Abstract. Epidemiological studies have consistently linked exposure to PM$_{2.5}$ with adverse health effects. The oxidative potential (OP) of aerosol particles has been widely suggested as a measure of their potential toxicity. Several acellular chemical assays are now readily employed to measure OP, however, uncertainty remains regarding the atmospheric conditions and specific chemical components of PM$_{2.5}$ that drive OP. A limited number of studies have simultaneously utilised multiple OP assays with a wide range of concurrent measurements and investigated the seasonality of PM$_{2.5}$ OP. In this work, filter samples were collected in winter 2016 and summer 2017 during the atmospheric pollution and human health in a Chinese megacity (APHH-Beijing) campaign, and PM$_{2.5}$ OP was analysed using four acellular methods; ascorbic acid (AA), dithiothreitol (DTT), 2-7-dichlorofluoroscin/hydrogen peroxidase (DCFH) and electron paramagnetic resonance spectroscopy (EPR). Each assay reflects different oxidising properties of PM$_{2.5}$, including particle-bound ROS (DCFH), superoxide radical production (EPR) and catalytic redox chemistry (DTT/AA), and combination of these four assays provided a detailed overall picture of the oxidising properties of PM$_{2.5}$ at a central site in Beijing. Positive correlations of OP (normalised per volume of air) of all four

assays with overall PM$_{2.5}$ mass was observed, with stronger correlations in winter compared to summer. In contrast, when OP assay values were normalised for particle mass, days with higher PM$_{2.5}$ mass concentrations (μg m^{-3}) were found to have lower

40 mass-normalised OP values as measured by AA and DTT. This finding supports that total PM$_{2.5}$ mass concentrations alone may not always be the best indicator for particle toxicity. Univariate analysis of OP values and an extensive range of additional measurements, 107 in total, including PM$_{2.5}$ composition, gas phase composition and meteorological data, provided detailed insight into the chemical components and atmospheric processes that determine PM$_{2.5}$ OP variability. Multivariate statistical analyses highlighted associations of OP assay responses with varying chemical components in PM$_{2.5}$ for both mass- and

45 volume-normalised data. AA and DTT assays were well predicted by a small set of measurements in multiple linear regression (MLR) models, and indicated fossil fuel combustion, vehicle emissions and biogenic SOA as influential particle sources in the assay response. Mass MLR models of OP associated with compositional source profiles predicted OP almost as well as volume MLR models, illustrating the influence of mass composition on both particle-level OP and total volume OP. Univariate and multivariate analysis showed that different assays cover different chemical spaces, and through comparison of mass- and

50 volume-normalised data we demonstrate that mass-normalised OP provides a more nuanced picture of compositional drivers and sources of OP compared to volume-normalised analysis. This study constitutes one of the most extensive and comprehensive composition datasets currently available, and provides a unique opportunity to explore chemical variations in PM$_{2.5}$ and how they affect both PM$_{2.5}$ OP and the concentrations of particle-bound ROS.

1 Introduction

55 Large-scale epidemiological studies have consistently linked the exposure of airborne particulate matter (PM) with a range of adverse human health effects (Hart et al., 2015; Laden et al., 2006; Lepeule et al., 2012). A recent study by the World Health Organisation estimated that 1 in 8 deaths globally in 2014 were linked to air pollution exposure (World Health Organisation, 2016) with urban areas in India and China particularly affected (Lelieveld et al., 2020). However, large uncertainty remains regarding the physical and chemical characteristics of PM that result in adverse health outcomes upon exposure (Bates et al.,

60 2019).

Studies have suggested that oxidative stress promoted by PM components *in vivo* could be a key mechanism that results in adverse health outcomes (Donaldson and Tran, 2002; Knaapen et al., 2004; Øvrevik et al., 2015). Oxidative stress occurs when excess concentrations of reactive oxygen species (ROS) overwhelm cellular anti-oxidant defences, resulting in an imbalance of the oxidant-antioxidant ratio in favour of the former, which can subsequently lead to inflammation and disease (Knaapen et

65 al., 2004; Li et al., 2003, 2008). The term ROS typically refers to H$_2$O$_2$, in some cases including organic peroxides, the hydroxyl radical ($\cdot$OH), superoxide (O$_2^{\cdot-}$) and organic oxygen-centred radicals. Particle-bound ROS is exogenously delivered into the lung through PM inhalation, or can be produced *in vivo via* redox-chemistry initiated by certain particle components, in addition to baseline tissue ROS produced by metabolic processes (Dellinger et al., 2001). The capability of PM to produce ROS with subsequent depletion of anti-oxidants upon inhalation is defined as oxidative potential (OP) (Bates et al., 2019).

