen in North America characterized by large agricultural activity, animal breeding, animal
39 farms and animal breeding and agricultural practices. South America is dominated by ammonia
40 emissions from biomass burning, which cause a strong seasonality. In Southeastern Asia,
41 ammonia emissions from fertilizer plants in China, Pakistan, India and Indonesia are the most
42 important, while a strong seasonality was observed with a spring and late summer peak due to
43 rice and wheat cultivation. Measurements of ammonia surface concentrations were better
44 reproduced with satellite-constrained emissions, so as measurements from CrIS (Cross-track
45 Infrared Sounder).

46

47 **1 Introduction**

48 Ammonia (NH₃) has received a lot of attention nowadays due to its major implications
49 for the population and the environment (Erisman, 2004; Erisman et al., 2007). These include
50 eutrophication of semi-natural ecosystems and acidification of soils (Stevens et al., 2010),
51 secondary formation of particulate matter in the atmosphere (Anderson et al., 2003), and
52 alteration of the global greenhouse balance (De Vries et al., 2011). More specifically in the
53 troposphere, ammonia reacts with the abundant sulfuric and nitric acids (Malm, 2004)
54 contributing 30 % to 50 % of the total aerosol mass of PM_{2.5} and PM₁₀ (Anderson et al., 2003).
55 Ammonium aerosols are therefore a very important component in regional and global aerosols
56 processes (Xu and Penner, 2012) also having significant implications for human health (Aneja
57 et al., 2009). Ammonia alters human health indirectly mainly through formation of PM_{2.5} (Gu
58 et al., 2014) that penetrate the human respiratory systems and deposit in the lungs and alveolar
59 regions (Pope III et al., 2002) causing premature mortality (Lelieveld et al., 2015). As regards
60 to the climate impact, the same ammonium aerosol particles affect Earth's radiative balance,
61 both directly by scattering incoming radiation (Henze et al., 2012) and indirectly as cloud
62 condensation nuclei (Abbatt et al., 2006). They may also cause visibility problems and
63 contribute to haze effect due to secondary PM formation.

64 Sources of ammonia include wild animals (Sutton et al., 2000), ammonia-containing
65 watersheds (Sørensen et al., 2003), traffic (Kean et al., 2009), sewage systems (Reche et al.,
66 2012), humans (Sutton et al., 2000), biomass burning (Sutton et al., 2008) and domestic coal
67 combustion (Fowler et al., 2004), volcanic eruptions (Sutton et al., 2008) and agriculture
68 (Erisman et al., 2007). The latter is responsible for the majority of ammonia global atmospheric
69 emissions. Specifically, in the United States and Europe about 80% of all emissions is related
70 to agriculture (Leip et al., 2015). Emissions have increased considerably since pre-industrial
71 times and are unlikely to decrease due to the growing demand for food and feed (Aneja et al.,
72 2008).

73 The growing attention in ammonia levels has enabled many monitoring actions in Europe
74 (European Monitoring and Evaluation Programme, EMEP), in Southeastern Asia (East Asia
75 acid deposition NETwork) and in the North America (Ammonia Monitoring Network in the
76 US, AMoN-US; National Air Pollution Surveillance Program (NAPS) sites in Canada) to
77 record surface concentrations of ammonia continuously. Recently, several satellite products
78 have been also developed in an effort to identify global levels of ammonia considering that the

79 relatively sparse existing monitoring network has an insufficient coverage for this purpose.
80 These are derived from satellite sounders as the Infrared Atmospheric Sounding Interferometer
81 (IASI) (Van Damme et al., 2017), the Atmospheric Infrared Sounder (AIRS) (Warner et al.,
82 2017), the Cross-track Infrared Sounder (CrIS) (Shephard and Cady-Pereira, 2015), the
83 Tropospheric Emission Spectrometer (TES) (Shephard et al., 2015), and Greenhouse Gases
84 Observing Satellite (Someya et al., 2020). Both IASI and CrIS ammonia products are being
85 continuously compared and evaluated against other observations and products. Relevant
86 analyses include comparison against column-integrated levels measured by Fourier transform
87 infrared spectroscopy (FTIR) (Dammers et al., 2016, 2017), ground-based measurements (Van
88 Damme et al., 2015; Kharol et al., 2018), bottom-up emissions (Van Damme et al., 2018;
89 Dammers et al., 2019) and atmospheric chemistry transport models (CTMs) (Shephard et al.,
90 2020; Whitburn et al., 2016a).

91 Despite its importance, ammonia is a poorly quantified trace gas, with uncertainties over
92 50% on the global emission budget and even higher on temporal and local scales (Dentener and
93 Crutzen, 1994; Faulkner and Shaw, 2008; Reis et al., 2009) and up to 300% for the agricultural
94 sector in Europe (European Environment Agency, 2019). In the present paper, we grid 10 years
95 (2008–2017) of satellite measurements of ammonia retrieved from IASI to calculate monthly
96 surface emissions (hereafter named NE) (see section 2). The same is done using the gridded
97 IASI ammonia column concentrations from Van Damme et al. (2018) (named as VD0.5 and
98 VDgrlf) (see section 2). The three different emission inventories together with a state-of-the-
99 art one, which is more often used by models (named as EGG), are then imported in a CTM to
100 simulate ammonia for the same 10-year period. More details of the different emissions used
101 here are shown in sections 2.4 and 2.1. Finally, an evaluation of simulated surface
102 concentrations against ground-based measurements from different monitoring stations and
103 satellite products allow to quantify the improvements in ammonia emissions.

104 **2 Methods**

105 **2.1 LMDz-OR-INCA chemistry transport model**

106 The Eulerian global CTM LMDz-OR-INCA was used to calculate ammonia lifetime, as
107 well as to simulate ammonia concentrations from the emission fluxes calculated from IASI
108 satellite products. The model couples the LMDz (Laboratoire de Météorologie Dynamique)
109 General Circulation Model (GCM) (Hourdin et al., 2006) with the INCA (INteraction with
110 Chemistry and Aerosols) model (Folberth et al., 2006; Hauglustaine et al., 2004) and with the

111 land surface dynamical vegetation model ORCHIDEE (ORganizing Carbon and Hydrology In
112 Dynamic Ecosystems) (Krinner et al., 2005). In the present configuration, the model has a
113 horizontal resolution of $2.5^{\circ} \times 1.3^{\circ}$, the vertical dimension is divided into 39 hybrid vertical
114 levels extending to the stratosphere. Large-scale advection of tracers is calculated from a
115 monotonic finite-volume second-order scheme (Hourdin and Armengaud, 1999), deep
116 convection is parameterized according to the scheme of Emanuel, (1991), while turbulent
117 mixing in the planetary boundary layer (PBL) is based on a local second-order closure
118 formalism. More information and a detailed evaluation of the GCM can be found in Hourdin et
119 al. (2006).

120 The model simulates atmospheric transport of natural and anthropogenic aerosols
121 recording both the number and the mass of aerosols. The aerosol size distribution is represented
122 using a modal approach that consists of the superposition of 5 log-normal modes that represent
123 both the size spectrum and whether the aerosol is soluble or insoluble (Schulz, 2007). The
124 aerosols are treated in three particle modes, sub-micronic (diameter $< 1 \mu\text{m}$) corresponding to
125 the accumulation mode, micronic (diameter $1\text{--}10 \mu\text{m}$) corresponding to coarse particles, and
126 super-micronic or super coarse particles (diameter $> 10 \mu\text{m}$). LMDz-OR-INCA accounts for
127 emissions, transport (resolved and sub-grid scale), and dry and wet (in-cloud/below-cloud
128 scavenging) deposition of chemical species and aerosols interactively. LMDz-OR-INCA
129 includes a full chemical scheme for the ammonia cycle and nitrate particle formation, as well
130 as a state-of-the-art $\text{CH}_4/\text{NO}_x/\text{CO}/\text{NMHC}/\text{O}_3$ tropospheric photochemistry. Further details
131 about specific reactions, reaction rates and other information entering into the description of
132 the ammonia cycle can be found in Hauglustaine et al. (2014).

133 The global transport of ammonia was simulated from 2007 to 2017 (2007 was the spin-
134 up period) by nudging the winds of the 6-hourly ERA Interim Reanalysis data (Dee et al., 2011)
135 with a relaxation time of 10 days (Hourdin et al., 2006). For the calculation of ammonia's
136 lifetime, the model ran with traditional emissions for anthropogenic, biomass burning and
137 oceanic emission sources using emissions from ECLIPSEv5 (Evaluating the CLimate and Air
138 Quality ImPacts of Short-livEd Pollutants), GFED4 (Global Fire Emission Dataset) and GEIA
139 (Global Emissions InitiAtive) (hereafter called EGG) (Bouwman et al., 1997; Giglio et al.,
140 2013; Klimont et al., 2017).

141 **2.2 Satellite ammonia**

142 **2.2.1 IASI ammonia**

143 The Infrared Atmospheric Sounding Interferometer (IASI) onboard the MetOp-A satellite
144 measures Earth's infrared radiation twice a day in a spectral range of 645–2,760 cm^{-1} with an
145 elliptical footprint with a diameter of 12 km at nadir (Clerbaux et al., 2009). Due to the larger
146 thermal conditions that lead to smaller uncertainties, only morning data were used in the present
147 assessment (Clarisse et al., 2010). Van Damme et al. (2018) reported limited impact of the IASI
148 overpasses of $4\% \pm 8\%$ on ammonia. The 10-year dataset used here is ANNI-NH₃-v2.1R-I
149 product (Van Damme et al., 2017) and relies on ERA-Interim ECMWF meteorological input
150 data (Dee et al., 2011). The Artificial Neural Network for IASI (ANNI) algorithm converts the
151 hyperspectral range index to an column-integrated NH₃ value (Whitburn et al., 2016a). The
152 latter relies on the fact that the indices can be converted to a column by taking into account the
153 spectral sensitivity to the ammonia abundance in the observed scene. The hyperspectral range
154 indexes are derived from linear retrievals using a constant gain matrix which includes a
155 generalized error covariance matrix (Van Damme et al., 2014b; Whitburn et al., 2016a). The
156 dataset also provides cloud coverage for each measurement (August et al., 2012). Only
157 measurements with a cloud fraction below 10% were processed in consistency with Van
158 Damme et al. (2018). Cloud coverage was not provided for all measurements until March 2010
159 resulting in smaller data availability before that date. Van Damme et al. (2014a) reported that
160 IASI better measures ammonia in spring and summer months, due to the strong dependence on
161 thermal contrast (error below 50%). For an individual observation, an IASI-retrieved column
162 is considered detectable when the vertical column density exceeds 9.68×10^{15} molecules cm^{-2}
163 (surface concentration $> 1.74 \mu\text{g m}^{-3}$) at a thermal contrast of 20 K, while the vertical column
164 density should be larger than 1.69×10^{16} molecules cm^{-2} ($3.05 \mu\text{g m}^{-3}$) at 10 K (Van Damme et
165 al., 2014a). Although the retrieval algorithm uses a fixed vertical profile, extended validation
166 of the resulting dataset has verified small uncertainties (Van Damme et al., 2015, 2018;
167 Dammers et al., 2016; Whitburn et al., 2016b). For instance, Van Damme et al. (2018) reported
168 a difference of $2\% \pm 24\%$ (global average) in column-integrated ammonia using different
169 vertical profiles in the retrieval algorithm.