70   OP is a fairly simple measure of PM redox activity, but reflects a complex interplay of particle size, composition and
chemistries which induce oxidative stress by free radical generation which triggers cellular signal transduction and damage.
These effects can be both localised (to lung epithelial surfaces and alveoli, reviewed by Tao et al., 2003) and systemic, through
immune system activation and cytokine release (Miyata and van Eeden, 2011), translocation of ultrafine particles into the
circulatory system (Oberdorster et al., 1992), increased circulating monocytes (Tan et al., 2000), and propagation to other cells

75   and organs (Laing et al., 2010; Meng and Zhang, 2006). Oxidative stress is implicated in the majority of toxicological effects
related to air pollution (Ghio et al., 2012; Kelly, 2003; Pope and Dockery, 2006; Risom et al., 2005). A rapid and simple metric
to capture the oxidative exposure burden which can be easily implemented for epidemiological studies will enable greater
insight into the mechanisms of PM toxicity beyond total PM mass concentrations alone.

There are now a wide range of acellular chemical methods that attempt to quantify particle-bound ROS and the entire OP of

80   PM, as typically acellular assays allow faster measurement and are less labour intensive compared to cell cultures or *in vivo*
methods (Bates et al., 2019). These include, but are not limited to, the dithiothreitol assay (DTT), ascorbic acid assay (AA), 2-
7-dichlorofluoroscin/hydrogen peroxidase assay (DCFH), electron paramagnetic spectroscopy (EPR), glutathione assay (GSH)
and 9-(1,1,3,3,tetramethylisoindolin-2-yloxyl-5-ethynyl)-10-(phenylethynyl)anthracene (BPEAnit). These acellular assays all
have differing sensitivities to specific particle components that may contribute to increased particle-bound ROS concentrations

85   and aerosol OP. For instance, DTT has been shown to be sensitive to soluble metals (Shinyashiki et al., 2009), including
copper and manganese (Charrier et al., 2015; Charrier and Anastasio, 2012), as well as a range of organic particle components
including water soluble organic carbon (WSOC, a mixture of 100's to 1000's of compounds), oxidised polycyclic aromatic
hydrocarbons (PAHs) e.g. quinones (Chung et al., 2006; McWhinney et al., 2013a), and humic-like substances (HULIS) (Dou
et al., 2015; Verma et al., 2015a). AA is particularly sensitive to redox-active transition metals, most notably Fe (Godri et al.,

90   2011) and Cu (Janssen et al., 2014; Pant et al., 2015), and has demonstrated sensitivity to organic carbon (Calas et al., 2018)
including secondary organic aerosol (Campbell et al., 2019a). EPR is applied to speciate and quantify radical species either
bound to aerosol particles (Arangio et al., 2016; Campbell et al., 2019b; Gehling and Dellinger, 2013), so-called
environmentally persistent free radicals (EPFR), or radicals formed upon suspension of particles into aqueous solution
(Gehling et al., 2014; Tong et al., 2016, 2017) or in some cases into synthetic lung lining fluid (Tong et al., 2018) consisting

95   of a mixture of AA, glutathione and uric acid. EPR has the advantage of not being influenced by the dark colour of particulate
suspensions (detection is *via* magnetic excitation rather than magnetic absorbance), does not require extraction of the PM from
the filter, and that speciation of the free radical generated can be explored using spin-trap reagents that are selective for specific
radicals (Miller et al., 2009). The DCFH assay has been shown to be particularly sensitive to hydrogen peroxide (H_2O_2) and
organic peroxides (Venkatachari and Hopke, 2008; Wragg et al., 2016), also present in secondary organic aerosol (SOA)

100   particles (Gallimore et al., 2017), and is a particularly useful assay for measuring particle-bound ROS (Wragg et al., 2016).
The application of these four commonly used assays simultaneously allows different mechanisms of ROS generation to be
assessed; the variability of particle-bound ROS (DCFH), the production of superoxide upon aqueous particle suspension (EPR)
and the catalytic generation of ROS via redox-active components (DTT/AA). Therefore, these data provide a broad picture of

the variability of both particle-bound ROS and OP, and comparison to a comprehensive compositional dataset provides a unique opportunity to probe the chemical changes in PM that affect the burden of particle-bound ROS and OP.

Despite several studies utilising the aforementioned assays, further exploratory work is required to determine specifically which sources, physical properties and chemical components influence aerosol OP variability. A limited number of studies have explored the role of chemical composition on aerosol OP, and it is often unclear which specific chemical components are responsible for driving aerosol OP; for example, studies show transition metals such as Cu and Mn dominate DTT activity (Charrier et al., 2015; Charrier and Anastasio, 2012), whereas others highlight the enhanced role of organics, in particular water soluble organic carbon (WSOC) such as HULIS, and quinones (Cho et al., 2005; Fang et al., 2016). Furthermore, several studies correlate volume-normalised OP measurements with compositional variability, but given the potential co-linearity of many aerosol components with overall mass, mass-normalised intrinsic OP values may provide additional insight into the effect of chemical composition on aerosol OP (Bates et al., 2019; Puthussery et al., 2020). Thus, a comprehensive characterisation of gaseous and particle phase pollution conditions combined with measurements utilising multiple OP assays simultaneously provides a wide range of information on particle-bound ROS and aerosol OP, allowing the identification of the most important components that drive aerosol OP. Ultimately, a greater understanding of the specific aerosol characteristics that influence OP, as well as specific sources that contribute more to aerosol OP, could allow the development of more targeted and efficient air pollution mitigation strategies. Further details of the selection of OP assays, their scope and biological applicability are described in **Section S2** of the Supplementary Information.