170 **2.2.2 CrIS ammonia**

171 The Cross-Track Infrared Sounder (CrIS) was first launched on the NASA Suomi
172 National Polar-orbiting Partnership (S-NPP) satellite on 28 October 2011 in a sun-synchronous
173 low Earth orbit. The CrIS sensor provides soundings of the atmosphere with a spectral

174 resolution of 0.625 cm^{-1} (Shephard et al., 2015). One of the main advantages of CrIS is its
175 improved vertical sensitivity of ammonia closer to the surface due to the low spectral noise of
176 $\sim 0.04\text{K}$ at 280K in the NH_3 spectral region (Zavyalov et al., 2013) and the early afternoon
177 overpass that typically coincides with high thermal contrast, which is optimal for thermal
178 infrared sensitivity. The CrIS Fast Physical Retrieval (CFPR) (Shephard and Cady-Pereira,
179 2015) retrieves an ammonia profile (14 levels) using a physics-based optimal estimation
180 retrieval, which also provides the vertical sensitivity (averaging kernels) and an estimate of the
181 retrieval errors (error covariance matrices) for each measurement. As peak sensitivity is
182 typically in the boundary layer between 900 and 700 hPa (~ 1 to 3 km) (Shephard et al., 2020),
183 the surface and total column concentrations are both highly correlated with the retrieved levels
184 in the boundary layer. Shephard et al. (2020) reports estimated total column random
185 measurement errors of 10–15%, with estimated total random errors of $\sim 30\%$. The individual
186 profile retrieval levels have estimated random measurement errors of ~ 10 to 30% , with
187 estimated total random errors increasing to 60 to 100% due to the limited vertical resolution.
188 These vertical sensitivity and error output parameters are also useful for using CrIS
189 observations in applications (e.g. data fusion, data assimilation; model-based emission
190 inversions (e.g., Cao et al., 2020; Li et al., 2019) as a satellite observational operator can be
191 generated in a robust manner. The detection limit of CrIS measurements has been calculated
192 down to $0.3\text{--}0.5\text{ ppbv}$ (Shephard et al., 2020). CrIS ammonia has been evaluated against other
193 observations over North America with the Ammonia Monitoring Network (AMoN) (Kharol et
194 al., 2018) and against ground-based Fourier transform infrared (FTIR) spectroscopy
195 observations (Dammers et al., 2017) showing small differences and high correlations.

196 **2.3 Inverse Distance Weighting (IDW) interpolation**

197 To process large amounts of measurements in a 2-dimensional grid of high resolution,
198 oversampling methods (Streets et al., 2013) can be used (Van Damme et al., 2018). However,
199 considering that the resolution of the CTM is $2.5^\circ \times 1.3^\circ$ (see section 2.4), there is no need to
200 process the measurements on such a high-resolution grid and therefore an interpolation method
201 was used. The method has been extensively used after the Chernobyl accident in 1986 to
202 process more than 500 thousand deposition measurements over Europe (De Cort et al., 1998;
203 Evangeliou et al., 2016).

204 IASI total column ammonia measurements were interpolated onto a grid of $0.5^\circ \times 0.5^\circ$
205 using a modified Inverse Distance Weighting (IDW) algorithm described by (Renka, 1988).

206 This method is preferred due to its ease of use and to its high quality of interpolation. The IDW
 207 interpolation is defined by:

$$208 \quad \hat{v}(x, y) = \frac{\sum_{i=1}^n w_i v_i}{\sum_{i=1}^n w_i} \quad \text{Eq. 1}$$

209 where $\hat{v}(x, y)$ is the interpolated value at point (x, y) , w_1, \dots, w_i are the relative weights and
 210 v_1, \dots, v_n are the observation values. The weights are defined by the inverse distance functions:

$$211 \quad w_i = \left(\frac{r_w - d_i}{r_w d_i} \right)^2 \quad \text{Eq. 2}$$

$$212 \quad \text{for } (r_w - d_i) = \begin{cases} r_w - d_i & \text{if } d_k < r_w, \\ 0 & \text{if } d_k \geq r_w. \end{cases}$$

213 where r_w denotes the radius of influence of the point (x_i, y_i) , d_i the Euclidean distance
 214 between point (x, y) and (x_i, y_i) , and d_k is the threshold distance. We used a threshold
 215 distance (d_k) of 50 km, which is similar to the size of each grid cell; different d_k values were
 216 included in a sensitivity study (see section 4.2). The Euclidean distance is calculated using
 217 Vincenty's formulae (Vincenty, 1975). Finally, the gridded IASI total column ammonia was re-
 218 gridding to the model resolution ($2.5^\circ \times 1.3^\circ$) using bilinear interpolation.

219 **2.4 Emission flux calculation of ammonia**

220 The emission fluxes of ammonia were calculated using a 1-dimensional box model that
 221 assumes first-order loss terms for ammonia and has been already used previously (Van Damme
 222 et al., 2018; Whitburn et al., 2016b). It takes into account the gridded column concentrations of
 223 ammonia that were calculated with the IDW interpolation method and all the potential removal
 224 processes of ammonia occurring in a hypothetical atmospheric box according to the following
 225 equation:

$$226 \quad E_{NH3} = M_{NH3} / \tau \quad \text{Eq. 3}$$

227 where M_{NH3} is the mass of ammonia in each atmospheric box (grid-cell) in molecules cm^{-2} and
 228 τ is the lifetime of ammonia in the box (given in seconds).

229 Van Damme et al. (2018) assumed a constant lifetime for ammonia, admitting that this is
 230 a limiting factor of their study on the basis that chemical loss and deposition are highly variable
 231 processes that can change the lifetime drastically. To tackle the large variability of the lifetime
 232 of ammonia, we used monthly gridded lifetime calculated from a CTM. This gives robustness
 233 in the calculated emissions fluxes considering that at regions where sulfuric and nitric acids are
 234 abundant, the chemical loss will be more intensive and, thus, lifetime will be much shorter
 235 affecting emissions dramatically.

236 The lifetime (τ) of ammonia in each grid-box results from the three processes affecting
 237 ammonia concentrations: transport (t_{trans}) in and out of the grid-cell, chemical loss (t_{chem})
 238 and deposition (t_{depo}):

$$239 \quad \frac{1}{\tau} = \frac{1}{t_{trans}} + \frac{1}{t_{chem}} + \frac{1}{t_{depo}} \quad \text{Eq. 4}$$

240 In a CTM, the lifetime can be easily calculated from the species mass balance equation (Croft
 241 et al., 2014):

$$242 \quad \frac{dC(t)}{dt} = S(t) - \frac{C(t)}{\tau(t)} \quad \text{Eq. 5}$$

243 where $C(t)$ is the atmospheric burden of ammonia at time t , $S(t)$ is the time-dependent source
 244 emission fluxes and $\tau(t)$ is the removal timescale. Assuming steady-state conditions and
 245 considering that emission fluxes of ammonia are continuous, there is a quasi-equilibrium
 246 between sources and removals of ammonia (Dentener and Crutzen, 1994), and the modeled
 247 lifetime of ammonia τ_{mod} can be defined as:

$$248 \quad \tau_{mod} = C_{NH3} / L_{NH3}^{trans,chem,depo} \quad \text{Eq. 6}$$

249 where C_{NH3} is the atmospheric burden of ammonia and $L_{NH3}^{trans,chem,depo}$ is the total loss due to
 250 any process affecting ammonia in the model (transport, chemical reactions, deposition).

251 We calculate ammonia emission fluxes using IASI satellite measurements that we
 252 interpolated (see section 2.3) to the model resolution ($2.5^\circ \times 1.3^\circ$) and applying a variable
 253 lifetime taken from a CTM (hereafter NE emissions). We also calculate ammonia emissions
 254 from the oversampled IASI data of Van Damme et al. (2018), after bilinear re-gridding to the
 255 model resolution ($2.5^\circ \times 1.3^\circ$), applying a constant lifetime for ammonia of 12 hours (hereafter
 256 VD0.5 emissions) and the same variable lifetime from a CTM as in the NE emissions (hereafter
 257 VDgrlf emissions).

258 **3 Results**

259 In this section, the main results of the monthly emissions (NE) are presented for the 10-
 260 year period (2008–2017) of IASI observations. We first describe the monthly modelled
 261 ammonia lifetimes (section 3.1). Then, we explain the main characteristics of the obtained
 262 emissions (section 3.2) and compare them with those calculated using the IASI gridded
 263 products from Van Damme et al. (2018) (VD0.5 and VDgrlf), as well as the ones from the state-
 264 of-the-art inventories of EGG and EDGARv4.3.1-GFED4 (Crippa et al., 2016; Giglio et al.,

265 2013) that are often used in CTMs (section 3.3). We finally turn our focus to emissions at
266 continental regions and document their seasonal variation in emissions (section 3.4).

267 **3.1 Modelled lifetime of ammonia**

268 The lifetime of ammonia has been reported to range from a few hours to a few days
269 (Behera et al., 2013; Pinder et al., 2008) so ammonia can only be transported over relatively
270 short distances. This short spread of ammonia is also due to the fact that (a) the majority of its
271 emissions are surface ones (major source is agricultural activity), and (b) its surface deposition
272 velocities are high for most surfaces (Hov et al., 1994). The atmospheric lifetimes of ammonia
273 were summarized in Van Damme et al. (2018). Specifically, Quinn et al. (1990) and more
274 recently Norman and Leck (2005) reported lifetimes of a few hours in the West Pacific, South
275 Atlantic and Indian Oceans, which is in agreement with Flechard and Fowler (1998), who
276 reported a 2-hour lifetime in an area of Scotland where most sources are of agricultural origin.
277 Similar to them, Dammers et al. (2019) recently reported a lifetime estimated from satellite
278 measurements of 2.35 ± 1.16 hours for large point sources based on satellite measurements. The
279 majority of ammonia lifetimes reported regionally or globally fall within 10 and 24 hours
280 independently of the different approaches (Hauglustaine et al., 2014; Hertel et al., 2012; Möller
281 and Schieferdecker, 1985; Sutton et al., 1993; Whitburn et al., 2016b), while Dentener and
282 Crutzen (1994) reported slightly higher lifetimes within a range between 0.9 and 2.1 days
283 depending on ammonia emission fraction of natural origin. Monthly averaged atmospheric
284 ammonia lifetimes in the present study were derived using the version of the LMDz-OR-INCA
285 that includes non-methane hydrocarbons (Hauglustaine et al., 2004).