In this work, $PM_{2.5}$ filter samples collected in winter 2016 and summer 2017 during the APHH campaign were analysed using four acellular methods; AA, DCFH, DTT and EPR, providing a wealth of data on the health-relevant properties of $PM_{2.5}$ including particle-bound ROS, redox-active components contributing to aerosol OP, and the formation of superoxide radicals upon sample extraction. As the APHH campaign simultaneously captured one of the most extensive and comprehensive datasets atmospheric composition datasets including a broad range of PM compositional data, we aimed to establish what individual PM components, meteorological and atmospheric conditions contributed to increased OP assay response, whether these influences and compositions differed substantially between assays, and if the compositions reflected particular PM sources. We included 107 different measurements, comprising transition metals, AMS measurements, total elemental and organic carbon, and a broad panel of organic species relating to biomass and fossil fuel burning, cooking emissions, vehicular markers, secondary organic aerosol compounds, plus gaseous species and general atmospheric conditions. We sought to investigate the differences between volume-based and mass-based responses, as mass-based analysis facilitates site and temporal comparisons more readily than volume measurements and provide details on intrinsic particle properties that influence OP. In order to highlight underlying trends in such a broad and complex dataset, we also applied multivariate statistical analysis and developed multiple linear regression models to fully characterise the chemical compositional factors driving each assay response.

2 Materials and methods

2.1 Air Pollution and Human Health in a Chinese Megacity Campaign (APHH)

2.1.1 Site description

High-volume 24 hr aerosol filter samples were collected at the Institute of Atmospheric Physics (IAP) in Beijing, China
140 (39°58'28" N, 116°22'15" E) (**Figure S1**). Winter PM was collected during the months of Nov-Dec 2016 and summer PM was collected during the months of May-June 2017. $n = 31$ filters for winter 2016 and $n = 34$ filters for summer 2017 were collected. A $PM_{2.5}$ high-volume sampler (RE-6070VFC, TICSH, USA) was used at a flow rate of ~1.06 m^3/min. $PM_{2.5}$ for subsequent OP analysis was collected onto quartz microfiber filters (Whatman, 20.3 x 25.4 cm) with a collection area of 405 cm^2.

2.1.2 $PM_{2.5}$ composition, gas phase composition and meteorological data

145 Oxidative potential measurements were correlated with a range of additional particle phase composition, gas phase composition and meteorological measurements conducted concurrently during the APHH-Beijing campaign (Shi et al., 2019). Briefly, the following composition data was collated: total organic and elemental carbon (OC, EC), soluble inorganic ions (K^+, Na^+, Ca^{2+}, NH_4^+, NO_3^-, SO_4^{2-} and Cl^-) measured using ion chromatography (IC), low-oxidised organic aerosol and more-oxidised organic aerosol (LOOOA/MOOOA) fractions using aerosol mass spectrometry (AMS), biomass burning markers
150 (galactosan, mannosan and levoglucosan), 16 polycyclic aromatic hydrocarbons (PAHs) (see (Elzein et al., 2019, 2020)), C_{24}-C_{34} n-alkanes, aerosol cooking markers (palmitic acid, stearic acid, cholesterol), vehicle exhaust markers (17a(H)-22, 29,30-trisnorhopane (C27a) and 17b(H)-21a-norhopane (C30ba)), isoprene SOA markers (2-methylglyceric acid, 2-methylerythritol, 2-methylthreitol, 3-hydroxyglutaric acid), C_5-alkene triols (cis-2-methyl-1,3,4-trihydroxy-1-butene, 3-methyl-2,3,4-trihydroxy-1-butene, trans-2-methyl-1,3,4-trihydroxy-1-butene), α-pinene SOA tracers (cis-pinonic acid, pinic acid, 3-methyl-
155 1,2,3-butanetricarboxylic acid (MBTCA), 2,3-dihydroxy-4-oxopentanoic acid, aged α-pinene SOA marker), β-caryophyllene SOA tracer (β-caryophyllinic acid) and an aromatic volatile organic compound (VOC) SOA tracer (3-isopropylpentanedioic acid) (Liu et al., 2020). The following additional data was obtained from the Centre for Environmental Data Analysis (CEDA) archive: concentrations of inorganic elements Al, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Sb, Ba and Pb in $PM_{2.5}$ using X-ray fluorescence (XRF) (Xu et al., 2020a), gas phase concentrations of methanol, acetonitrile, acetaldehyde, acrolein, acetone,
160 isoprene, methacrolein, methyl ethyl ketone, benzene, toluene, C_2-benzenes and C_3-benzenes measured using proton transfer reaction time-of-flight mass spectrometry (PTR-ToF-MS) (Acton et al., 2018), gas phase concentrations of O_3, CO, NO, NO_2, NO_y and SO_2 as well as relative humidity (RH) and air temperature measurements (Shi et al., 2019), photolysis rates for J O^1D and J NO_2 (Whalley et al., 2020) and gas phase concentrations of hydroxyl radicals (OH), peroxy radicals (HO_2) and organic peroxy radicals (RO_2) measured using fluorescence assay gas expansion (FAGE) (Whalley et al., 2020).

 2.2 Oxidative potential measurements

2.2.1 Reagents

Chemicals and gases were obtained from Sigma-Aldrich unless otherwise indicated and were used without further purification: ascorbic acid (≥99.0 %,), Chelex[TM] 100 sodium form, 0.1 M HCl solution, 0.1 M NaOH solution, dichlorofluorescein-diacetate (DCFH-DA), 1 M potassium phosphate buffer solution, horseradish peroxidase (HRP), methanol (HPLC grade), and *o*-phenylenediamine (≥99.5 %). H_2O used for the DCFH, HRP and AA solution were obtained from a Milli-Q high purity water unit (resistivity ≥ 18.2 M Ω cm^{-1}, Merck Millipore, USA). For DTT analysis, 9,10-phenanthrenequinone (PQN) (≥99 %), 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) (99 %), DL-dithiothreitol (DTT) (≥98 %), potassium phosphate dibasic (≥98 %, Krebs buffer), potassium phosphate monobasic (≥98 %, Krebs buffer), and methanol (≥99.9 %) were all obtained from Fisher Chemical. Nitrogen (oxygen free) was obtained from BOC (Cambridge, UK).

2.2.2 Acellular oxidative potential assays

Four offline acellular methods for measuring PM$_{2.5}$ oxidative potential and particle-bound ROS were utilised in this work; The DCFH/HRP assay (Fuller et al., 2014), which quantifies the fluorescent product 2,7-dichlorofluoroscein, an assay that is particularly sensitive to species which are likely particle-bound ROS, the ascorbic acid (AA) assay (Campbell et al. (2019)) which quantifies the dominant product of AA oxidation, dehydroascorbic acid (DHA) *via* condensation with a dye and fluorescence spectroscopy. This is an AA-only assay and does not contain other components normally present in synthetic lung fluid (SLF); filter extracts are performed at pH 7, whereas the AA reaction with the filter extract is performed at pH 2 to improve assay stability and sensitivity (Campbell et al. (2019)). Electron Paramagnetic Resonance spectroscopy (EPR) (Miller et al., 2009) specifically targets the measurement of superoxide ($O_2^{.-}$) and the dithiothreitol (DTT) assay (e.g. Cho et al., 2005) quantifies the rate of loss of DTT via absorbance measurements. These acellular methods have been widely applied in the literature to study particle OP and particle-bound ROS (Bates et al., 2019). For detailed descriptions of the assay protocols, see Section S3 in the Supplementary Information. Assessing OP and particle-bound ROS in filters with the aforementioned assays is performed offline. There is potential to underestimate PM OP and particle-bound ROS using offline filter-based analysis, as short-lived components which contribute to particle-bound ROS and OP may undergo degradation prior to analysis. However, using an offline method allows the opportunity to correlate with a wide range of additional composition measurements, allowing a more explicit characterisation of the chemical components of PM that contribute to observed acellular assay responses.

2.3 Statistical analysis

We aimed to analyse the data as thoroughly as possible with respect to characterising the OP measured by each assay, and to attempt to robustly connect assays to both individual measurements and potential PM sources. As data were collated from

195   several different experimental projects, and as analytical uncertainty values were not available for the majority of the data, the use of positive matrix factorisation (PMF) was not undertaken for source apportionment, and will be published subsequently for selected analyses (Xu et al., 2020a). Multiple analytical platforms were used for the acquisition of compositional data, uncertainty estimates for each measurement were not easily estimable, a factor-based chemical mass balance approach was not required specifically, and temperature, relative humidity, actinic flux and other non-mass measurements could also be

200   influential on the OP response, and are factors mainly independent of PM sources. On this basis we considered that PMF would not ultimately give useful models in the specific context of OP. However, these issues are managed adequately by principal components analysis (PCA), which is a useful general unsupervised method for examining underlying variance and latent effects in data, and handles multicollinearity well, although it is not optimal for chemical mass balance source apportionment (Paatero and Tapper, 1994).

205   PCA and partial least squares regression (PLSR) models were produced in SIMCA+ 16.0 (Umetrics, Umeå, Sweden). Missing values were not altered prior to model construction, although measurements with more than 56% missing values per season were discarded from models. R^2 and Q^2 values were used to assess the goodness-of-fit of the model and the goodness-of-prediction of the data through 7-fold cross-validation respectively. Data were unit-variance scaled and mean-centred to remove effects related to absolute data magnitude. Models were allowed to optimise to the maximum number of latent variables (LV)

210   at which the cumulative Q^2 value stabilised, which for most PLSR models was a single LV. PLSR model robustness was assessed through permutation testing, where the classifier (i.e. OP assay response) for all samples was randomly permuted 999 times and the PLSR model constructed for each permutation; the model was considered robust if the real model R^2 and Q^2 values outperformed those from all random permutation models. Negative Q^2 values indicate no predictive power of the data in the model, and LVs with Q^2 significantly lower than the R^2 value (arbitrarily defined for this study as Q^2 at more than 10%

215   below the R^2) can be considered at least partially overfitted.