286 Ammonia lifetime depends on numerous factors such as the presence of ammonia's
287 reactants (sulfuric and nitric acids, through SO_2 and NO_x emissions), meteorological parameters
288 (atmospheric water vapour, and temperature, atmospheric mixing and advection) and ammonia
289 emissions. In ammonia-poor conditions, all ammonia is rapidly removed by neutralising
290 sulfuric acid with an intermediate production of bisulfate. If ammonia increases further
291 (ammonia-rich conditions), then reaction with nitric acid occurs forming nitric ammonium. At
292 this point, the ammonia/sulfuric acid/nitric acid equilibrium becomes very fragile. If sulfate
293 concentrations decrease, then free ammonia is produced, which gradually reacts with nitric acid
294 resulting in production of aerosol phase nitric ammonium. But if particles are aqueous, then
295 sulfate ions in solution increase the equilibrium vapour pressure of ammonia with nitric acid
296 reversing the reaction towards gaseous phase reactants. So, sulfate reductions are linked with

297 non-linear increases of aerosol nitrates and decreases of aerosol ammonium and water (Seinfeld
298 and Pandis, 2000).

299 The calculated ammonia lifetime is shown in **Figure 1a** averaged for the whole study
300 period. The average lifetime was calculated to be 11.6 ± 0.6 hours, which is in the range of the
301 previously reported values. Lower values (~ 10 hours) were observed in clean remote areas
302 characterized by low ammonia emissions (e.g., Amazon forest, Sahara and Australia), while in
303 the rest of the globe the lifetime was closer to the average value. The highest lifetimes (~ 16
304 hours) occur over Southern Brazil and Venezuela, which are both areas with relatively high
305 ammonia emissions and low sulfuric and nitric acid concentrations (**Figure 1c**). These
306 conditions are characterized by a low atmospheric sulfuric and nitric acids availability to
307 remove ammonia rapidly, hence causing an increase in lifetime.

308 **3.2 Satellite-constrained emissions**

309 The average ammonia emissions calculated from the 10-year IASI observations are
310 shown in **Figure 1b** (also in **Fig. S 1a**), the reactants' atmospheric burden in **Figure 1c** and their
311 seasonal variability in **Figure 1d** together with monthly modelled lifetimes. The year-by-year
312 total ammonia emissions are depicted in **Fig. S 1** with a monthly temporal resolution. Emissions
313 decline from 242 Tg yr^{-1} in 2008 to 212 Tg yr^{-1} in 2011. In 2012 – 2014, emissions show little
314 variation (194 , 204 and 195 Tg yr^{-1} , respectively), before they increase steeply to 248 Tg yr^{-1}
315 in 2015. Finally, in 2016 and 2017 they remain at the same high level (197 and 227 Tg yr^{-1} ,
316 respectively).

317 The global average annual emission calculated from VD0.5 amounts to 189 Tg (9-year
318 average), which is comparable to the average of the 10-year period that we have calculated in
319 the present study (average \pm sd: $213 \pm 18.1 \text{ Tg yr}^{-1}$). The increase in the emissions we calculate
320 during 2015 and 2017 stand out. The explanation for these increases could be twofold: (i) if
321 sulfur dioxide (a precursor of sulfuric acid) emissions decreased over time, less sulfuric acid is
322 available to neutralize ammonia, hence resulting in higher ammonia column concentrations
323 seen by IASI that could be attributed to new emissions erroneously (see section 2.4); (ii) if
324 sulfur dioxide and sulfuric acid presented a constant year-by-year pattern or even increased,
325 then the calculated ammonia emissions would be likely real.

326 To sort out between these two possibilities, we used sulfur dioxide measurements from
327 NASA's Ozone Monitoring Instrument (OMI, Yang et al., 2007) instrument, whereas sulfate

328 column concentrations were taken from the Modern-Era Retrospective Analysis for Research
329 and Applications, Version 2 (MERRA2, Gelaro et al., 2017) reanalysis data from NASA's
330 Global Modeling and Assimilation Office (GMAO). Fig. S 2 shows timeseries of column
331 concentrations of sulfur dioxide and sulfates from OMI and MERRA2 averaged globally, for
332 continental regions (Europe, North America, South America, Africa), as well as for regions
333 where ammonia emissions are particularly high (India and Southeastern Asia, North China
334 Plain). Although column concentrations of both sulfur dioxide and sulfates present strong
335 interannual variability (Fig. S 2), their global concentrations show a strong decreasing trend
336 after 2015. The observed decrease indicates that sulfate amounts that neutralize ammonia and
337 form ammonium sulfate, thus it is likely that the higher ammonia concentrations seen from
338 IASI after 2015 are not necessarily a result of emission increases. This is not seen from the
339 respective precursor of the atmospheric nitric acid, nitrogen dioxide (Fig. S 2). Sulfur dioxide
340 emissions over Europe and North American have been reduced by 70–80% since 1990
341 (Vestreng et al., 2007). The largest emission reductions occurred in North America after 2005
342 (Hand et al., 2012; Hoesly et al., 2017; Lehmann et al., 2007; Sickles and Shadwick, 2015),
343 while in Europe before 2000 (Crippa et al., 2016; Hoesly et al., 2017; Torseth et al., 2012;
344 Vestreng et al., 2007). These large regional reductions of sulfur dioxide resulted in a global
345 decrease until 2000, then slightly increased until 2006, due to a sharp rise in emissions in China,
346 and declined again, due to stricter emission restriction in China (Klimont et al., 2013; Li et al.,
347 2017, 2018; Saikawa et al., 2017a; Wang et al., 2017; Xing et al., 2015; Zhang et al., 2012;
348 Zheng et al., 2018) and regulations in Europe and North America (Aas et al., 2019; Crippa et
349 al., 2016; Hoesly et al., 2017; Klimont et al., 2013; Reis et al., 2012). This was not the case for
350 India, where the emissions have been increasing (Hoesly et al., 2017; Klimont et al., 2017;
351 Saikawa et al., 2017b) making it the world's second largest sulfur dioxide emitting country after
352 China (Krotkov et al., 2016).

353 Looking closely into regions with large changes in ammonias reactants and/or their
354 precursors after 2015 (Figure 2), we immediately see that a region of interest is the North China
355 Plain. The North China Plain has been identified as an ammonia hotspot mainly due to extensive
356 agricultural activities (Clarisse et al., 2009; Pan et al., 2018). To improve air quality over China,
357 the Chinese government implemented new emission regulations aimed at decreasing the
358 national total NO_x emissions by 10% between 2011 and 2015 (Liu et al., 2017). Several recent
359 studies (Duncan et al., 2016; Krotkov et al., 2016) have highlighted the effectiveness of the air
360 quality policy, as evidenced by a decreasing trend in nitrogen dioxide columns over China since

361 2012. De Foy et al. (2016) reported that NO_x reduction goals had already been achieved in
362 2016, as seen from satellites. A similar decreasing trend has been reported for sulfur dioxide
363 (Koukouli et al., 2018; Krotkov et al., 2016; Wang et al., 2013). For instance, Liu et al. (2018)
364 reported a sulfur dioxide reduction of about 60% over the recent few years in the North China
365 Plain, sulfuric acid decreased by 50%, while ammonia emissions declined by only 7% due to
366 change in agricultural practices.

367 The suggested decrease in ammonia reactants over the North China Plain is illustrated by
368 the calculated sulfur dioxide column concentration anomaly from OMI (Figure 2) and by the
369 sulfuric acid concentration anomaly from MERRA-2 after 2015 (the highest calculated one)
370 (Fig. S 3). Nitrogen dioxide concentration do not show any noticeable annual change, despite
371 their strong seasonal cycle (Fig. S 2). The IASI-constrained ammonia emissions calculated here
372 show only a tiny increase of 0.19 ± 0.04 kt y⁻¹ after 2015 in the North China Plain and of 10 ± 3.1
373 Tg y⁻¹ globally with respect to the 10-year average (Figure 2). This is due to the change of sulfur
374 dioxide and nitrogen oxide emission regulations in China, which in turn led to reduced
375 inorganic matter (sulfates, nitrates and ammonium) resulting in regional increases of gaseous
376 ammonia (Lachatre et al., 2019).

377 It should be noted here that decreases in sulfur dioxide and nitrogen dioxide have been
378 reported to have occurred since 2005, at least in Eastern USA and to a lesser extent in Eastern
379 Europe (Krotkov et al., 2016). At the same time, sulfur dioxide and nitrogen dioxide
380 concentrations had started increasing after 2005 in India, a country that shows the largest
381 agricultural activity in the world and is now the second largest sulfur dioxide emitting country
382 after China (Krotkov et al., 2016). The latter has balanced the global sulfur dioxide and nitrogen
383 dioxide budget, explaining that the decreasing trend after 2015 that we report has been affected
384 by our choice to present global averages.

385 **3.3 Comparison with traditional emission datasets**

386 In this section, we quantify the main differences of our IASI-constrained emission dataset
387 with other state-of-the-art inventories used in global models and for different applications (air
388 quality, climate change etc...). Aside from comparing our emissions with those calculated using
389 Van Damme et al. (2018) data with a constant lifetime (hereafter called VD0.5), we extend our
390 comparison to more traditional datasets such as those of ECLIPSEv5-GFED4-GEIA (EGG) for
391 2008–2017, and EDGARv4.3.1-GFED4 (Crippa et al., 2016; Giglio et al., 2013) for 2008–2012
392 period. Finally, the ammonia emissions presented in this study (NE emissions) are compared

393 to emissions calculated from Van Damme et al. (2018) gridded IASI column data applying a
394 variable (modelled) ammonia lifetime presented in Figure 1b (hereafter referred as VDgrlf).

395 The 10-year comparison of our calculated emissions with VD0.5 is shown in Figure 3.
396 The 10-year average difference amounts to 29 ± 15 Tg yr⁻¹ (average \pm sd). In all years, the largest
397 differences could be seen over Latin America and over tropical Africa. Our emissions (NE)
398 show a different structure in the Indo-Gangetic Plain and situated slightly more northerly than
399 those in VD0.5. The difference might be due to the IDW interpolation used to process the IASI
400 ammonia in the NE emissions compared with the oversampling method used in VD0.5 (see
401 section 2.3). Nevertheless, Northern India has been identified as a hot-spot region for ammonia,
402 mainly due the importance of agricultural activities in the region (Kuttippurath et al., 2020;
403 Tanvir et al., 2019).