Spearman rank correlations (R_s) between OP measurements and $PM_{2.5}$ were calculated using OriginPro (2020) or R, and were used to assess the relationships between assay responses and individual measurements, with Mann-Whitney-U tests (in R) used for pairwise testing of the differences in seasonal response for both assays and individual measurements. All other multivariate analyses, multiple linear regression models and selected univariate analyses were produced in R 4.0.2 (R Core

220   Team, Vienna, Austria), implemented in RStudio 1.3.959 (Boston, Massachusetts, USA).

For multiple linear regression models, outlier values were arbitrarily deemed to be those greater than 5 times the standard deviation and replaced with the season median where appropriate for analysis. Measurement subsets manually selected as relevant to source composition were then subjected to a variable selection process, whereby pairwise Spearman correlations for all measurements were calculated, and measurements removed from subsets if they were highly correlated with other

225   measurements but predicted OP more poorly than the other co-correlated measurements, to reduce the number of variables contributing identical information in the final models. Multiple linear regression models were then further optimised from this initial subset using the *regsubsets* function in the *leaps* R package, to allow for between 4-8 variables which best predicted the OP response (models could be constructed with fewer or even more measurements, but the aim was to examine a small panel

of contributors to potential source compositions). The variable selection process precludes the use of linear regression mode
performance indicators such as the Aikake or Bayesian information criteria, as the model component sets are not identical.
The stability of model predictions and features were assessed using bootstrap resampling of data, by randomly splitting one
fifth of the data as a test set and using the remaining samples to construct the model and predict the left-out samples, for 500
random iterations. Stability was also assessed though overall variance in OP predictions, measurement feature coefficients and
model residuals plots, and run order/date bias (not differentiable as samples were analysed in date order) was assessed in
residuals plots. Although not all data distributions were strictly normal when examined in the univariate kernel density plots,
data were not log-transformed for multiple linear regression models, as this creates non-linearity in the model component
response, which can complicate interpretation. Model residuals were plotted for manual examination and were all generally
normally distributed despite the relatively small number of samples, and biases were related to periods of missing
measurements or samples with values below the limit of quantification. Code developed for analysis is publicly available at
https://github.com/katewolfer/Beijing.

3 Results and discussion

Both volume-normalised (OP_v, per m^3 air) and particle mass normalised (OP_m, per µg $PM_{2.5}$) values are considered in this
work, where the OP value of the specific assay and sample is normalised by the volume of air collected or by the total $PM_{2.5}$
mass on the filter, respectively. OP_v is useful when considering exposure or epidemiological outcomes, but OP_m is likely a
more informative metric when exploring how chemical composition influences $PM_{2.5}$ OP, and potentially enabling better OP
response, site and composition intercomparisons (Bates et al., 2019). Henceforth, OP_v and OP_m will be used when discussing
the overall response of all four methods; specific discussion of the acellular methods will be referred to as AA_v, DTT_v, $DCFH_v$
and EPR_v for volume-normalised values, and AA_m, DTT_m, $DCFH_m$ and EPR_m for mass-normalised values. For comparison of
mass normalised OP_m values, $PM_{2.5}$ composition measurements were also normalised for total PM mass (*e.g.* ng/µg per µg
$PM_{2.5}$)

3.1 Seasonal variation of OP_m and OP_v

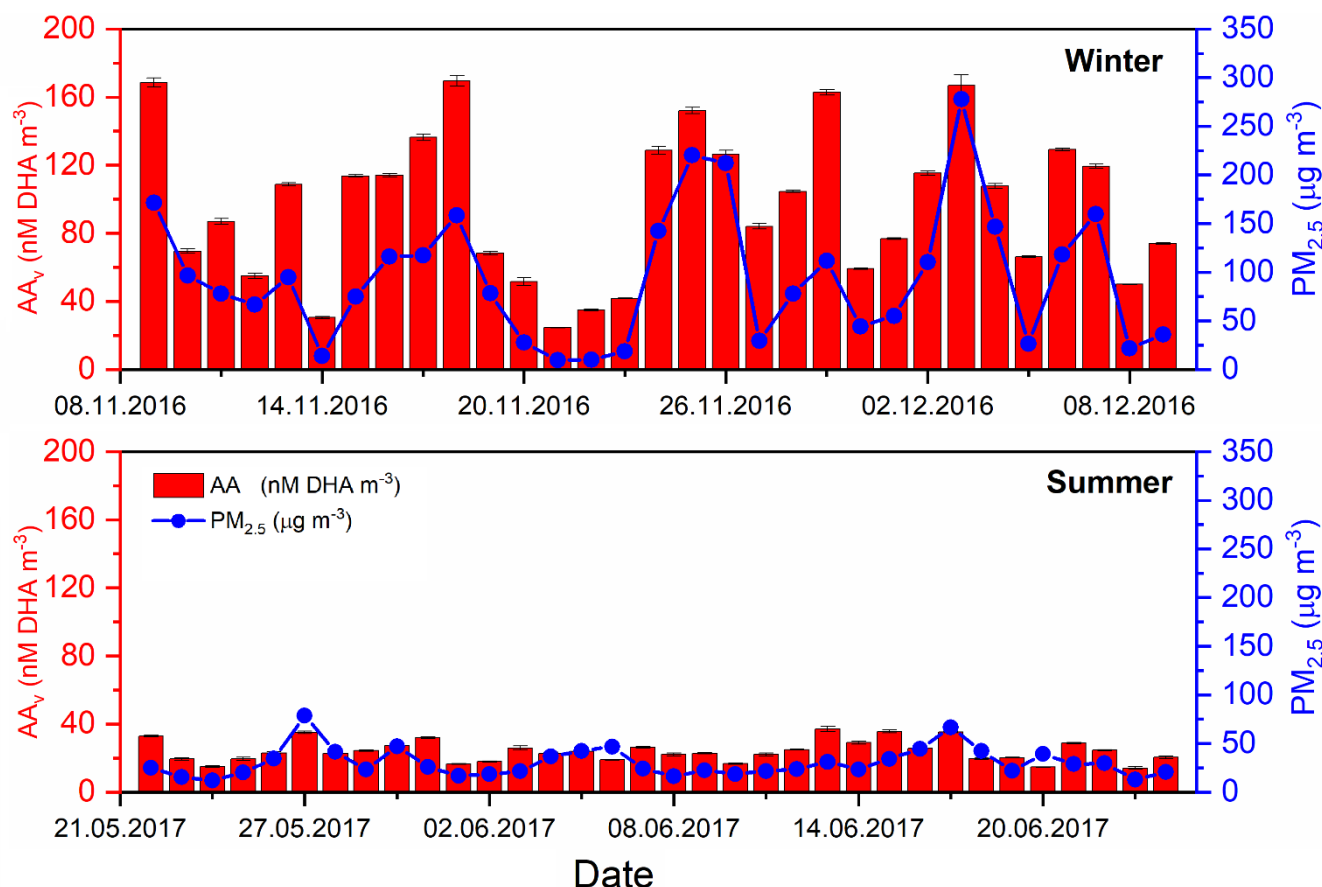
24-hour $PM_{2.5}$ mass concentrations in winter 2016 (08/11/2016-09/12/2016) ranged from 8.1 – 328.7 µg m^{-3}, with an average
$PM_{2.5}$ mass of 98.7 ± 75 µg m^{-3}, whereas in summer 2017 (21/05/2017-24/06/2017) $PM_{2.5}$ concentrations ranged of 13.6 – 85
µg m^{-3} with an average of 36.7 ± 16 µg m^{-3} (**Figure S7**) (Shi et al., 2019; Xu et al., 2020a). Average seasonal values for each
assay are summarised in Table S1. An example data set showing 24-hr average data, for AA_v and $PM_{2.5}$ mass in both the winter
and summer campaign, is shown in **Figure 1** (for $DCFH_v$, DTT_v and EPR_v, see **Section S6** "Summary statistics for all
measurements" in the Supplementary Information).


Figure 1. 24-hour averaged volume-normalised AA$_v$ (red bars) and PM$_{2.5}$ mass (blue dots), analysed from 24-hour high volume filters, for both winter 2016 (08/11/2016 – 08/12/2016) and summer 2017 (21/05/2017 - 24/06/2017) (Shi et al., 2019; Xu et al., 2020a). Substantially higher average PM$_{2.5}$ mass concentrations (μg m^{-3}) and AA$_v$ were observed in the winter season compared to the summer (see Table S1 for summary). DCFH$_v$, DTT$_v$ and EPR$_v$ 24-hour averaged datasets can be found in Figures S8-S10 respectively.

For all assays, a higher average PM$_{2.5}$ OP$_v$ was observed in the winter compared to the summer in Beijing (**Table S1**). The average AA$_v$ was 96.7 ± 42.7 nM [DHA] m^{-3} in the winter, whereas a mean value of 24.1 ± 6.1 nM [DHA] m^{-3} was observed in the summer. Given the recent introduction of this AA-based assay, which measures the formation of the AA oxidation product DHA rather than measuring the decay of AA *via* UV absorbance, limited literature values are available for direct comparison (Campbell et al., 2019a). Average DCFH$_v$ in the winter was 0.71 ± 0.52 nmol H$_2$O$_2$ m^{-3} compared to 0.17 ± 0.11 nmol H$_2$O$_2$ m^{-3} in the summer, which is within the range of DCFH$_v$ values observed in previous studies in Taiwan, the USA and Singapore (OP$_{DCFH}$ 0.02 - 5.7 nmol H$_2$O$_2$ m^{-3}) (Hasson and Paulson, 2003; Hewitt and Kok, 1991; Hung and Wang, 2001; See et al., 2007; Venkatachari et al., 2005). Mean observed values for DTT$_v$ in the winter and summer were 2.9 ± 0.11 nmol min^{-1} m^{-3} and 0.9 ± 0.40 nmol min^{-1} m^{-3}, respectively. The mean values of DTT$_v$ observed in this study are greater than those measured in similar studies in Beijing (Liu et al., 2014) (0.11-0.49, mean = 0.19 nmol min^{-1} m^{-3}) with similar mass concentrations of PM$_{2.5}$ (mean = 140 μg m^{-3}), although they are within the range of DTT$_v$ values observed in a number of