404 Fig. S 4 and Fig. S 5 present a comparison of our calculated emissions (NE) with the basic
405 state-of-the-art datasets of EGG and EDGARv4.3.1-GFED4, respectively. In both datasets,
406 ammonia emissions remain almost constant over time (average \pm sd: 65 ± 2.8 Tg yr⁻¹ and 103 ± 5.5
407 Tg yr⁻¹, respectively). The total calculated ammonia emissions in EGG and EDGARv4.3.1-
408 GFED4 are up to three times lower than those calculated from NE (average \pm sd: 213 ± 18.1 Tg
409 yr⁻¹) or from VD0.5 (9-year average: 189 Tg yr⁻¹). This results in 10-year annual differences
410 that are very significant (average \pm sd: 150 ± 19.3 Tg yr⁻¹ and 111 ± 19.2 Tg yr⁻¹, respectively); the
411 largest differences appear over South America (EGG: 7.1 ± 0.3 Tg yr⁻¹, VD0.5: 22 Tg yr⁻¹, NE:
412 28 ± 3.0 Tg yr⁻¹, VDgrlf: 24 ± 1.3 Tg yr⁻¹), while European emissions are practically identical in
413 all datasets except EGG (EGG: 6.9 ± 1.1 Tg yr⁻¹, VD0.5: 11 Tg yr⁻¹, NE: 15 ± 2.2 Tg yr⁻¹, VDgrlf:
414 11 ± 1.0 Tg yr⁻¹). Emissions from South China Plain are much higher in the two traditional
415 datasets than those presented in this paper (EGG: 25 ± 1.2 Tg yr⁻¹, VD0.5: 36 Tg yr⁻¹, NE: 38 ± 2.8
416 Tg yr⁻¹, VDgrlf: 39 ± 1.8 Tg yr⁻¹). Ammonia emissions derived over China in this work (NE) are
417 among the highest worldwide (Fig. S 1), which agrees well with the 9-year average emissions
418 calculated in VD0.5 inventory over China (see Figure 3). To assess to which extent emissions
419 from EGG and EDGARv4.3.1-GFED4 are underestimated can only be done by comparing
420 ammonia with ground or satellite observations.

421 The comparison of the annual ammonia emissions in the NE dataset to the modified
422 VDgrlf emissions is shown in Fig. S 6. The latter showed a better agreement to the emissions
423 presented in this study with mean annual different of 14 ± 19 Tg yr⁻¹ (average \pm sd). Previously

424 observed emission differences in the two state-of-the-art inventories over South America and
425 Africa have been now minimized, as well as the displacement north of the Indo-Gangetic Plain
426 emissions remains important. Nevertheless, the smaller differences of our emissions (NE) from
427 those of VDgrlf as compared with the respective difference from the VD0.5 emissions, show
428 the large impact that a more realistic variable lifetime might have in emission calculations with
429 this methodology in these regions.

430 **3.4 Region-specific ammonia emissions and seasonal variation**

431 **Figure 4** illustrates specific regions that show the largest ammonia emissions (Europe,
432 North America, South America and Southeastern Asia). These emissions correspond to the
433 IASI-constrained emissions calculated in this study (NE) and are presented as total annual
434 emissions averaged over the 10-year period of study. At the bottom panels of the same figure,
435 the seasonal variation of the emissions is shown for each of the four hot-spot regions and each
436 of the 10 years of the study.

437 European total ammonia emissions were estimated to be $15 \pm 2.2 \text{ Tg yr}^{-1}$ (average \pm sd),
438 more than double compared with those reported in EGG ($6.9 \pm 1.1 \text{ Tg yr}^{-1}$) and similar to those
439 in VD0.5 (11 Tg yr^{-1}) or those in VDgrlf ($11 \pm 1.0 \text{ Tg yr}^{-1}$). The greatest emissions were
440 calculated for Belgium, the Netherlands and the Po Valley in Italy (**Figure 4**). High emissions
441 are also found in North and Northwestern Germany and over Denmark. In contrast, very low
442 emissions are found in Norway, Sweden and parts of the Alps. It is not possible to quantitatively
443 distinguish between different sources of ammonia. It has been reported that approximately 75%
444 of ammonia emissions in Europe originate from livestock production (Webb et al., 2005), and
445 90% from agriculture in general (Leip et al., 2015). More specifically, ammonia is emitted from
446 all stages of manure management, from livestock buildings during manure storage and
447 application to land, as well as from livestock urine. These emissions are strong over most of
448 Northwestern European countries, although sources like fertilization and non-agricultural
449 activities (traffic and urban emissions) can be also important. An example is Tange in Germany,
450 which shows a late summer peak due to growing crops application. No obvious seasonality in
451 the emissions can be seen for Europe as a whole, as the hot-spot regions are rather few compared
452 to the overall surface of Europe. An exception to this stable emission situation over the year
453 occurs during 2010 and during 2015, years for which a late summer peak. In 2010, large
454 wildfires in Russia resulted in high ammonia emissions (R'Honi et al., 2013), while year 2015

455 has been also characterized as an intense fire year (though not like 2010), with fires occurring
456 in Eurasia (Min Hao et al., 2016).

457 North America and in particular the US (Figure 4) has been characterized by four hot-
458 spot regions. First, a small region in Colorado, Central US, which is the location of a large
459 agricultural region that traditionally releases large ammonia emissions (Malm et al., 2013).
460 Another example is the state of Iowa (home to more than 20 million swine, 54 million chickens,
461 and 4 million cattle), northern Texas and Kansas (beef cattle), and southern Idaho (dairy cattle)
462 (McQuilling, 2016). Furthermore, the three major valleys in Salt Lake, in Cache, and in Utah
463 in the midwestern US show an evident, but lower intensity hot-spot, as they are occupied by
464 massive pig farms associated to open waste pits. The largest emissions were calculated for the
465 San Joaquin Valley in California (vegetables, dairy, beef cattle and chickens) and further to the
466 South (Tulare and Bakersfield), an area characterized by feedlots (Van Damme et al., 2018;
467 McQuilling, 2016). North American annual ammonia emissions over the 10-year period were
468 averaged $1.1 \pm 0.1 \text{ Tg yr}^{-1}$ (average \pm sd). These values are over two orders of magnitude higher
469 than those in EGG ($0.062 \pm 0.0013 \text{ Tg yr}^{-1}$). Note that his estimate is three times lower than those
470 reported in VD0.5 (3.1 Tg yr^{-1}) or in VDgrlf ($3.4 \pm 0.5 \text{ Tg yr}^{-1}$). The 2008–2017 interannual
471 variability (Figure 4) all show a minimum in winter. Maximum emissions were observed in late
472 spring, due to the contribution from mineral fertilizer and manure application, in summer, due
473 to influence of livestock housing emissions, and some years both in spring and summer (Makar
474 et al., 2009; Zhu et al., 2013, 2015). A topographical dependence was also seen in midwest
475 emissions that peaked in April, whereas over the rest of the US maximum emissions were
476 appeared in summer (Paulot et al., 2014).

477 Ammonia emissions have different characteristics in South America and in Western
478 Africa as both are fire-dominated regions. For simplicity we only present South America in
479 Figure 4. This region is dominated by natural ammonia emissions mainly from forest, savanna
480 and agricultural fires (Whitburn et al., 2014, 2016b) and volcanoes (Kajino et al., 2004;
481 Uematsu et al., 2004). This causes a strong seasonal variability in the ammonia emissions with
482 the largest fluxes observed from August to October in all years (Figure 4). This strong
483 dependence of South America from biomass burning emissions was first highlighted by Chen
484 et al. (2013) and by van Marle et al. (2017). It also became particularly pronounced during the
485 large wildfires in the Amazon rainforest in summer 2019 (Escobar, 2019). We estimated the
486 10-year average ammonia emissions to be $28 \pm 3.0 \text{ Tg yr}^{-1}$ (average \pm sd) in agreement with

487 VD0.5 (22 Tg yr⁻¹) and VDgrlf (24±1.3 Tg yr⁻¹). The respective emissions in EGG are four
488 times lower than these estimates (7.1±0.3 Tg yr⁻¹).

489 The last column to the right of **Figure 4** presents the 10-year average annual ammonia
490 emissions and their respective interannual variability in Southeastern Asia. We define this
491 region spanning from 70°E–130°E in longitude and from 0°N–45°N in latitude. Ammonia
492 emissions were estimated to be 38±2.8 Tg yr⁻¹ (average±sd) similar to VD0.5 (36 Tg yr⁻¹) and
493 VDgrlf (39±1.8 Tg yr⁻¹) and slightly higher than those presented in EGG (25±1.2 Tg yr⁻¹). They
494 comprise ammonia fertilizer plants, such as in Pingsongxiang, Shizuishan, Zezhou-Gaoping,
495 Chaerhan Salt Lake, Delingha, Midong-Fukang and Wucaiwan (China), Indo-Gangetic Plain
496 (Pakistan and India), Gresik (Indonesia). China and India contribute more than half of total
497 global ammonia emissions since the 1980s with the majority of these emissions to originate
498 from rice cultivation followed by corn and wheat (crop-specific emissions). More specifically,
499 emissions from these crops due to synthetic fertilizer and livestock manure applications are
500 concentrated in North China Plain (Xu et al., 2018). Considering that Southeastern Asia is the
501 largest agricultural contributor in the global ammonia budget, a strong seasonality in the
502 emissions was observed. Temporal ammonia emissions peak in late summer of most years,
503 when emissions from rice cultivation, synthetic fertilizer application and livestock manure
504 spreading (Xu et al., 2016) are important, and in spring when wheat cultivation dominates
505 (Datta et al., 2012). Of course, the respective emissions from biomass burning should also be
506 mentioned. However, these are difficult to be distinguish and are expected to be a relatively
507 small source compared to agricultural emissions.

508 **4 Discussion**

509 In this section, we conduct simulations over the 10-year period (2008–2017, 1-year spin-
510 up), with all the emissions derived and compare the NH₃ concentrations with ground-based
511 observations over Europe, North America, Southeastern Asia (section 4.1), and observations
512 from CrIS (section 4.1). These simulations consist in: (i) a simulation using traditional
513 emissions using EGG; (ii) a simulation using emissions calculated from IASI data from Van
514 Damme et al. (2018) applying a constant lifetime of 12 hours for ammonia (VD0.5); (iii) a
515 simulation using gridded emissions presented in the present paper (NE) calculated as described
516 in section 2; and (iv) a simulation using emissions calculated from IASI data from Van Damme
517 et al. (2018) applying a variable (modelled) lifetime (VDgrlf). Finally, we perform a sensitivity

518 analysis in order to define the levels of uncertainty of our emissions in section 4.2 and discuss
519 potential limitation of the present study in section 4.3.

520 **4.1 Validation against ground-based observations and satellite products**

521 **Figure 5** shows a comparison between modelled surface concentrations of ammonia with
522 ground measurements from Europe (EMEP, <https://emep.int/mscw/>), North America (AMoN,
523 <http://nadp.slh.wisc.edu/data/AMoN/>) and Southeastern Asia (EANET,
524 <https://www.eanet.asia>). To avoid overplotting, the Gaussian kernel density estimation (KDE)
525 was used, which is a non-parametric way to estimate the probability density function (PDF) of
526 a random variable (Parzen, 1962):

$$527 \quad f(x) = \frac{1}{Nh} \sum_{i=1}^N K\left(\frac{x-x_i}{h}\right) \quad \text{Eq. 7}$$

528 where K is the kernel, x_i the univariate independent and identically distributed point of the
529 relationship between modelled and measured ammonia and h is a smoothing parameter called
530 the bandwidth. KDE is a fundamental data smoothing tool that attempts to infer characteristics
531 of a population, based on a finite dataset. It weighs the distance of all points in each specific
532 location along the distribution. If there are more points grouped locally, the estimation is higher
533 as the probability of seeing a point at that location increases. The kernel function is the specific
534 mechanism used to weigh the points across the data set and it uses the bandwidth to limit the
535 scope of the function. The latter is computed using the Scott's factor (Scott, 2015). We also
536 provide the mean fractional bias (MFB) for modelled and measured concentrations of ammonia
537 as follows:

$$538 \quad MFB = \frac{1}{N} \frac{\sum_{i=1}^N (C_m - C_o)}{\frac{C_m + C_o}{2}} \times 100\% \quad \text{Eq. 8}$$

539 where C_m and C_o are the modelled and measured ammonia concentrations and N is the total
540 number of observations. MFB is a symmetric performance indicator that gives equal weights
541 to under- or over-estimated concentrations (minimum to maximum values range from -200%
542 to 200%). Furthermore, we assess the deviation of the data from the line of best fit using the
543 root mean square error (RMSE) defined as:

$$544 \quad RMSE = \sqrt{\sum_{i=1}^N \frac{(C_m - C_o)^2}{N}} \quad \text{Eq. 9}$$

545 From 134 European stations, nearly 300,000 measurements made at a daily to weekly
546 temporal resolution over the period of study (2007–2018) are presented on **Figure 5**. All
547 emission datasets underestimate ammonia surface concentration over Europe. The most
548 accurate prediction of concentrations was achieved using the traditional EGG emissions that

549 underestimated observations by 67%, also being the least scattered from the best fit
550 ($RMSE_{EGG} = 4.06 \mu g N m^{-3}$), followed by the emissions presented in this paper ($MFB_{NE} =$
551 -72% , $RMSE_{NE} = 4.65 \mu g N m^{-3}$), although they were more variable. VD0.5 or VDgrlf
552 emissions further underestimated observations, though they were less sparse (Figure 5d). About
553 12% of the modelled concentrations using EGG were outside of the 10-fold limit from the
554 observations, in contrast to only 17% and 15% in VD0.5 and VDgrlf, and 20% in NE. With
555 regards to the spatial comparison with the observed concentrations, all datasets cause
556 overestimations in the ammonia concentrations predicted in Western Europe. EGG appears to
557 be the most accurate in Central Europe (all stations with suffix DE00), NE emissions in all
558 Spanish stations (suffix ES00) and VD0.5 and VDgrlf emissions in Italian stations (Fig. S 7).

559 The comparison of simulated ammonia concentrations to observations over North
560 America includes 119 stations, which represent nearly 27,000 observations (Figure 6) with a
561 weekly, bi-weekly or monthly resolution. The only emission dataset that lead to an
562 underestimation of ammonia concentrations was EGG ($MFB_{EGG} = -28\%$). Two others,
563 VD0.5 and VDgrlf caused ammonia observations to be strongly overestimated ($MFB_{VD0.5} =$
564 **52% and $MFB_{VDgrlf} = 54\%$**), while NE slightly ($MFB_{NE} = 32\%$). All inventories resulted
565 in about the same variability in ammonia concentrations with RMSEs between 4.15 and 4.17
566 $\mu g N m^{-3}$ (Figure 6). About 10% of the predicted concentrations using EGG emissions were at
567 least 10 times off from the measured ones, more than twice the number of measurements
568 compared to the other dataset. NE emissions better capture levels in the easternmost stations of
569 the US (AL99, AR15, CT15, IL37, IN22, MI52, NY56, ON26) and in California (CA83) and
570 Oklahoma (OK98), which are close to hot-spot regions (see section 3.4). EGG emissions
571 perform better in Northwestern (ID03), Central (KS03) and several stations located over the
572 Eastern United States (KY03, KY98, OH09, AR03, IL46, KS03, GA41). The emission
573 inventory VD0.5 leads to a very good agreement in ammonia concentrations over all stations
574 of the North American continent (AL99, GA40, ID03, GA41, IL37, IL46, IN20, IN22, KS97,
575 PA00, MD99, MI52, TN04, NM99, NY96, OH99, OK98) (Fig. S 8).

576 In Southeastern Asia 62 stations from 13 countries were included in the comparison from
577 the EANET monitoring network (Figure 7). These included about 8,000 surface measurements
578 in monthly or 2-weekly resolution. As a whole, all emission inventories underestimate station
579 concentrations of EANET with MFBs between -102% (EGG) and -61% (VD0.5 and VDgrlf).
580 The least spread model concentrations were those simulated using VD0.5 and VDgrlf

581 ($RMSE = 4.61 - 4.65 \mu g N m^{-3}$). Around 19% of model concentrations using EGG were
582 outside the 10-fold limit of the 1×1 line with observations, 12% using NE emissions and only
583 5% and 6% using VD0.5 and VDgrlf, respectively. VD0.5 and VDgrlf emissions capture well
584 the Japanese (suffix JPA) and Taiwanese stations (suffix THA). Given the short lifetime and
585 the relatively coarse spatial scales, the model fails to capture the variability that exists within
586 each gridbox (Fig. S 9).

587 To give an overview of the comparison of the modelled surface concentrations of
588 ammonia from the four different simulations, each with different emissions (EGG, VD0.5, NE
589 and VDgrlf), we present station-by-station calculated MFB values in Figure 8. Although the
590 traditional EGG emissions capture many stations very well, there are large MFB values
591 observed in Eastern and Western USA (AMoN), Northern Europe (EMEP), whereas large
592 overestimations are observed in most of the Southeastern Asian stations (EANET). The large
593 bias at several AMoN stations decrease when using satellite-derived emissions. All datasets
594 miscalculated surface concentrations in Southeastern Asia, although some stations present
595 lower MFBs when using IASI constrained emissions. Note that large differences when
596 comparing bias from all measurements versus station-by-station bias have been calculated as a
597 result of the different frequency of measurements in each station.

598 To further show whether the satellite-derived emissions presented here (NE) capture
599 surface concentrations of ammonia or not, we used surface ammonia concentrations from CrIS
600 from 1st May 2012 to 31st December 2017. The comparison is shown as PDF of surface
601 modelled against CrIS concentrations of ammonia calculated with the Gaussian KDE for North
602 America, Europe and Southeastern Asia in Figure 9. NE emissions slightly overestimate
603 ammonia ($MFB = 0.09 - 0.10$). NE emissions generally result in higher surface
604 concentrations, also showing large $RMSEs$ ($3.28 - 5.26 \mu g N m^{-3}$). However, 90% of the
605 modelled concentrations were within a factor of 10 from the CrIS observation. .

606 4.2 Uncertainty analysis

607 A sensitivity analysis in order to calculate the level of uncertainty that each of the
608 parameter gives to the modelled surface concentrations of ammonia was also performed. The
609 relative uncertainty was calculated as the standard deviation of ammonia's surface
610 concentrations from a model ensemble of 10 members (Table 1) divided by the average. The
611 first six members are the surface concentrations that resulted from simulations of ammonia
612 emissions after perturbation of the Euclidian distance d_k in the parameters of the IDW

613 interpolation. The remaining four members are simulated concentrations using the previously
614 reported emissions datasets (EGG, VD0.5, NE and VDgr1f). The results are shown as a 10-year
615 (2008–2017) annual average relative uncertainty in Figure 10 and as annual average relative
616 uncertainty of surface concentrations for every year of the 10-year period in Fig. S 10.

617 The surface concentrations resulting from the different calculated emissions mainly
618 affects oceanic regions, with values reaching 100%. The reason for this could be threefold.
619 First, the IDW interpolation shows to be affected by severe outlier values, which are found in
620 several oceanic regions (Fig. S 11); this creates high gridded column ammonia concentrations
621 and, in turn, fluxes at regions that are not supported by previous findings or measurements.
622 Second, the methodology with which ammonia concentrations are retrieved in IASI has certain
623 limitation, with respect to (i) the use of constant vertical profiles for ammonia, (ii) potential
624 dependencies of total column ammonia and temperature that are not taken into account, and
625 (iii) instrumental noise that can cause bias (Whitburn et al., 2016a). Third, there is much less
626 ammonia over the Ocean, hence the relative error bars are much larger. Large uncertainties in
627 surface ammonia concentrations were observed in regions characterized by large anthropogenic
628 contribution, such as North India, North China Plain and Central USA. Smaller uncertainties
629 were found in Central Africa and in Amazonia, regions that are linked with episodic biomass
630 burning emissions (Figure 4).

631 **4.3 Limitations of the present study**

632 We discuss the importance of certain limitations in the methodology of the present study
633 and in the validation of the results. These limitations will also be commented upon in the overall
634 conclusion of the paper.