previous studies in several locations, including Europe (Jedynska et al., 2017; Yang et al., 2015), the US (Fang et al., 2015; Verma et al., 2014) and Northern China (Liu et al., 2018) (0.1-14.7 nmol min^{-1} m^{-3}). The mean EPR_v values, relating to the specific detection of $O_2^{\cdot-}$, were $2.4\times10^6 \pm 1.6\times10^6$ and $5.8\times10^5 \pm 4.1\times10^6$ counts m^{-3} in the winter and summer campaign, respectively.

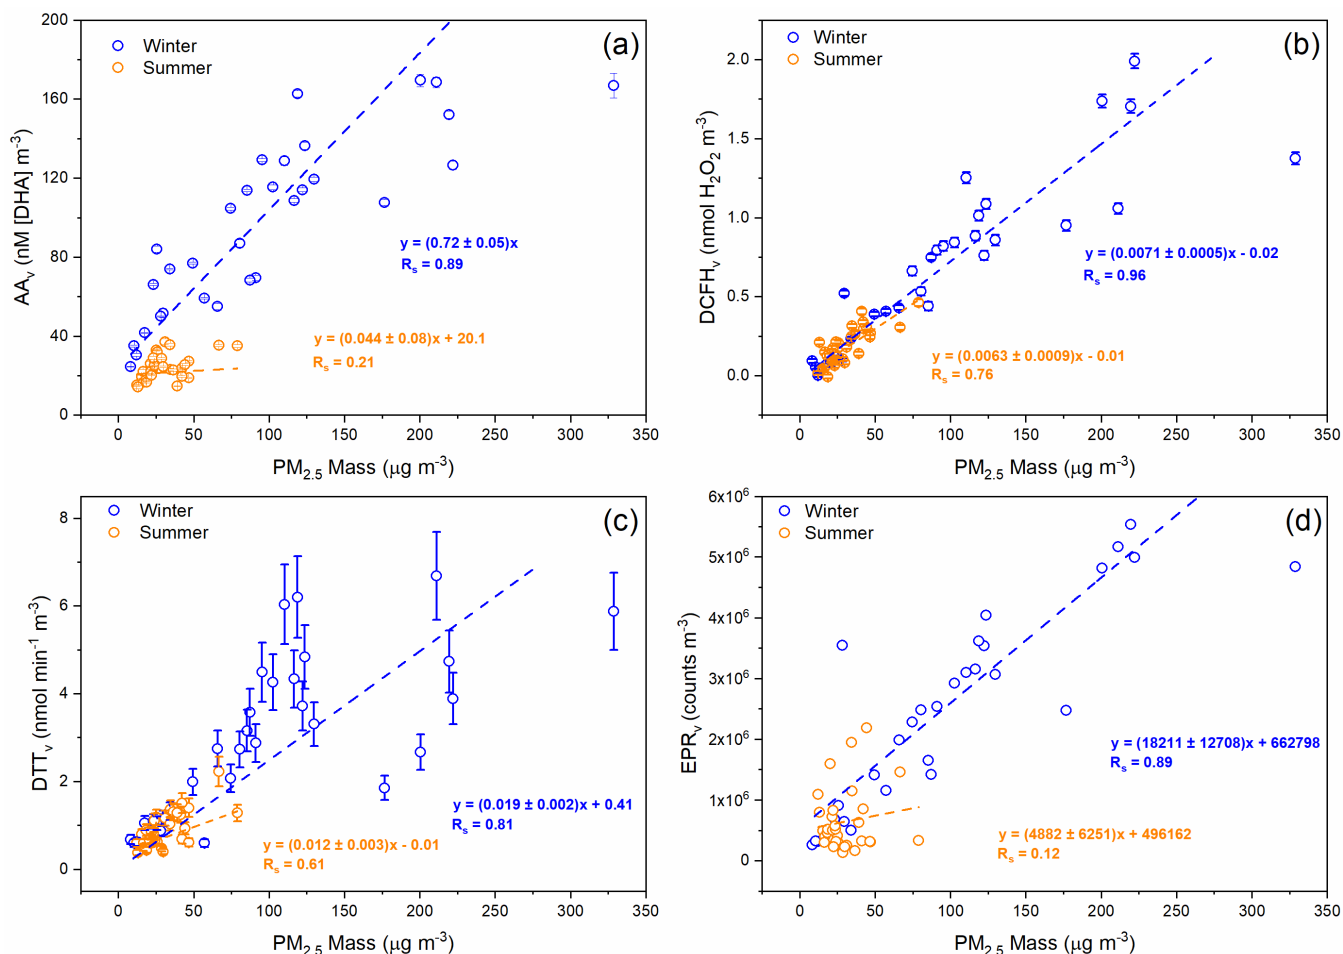
Spearman rank correlation coefficients (R_s) of aerosol OP_v with $PM_{2.5}$ vary between the winter and summer season, and also between OP assays, as illustrated in **Figure 2**. All four assays, when normalised per volume (OP_v), show a stronger correlation with $PM_{2.5}$ mass concentration in the winter compared to the summer, consistent with results observed in Chamonix, France by Calas *et al*. (Calas et al., 2018) For example, $DCFH_v$ correlates well with 24-hr average total $PM_{2.5}$ mass concentration (µg m^{-3}) in both winter ($R_s = 0.96$) and summer ($R_s = 0.76$) **(Figure 2B)**, whereas AA_v correlates well in the winter ($R_s = 0.89$) and poorly in summer ($R_s = 0.21$). Similar correlations of $DCFH_v$ with $PM_{2.5}$ mass concentrations in both winter and summer suggest that species influencing $DCFH_v$ variability (e.g. H_2O_2 and organic peroxides, likely particle-bound ROS) present in the particles are relatively consistent between both seasons. Similar to AA_v, differences between the seasons are also observed for DTT_v and EPR_v, where correlations of aerosol OP_v vs. $PM_{2.5}$ are stronger in winter compared to summer (**Figure 2C and 2D**), also generally consistent with previous studies, although in contrast to Calas et al. (2018), who observed no difference in EPR_v between seasons in Chamonix, although in that study the spin trap DMPO was used to study hydroxyl radicals, whereas in this study we focus on the formation of superoxide upon particle suspension in aqueous solution. The differences in the correlation shown in **Figure 2** suggests that the four assays are sensitive to different PM components and that in winter and summer different PM sources or components are important for the assay's responses (Calas et al., 2018; Saffari et al., 2013; Verma et al., 2014). **Figure 2** demonstrates that $PM_{2.5}$ mass could be a reasonable predictor of total OP_v in winter but the poorer correlations between all OP_v assays and $PM_{2.5}$ in the summer indicate that a more detailed understanding is necessary to elucidate and ultimately predict aerosol OP. However, the variability in the strength of correlation between OP_v and $PM_{2.5}$ mass as well as the seasonal difference indicates that compositional differences in $PM_{2.5}$ or additional atmospheric processes influence $PM_{2.5}$ OP.