635 Regarding the methodology, emissions of short-lived species are determined, among
636 other methods, using top-down approaches. When only satellite measurements are available,
637 they are usually averaged over a particular location and surface emissions are calculated using
638 a mass balance approach (Lin et al., 2010; Zhao and Wang, 2009). This is done by assuming a
639 1-dimensional box-model, where atmospheric transport between grids is assumed to be
640 negligible and loss due to deposition or chemical reactions very fast. The solution to this
641 problem is the use of Kernels (Boersma et al., 2008), which makes the computation of the
642 emissions very intense. It has been reported that for resolutions, such as those used in the
643 present paper ($2.5^{\circ} \times 1.3^{\circ}$), non-local contributions to the ammonia emissions are relatively
644 small (Turner et al., 2012). Although, the use of Kernels is the proper way to account for non-
645 local contributions, we believe that negligible transport here is a fair assumption, due to the

646 small lifetimes of ammonia calculated from the CTM (11.6 ± 0.6 hours); therefore,
647 transportation from the adjacent grid-cells should be small. Note that although this method has
648 been suggested for short lived climate pollutants, it is not suitable for species with lifetime from
649 days to weeks (e.g. black carbon, Bond et al., 2013). Another important process that is not yet
650 considered in our model is the treatment of ammonia's air-surface exchange. Although bi-
651 directional air-surface exchange (dry deposition and emission) of ammonia has been observed
652 over a variety of land surfaces (grasslands, tree canopies etc...), the majority of the CTMs treats
653 the air-surface exchange of ammonia as dry deposition only. This might cause underestimation
654 of the daytime ambient ammonia concentration due to the overestimated dry deposition,
655 considering that the observed bi-directional exchange of ammonia mainly occurs during the
656 daytime (see Zhang et al., 2010, and references therein).

657 Another limitation of the present study is that the same model is used for the calculation
658 of the modelled lifetimes and for the validation of the emissions that were calculated using
659 these lifetimes (NE and VDgrlf). A more accurate validation would require an independent
660 model for the simulations of surface concentrations using these emissions. Nevertheless, the
661 IASI-constrained emissions of ammonia presented here are publicly available for use in global
662 models.

663 **5 Conclusions**

664 In the present paper, satellite measurements from IASI were used to constrain global
665 ammonia emissions over the period 2008–2017. The data were firstly processed to monthly
666 ammonia column concentrations with a spatial resolution of $2.5^\circ \times 1.3^\circ$. Then, using gridded
667 lifetime for ammonia calculated with a CTM, monthly fluxes were derived. This contrasts with
668 previously reported methods that used a single constant lifetime. This enables a more accurate
669 calculation in regions where different abundances of atmospheric sulfuric and nitric acid, as
670 well as in their precursors (sulfur and nitrogen dioxide, respectively) can neutralize ammonia
671 through heterogeneous chemical reactions to sulfate and nitrate aerosols. The calculated
672 ammonia emission fluxes were then used to simulate ammonia concentrations for the period
673 2008–2017 (referred to as NE). The same simulations were repeated using baseline emissions
674 from ECLIPSEv5-GFED4-GEIA (referred to as EGG), emissions constrained by Van Damme
675 et al. (2018) IASI data using a constant lifetime for ammonia (named as VD0.5) and emissions
676 based on Van Damme et al. (2018) retrievals using a modelled lifetime from a CTM (named as

677 VDgrlf). The simulated surface concentrations of ammonia were compared with ground
678 measurements over Europe (EMEP), North America (AMoN) and Southeastern Asia (EANET),
679 as well as with global satellite measurements from CrIS. The main conclusions can be
680 summarized as follows:

- 681 • The 10-year average annual ammonia emissions calculated here (NE) were estimated to be
682 $213 \pm 18.1 \text{ Tg yr}^{-1}$, which is 15% higher than those in VD0.5 (189 Tg yr^{-1}), and 6% higher
683 than those in VDgrlf ($201 \pm 10.4 \text{ Tg yr}^{-1}$). These emission values amount to twice the
684 published from datasets, such as EGG ($65 \pm 2.8 \text{ Tg yr}^{-1}$) and EDGARv4.3.1-GFED4,
685 ($103 \pm 5.5 \text{ Tg yr}^{-1}$).
- 686 • In the North China Plain, a region characterized by intensive agricultural activities, a small
687 increase of ammonia emissions is simulated after 2015. This is attributed to decreases in
688 sulfur species, as revealed from OMI and MERRA-2 measurements. Less sulfates in the
689 atmosphere leads to less ammonia neutralization and hence to larger loads in the
690 atmospheric column as measured by IASI.
- 691 • In Europe, the 10-year average of ammonia emissions were estimated at $15 \pm 2.2 \text{ Tg yr}^{-1}$
692 (NE), twice as much as those in EGG ($6.9 \pm 1.1 \text{ Tg yr}^{-1}$) and similar to those in VD0.5 (11
693 Tg yr^{-1}) or VDgrlf ($11 \pm 1.0 \text{ Tg yr}^{-1}$). The strongest emission fluxes were calculated over
694 Belgium, Netherlands, Italy (Po Valley), Northwestern Germany and Denmark. These
695 regions are known for industrial and agricultural applications, animal breeding activities,
696 manure/slurry storage facilities and manure/slurry application to soils.
- 697 • Some hot-spot regions with high ammonia emissions were distinguished in North America:
698 (i) in Colorado, due to large agricultural activity, (ii) in Iowa, northern Texas and Kansas,
699 due to animal breeding, (iii) in Salt Lake, Cache, and Utah, due to animal farms associated
700 with open waste pits and (iv) in California, due to animal breeding and agricultural
701 practices. Ammonia emissions in North America were $1.1 \pm 0.1 \text{ Tg yr}^{-1}$ or two orders of
702 magnitude higher than in EGG ($6.2 \pm 0.1 \text{ kt yr}^{-1}$) and three times lower than those in VD0.5
703 (3.1 Tg yr^{-1}) or in VDgrlf ($3.4 \pm 0.5 \text{ Tg yr}^{-1}$), with maxima observed in late spring, due to
704 fertilization and manure application and summer, due to livestock emissions.
- 705 • South America is dominated by natural ammonia emissions mainly from forest, savanna
706 and agricultural fires causing a strong seasonality with the largest fluxes between August
707 and October. The 10-year average ammonia emissions were as high as $28 \pm 3.0 \text{ Tg yr}^{-1}$
708 similar to VD0.5 (22 Tg yr^{-1}) and VDgrlf ($24 \pm 1.3 \text{ Tg yr}^{-1}$) and four times higher than EGG
709 ($7.1 \pm 0.3 \text{ Tg yr}^{-1}$).

- 710 • In Southeastern Asia, the 10-year average ammonia emissions were 38 ± 2.8 Tg yr⁻¹, in
711 agreement with VD0.5 (36 Tg yr⁻¹) and VDgrlf (39 ± 1.8 Tg yr⁻¹) and slightly higher than
712 those in EGG (25 ± 1.2 Tg yr⁻¹). The main sources were from fertilizer plants in China,
713 Pakistan, India and Indonesia. China and India hold the largest share in the ammonia
714 emissions mainly due to rice, corn and wheat cultivation. A strong seasonality in the
715 emissions was observed with a late summer peak in most years, due to rice cultivation,
716 synthetic fertilizer and livestock manure applications and in spring due to wheat
717 cultivation.
- 718 • Large bias was calculated in several ground-based stations when using the state-of-the-art
719 emissions EGG. The bias decreased substantially when satellite-derived emissions were
720 used to simulate surface concentrations of ammonia.

721

722 *Data availability.* All data and python scripts used for the present publication are open through
723 the web address <https://folk.nilu.no/~nikolaos/acp-2020-1008/> or can be obtained from the
724 corresponding author upon request.

725

726 *Competing interests.* The authors declare no competing interests.

727

728 *Acknowledgements.* We thank Espen Sollum for his continuous contribution and help with
729 big data analysis.

730

731 *Financial support.* This study was supported by the Research Council of Norway (project ID:
732 275407, COMBAT – Quantification of Global Ammonia Sources constrained by a Bayesian
733 Inversion Technique). Lieven Clarisse and Martin Van Damme are supported by the F.R.S.–
734 FNRS.

735

736 *Author contributions.* N.E. performed the simulations, analyses, wrote and coordinated the
737 paper. S.E. contributed to the lifetime calculations. Y.B., D.H. and A.C. set up the CTM model.
738 M.V.D., P.-F.C. and L.C. provided the IASI data, while M.W.S. and K.E.C.-P. provided the
739 observations from CrIS. All authors contributed to the final version of the manuscript.

1262

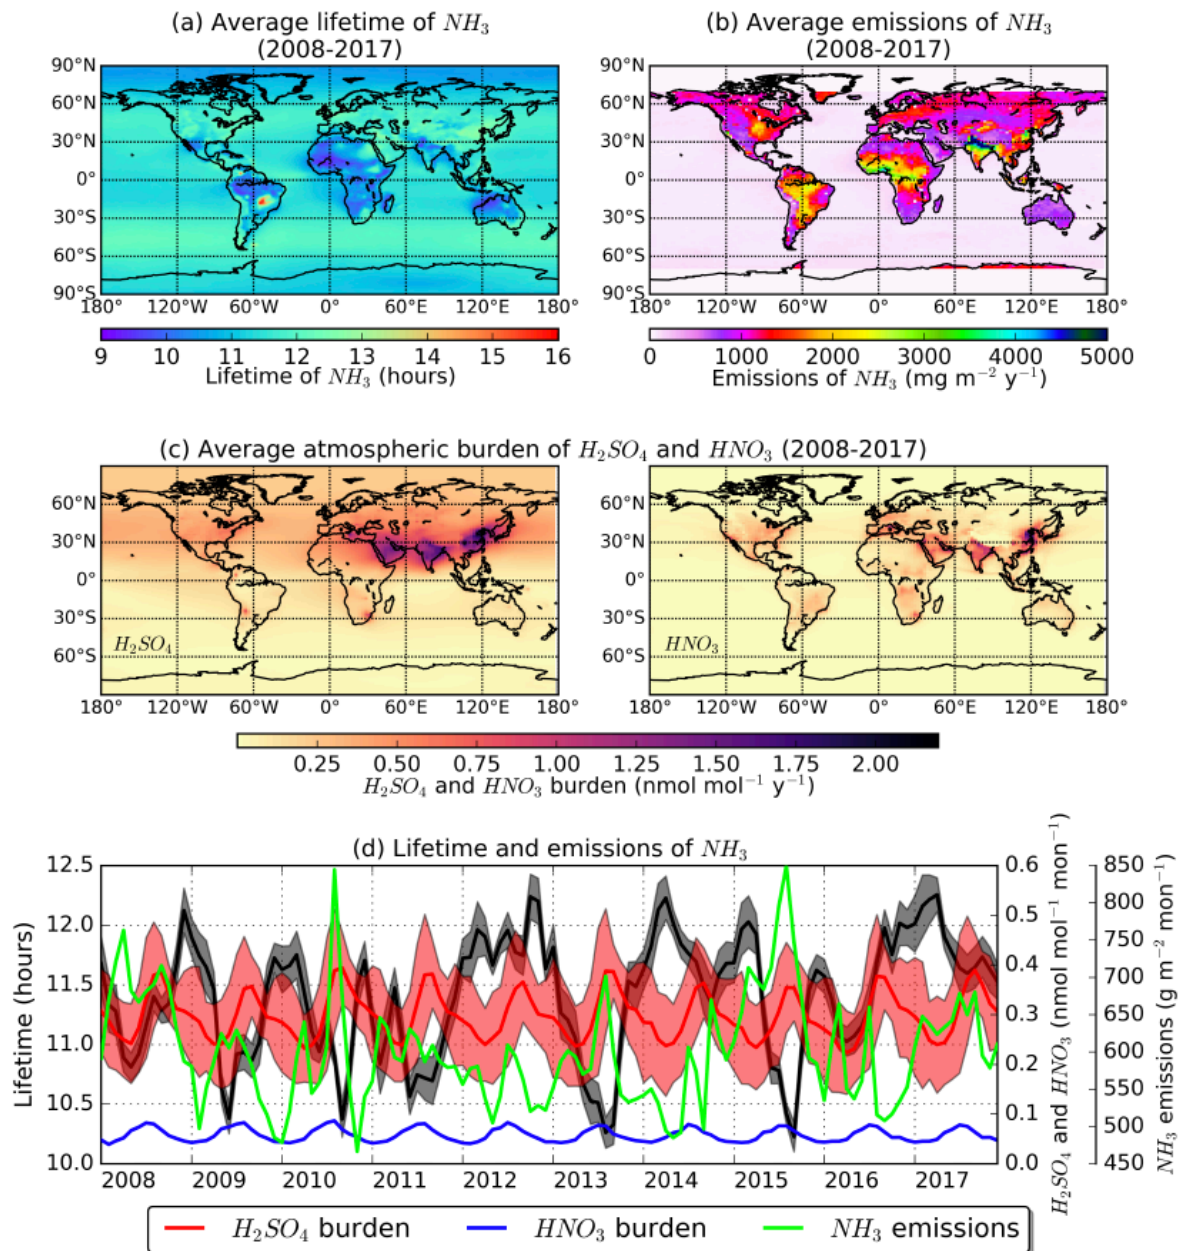

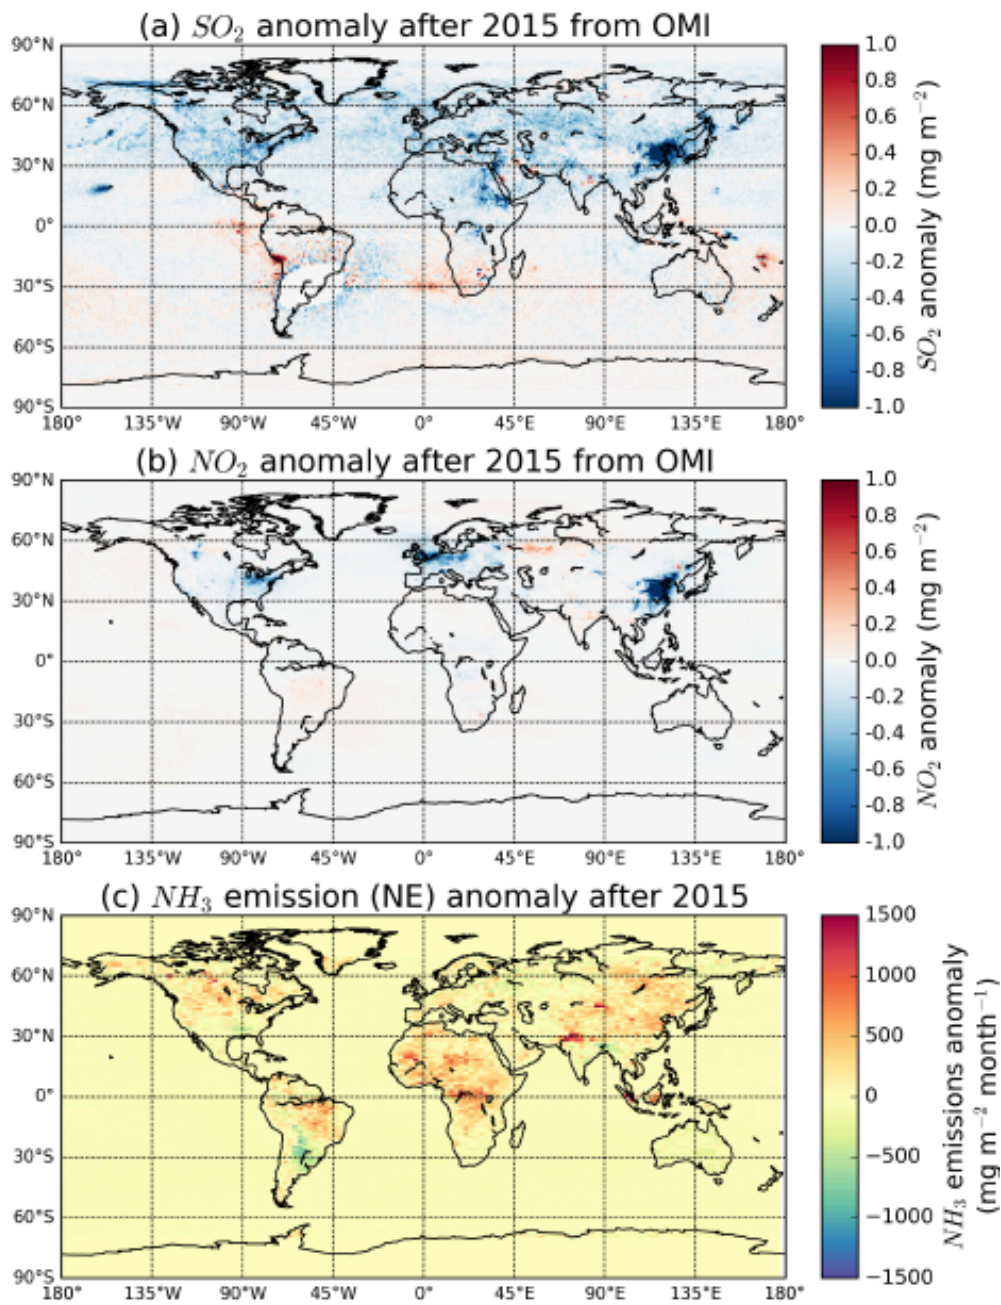

Figure 1. (a) 10-year average model lifetime of ammonia calculated from the LMDz-OR-INCA, (b) total annual emissions averaged over the 10-year period (NE emissions), (c) atmospheric burden of the reactants sulfuric and nitric acid calculated in the model, and (d) monthly timeseries of lifetime (black), ammonia emissions (green), sulfuric (red) and nitric acid column concentrations (blue) for the whole 10-year period.

1272

1273 Figure 2. Annual average total column (a) sulfur dioxide and (b) nitrogen dioxide anomaly
 1274 after 2015 from OMI, and (c) annual average emission anomaly of ammonia calculated from
 1275 IASI in the present study (NE).

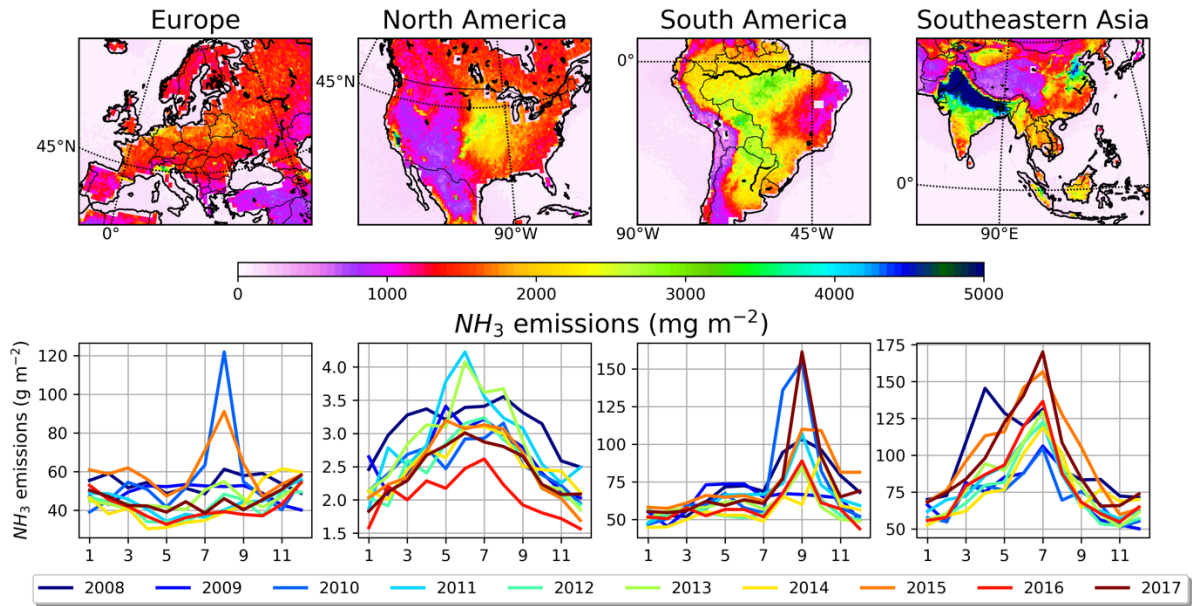

1276

1277
 1278 Figure 3. Global differences of ammonia emissions calculated in the present study (NE) from
 1279 those calculated using Van Damme et al. (2018) gridded concentrations applying a constant
 1280 lifetime of 0.5 days (VD0.5). The results are given as 10-year average (2008–2017) and the
 1281 number denotes the annual difference in the emissions.

1282

HOT-SPOT REGIONS AND SEASONALITY OF NH_3 EMISSIONS

1283
 1284 Figure 4. Total annual emissions of ammonia averaged over the 10-year period (2008–2017) in
 1285 Europe, North and South America and Southeastern Asia, which are regions characterized by
 1286 the largest contribution to global ammonia budget. In the bottom panels the monthly variation
 1287 of the emissions is shown for each year of the study period.

1288

**COMPARISON WITH OBSERVATIONS FROM EMEP
(N=299075)**

1289

1290

Figure 5. Validation of modelled concentrations of ammonia for different emissions datasets (EGG, VD0.5, NE and VDgrlf) against ground-based measurements from EMEP for the 10-year (2008–2017) study period. Scatterplots of modelled against measured concentrations for the aforementioned emission inventories were plotted with the Kernel density estimation, which is a way to estimate the probability density function (PDF) of a random variable in a non-parametric way.

1293

1294

1295

1296

**COMPARISON WITH OBSERVATIONS FROM AMON
(N=27096)**

1297

1298 Figure 6. Validation of modelled concentrations of ammonia for different emissions datasets
 1299 (EGG, VD0.5, NE and VDgrlf) against ground-based measurements from AMON for the 10-
 1300 year (2008–2017) study period. Scatterplots of modelled against measured concentrations for
 1301 the aforementioned emission inventories were plotted with the Kernel density estimation, which
 1302 is a way to estimate the probability density function (PDF) of a random variable in a non-
 1303 parametric way.

1304

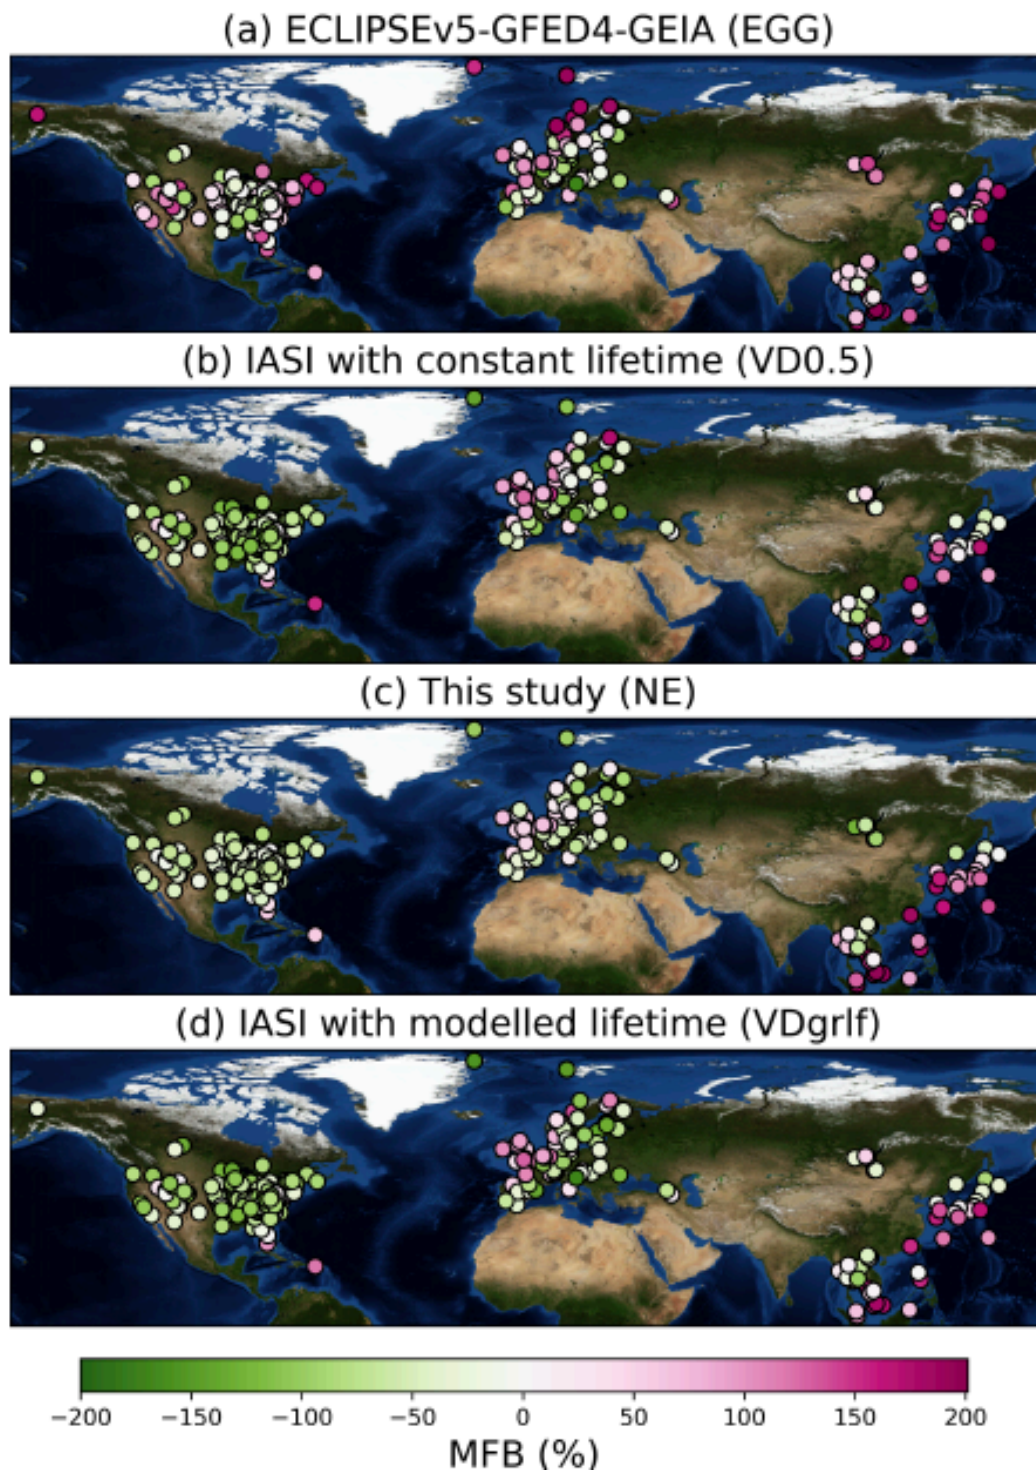

**COMPARISON WITH OBSERVATIONS FROM EANET
(N=7740)**

1305

1306 Figure 7. Validation of modelled concentrations of ammonia for different emissions datasets
 1307 (EGG, VD0.5, NE and VDgrlf) against ground-based measurements from EANET for the 10-
 1308 year (2008–2017) study period. Scatterplots of modelled against measured concentrations for
 1309 the aforementioned emission inventories were plotted with the Kernel density estimation, which
 1310 is a way to estimate the probability density function (PDF) of a random variable in a non-
 1311 parametric way.

1312

1313

1314 Figure 8. Overview of the comparison with ground-based measurements of ammonia. MFB
 1315 for each of the stations from AMoN, EMEP and EANET monitoring stations calculated after
 1316 running LMDz-OR-INCA with the emissions of EGG, VD0.5, NE and VDgrlf for the period
 1317 2008–2017.

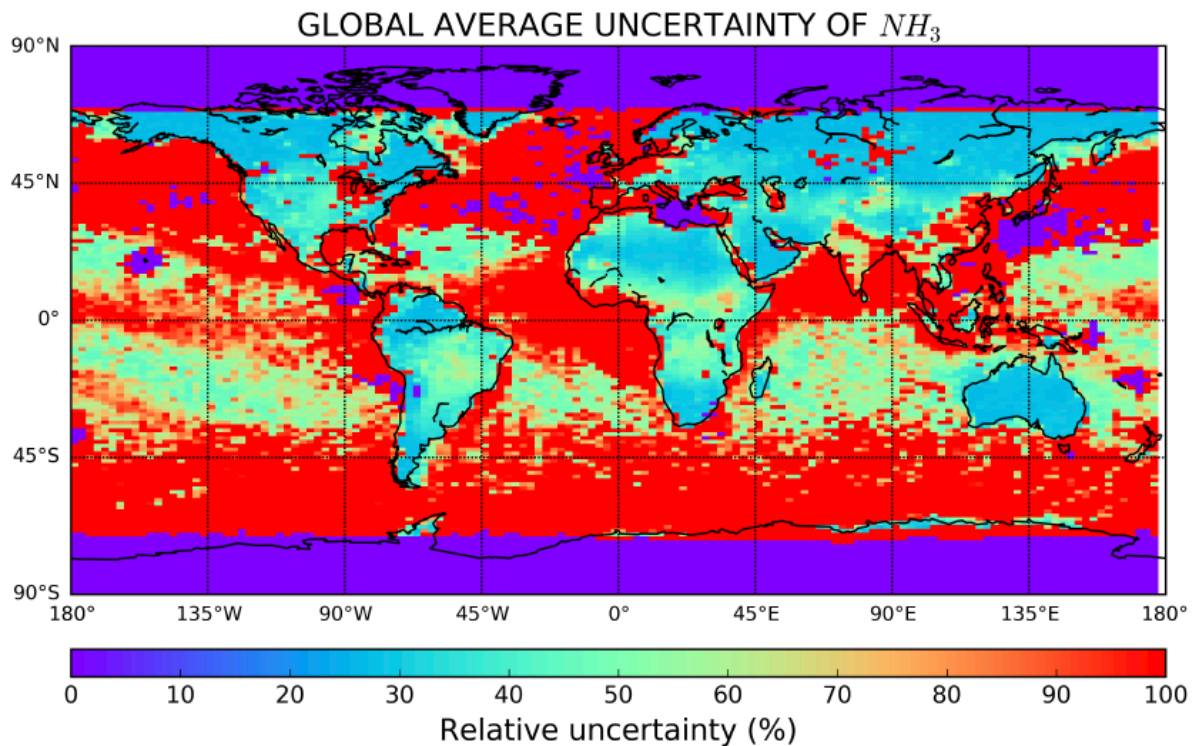

1318

COMPARISON WITH OBSERVATIONS FROM CRIS

1319
1320 Figure 9. Kernel density estimation (KDE) of the probability density function (PDF) of
1321 modelled versus CrIS concentrations of ammonia in a non-parametric way. Modelled
1322 concentrations are results of simulations using NE emissions datasets for the period 2012–2017,
1323 for which CrIS data were available. The comparison is shown for North America, Europe and
1324 Southeastern Asia.

1325

1326
 1327 Figure 10. 10-year average relative uncertainty of modelled surface concentrations expressed
 1328 as the standard deviation of surface concentrations from a model ensemble (Table 1) divided
 1329 by the average.

1330

1331 Table 1. Model ensemble simulations using different emissions for ammonia that were used in
 1332 the calculations of uncertainty. Uncertainties were calculated as the standard deviation of the
 1333 surface concentrations of ammonia from the 10 ensemble members for the 10-year period
 1334 (2008–2017).

	Parameter perturbed	10-year average emissions (Tg yr ⁻¹)
Ensemble 1	$d_k = 0$ in Eq. 2	121±50.6
Ensemble 2	$d_k = 10$ in Eq. 2	175±33.3
Ensemble 3	$d_k = 20$ in Eq. 2	189±28.7
Ensemble 4	$d_k = 60$ in Eq. 2	218±15.5
Ensemble 5	$d_k = 100$ in Eq. 2	208±51.8
Ensemble 6	$d_k = 500$ in Eq. 2	223±26.5
Ensemble 7	EGG	65±2.8
Ensemble 8	VD0.5	189
Ensemble 9	NE	213±18.1
Ensemble 10	VDgrlf	201±10.4