Figure 2. Comparison of $PM_{2.5}$ OP_v during winter 2016 (blue) and summer 2017 (orange) vs. $PM_{2.5}$ mass (µg m^{-3}). (a) AA_v, (b) $DCFH_v$, (c) DTT_v and (d) EPR_v. Each datapoint represents a 24-hour average for OP measurements and $PM_{2.5}$ mass. Corresponding R_s and linear fit equations are included. For AA_v, $DCFH_v$ and DTT_v, error bars represent the standard deviation observed over three repeat measurements for each filter sample, and in some cases the error is smaller than the data point. Uncertainty values are unavailable for EPR_v measurements.

To gain further insights into the potential particle-level compositional differences underlying assay OP response, the OP data for the four assays was normalised to the $PM_{2.5}$ mass in each sample. As shown in **Figure 3**, mass-normalised OP_m values vary up to a factor of ten within a single season. AA_m, $DCFH_m$, DTT_m and EPR_m for both winter and summer are also displayed in Figure 3, with colour bars indicating the 24-hr average total $PM_{2.5}$ mass (µg m^{-3}) for the corresponding OP_m measurement. The average OP_m response observed in this study shows a similar trend to OP_v (**Table S2**), where higher OP_m values are observed for winter compared to summer (Figure 3), as observed previously (Liu et al., 2018; Saffari et al., 2014). This demonstrates that there are specific properties of $PM_{2.5}$ in the winter that result in overall higher intrinsic OP_m compared to the summer.

For AA_m, an inverse relationship between total $PM_{2.5}$ mass concentration and AA_m is observed in both seasons, where days with high $PM_{2.5}$ mass loadings have correspondingly low AA_m values in both the winter and summer, with almost a factor of

6 difference between the AA_m on the highest $PM_{2.5}$ mass day ($PM_{2.5}$ = 328 µg m^{-3}, AA_m = 0.6 nM [DHA] µg^{-1}) and lowest $PM_{2.5}$ mass day observed during the winter campaign ($PM_{2.5}$ = 8 µg m^{-3}, AA_m = 3.53 nM [DHA] µg^{-1}). A similar trend is observed for DTT_m, where in general days with higher overall $PM_{2.5}$ mass concentrations have correspondingly low DTT_m

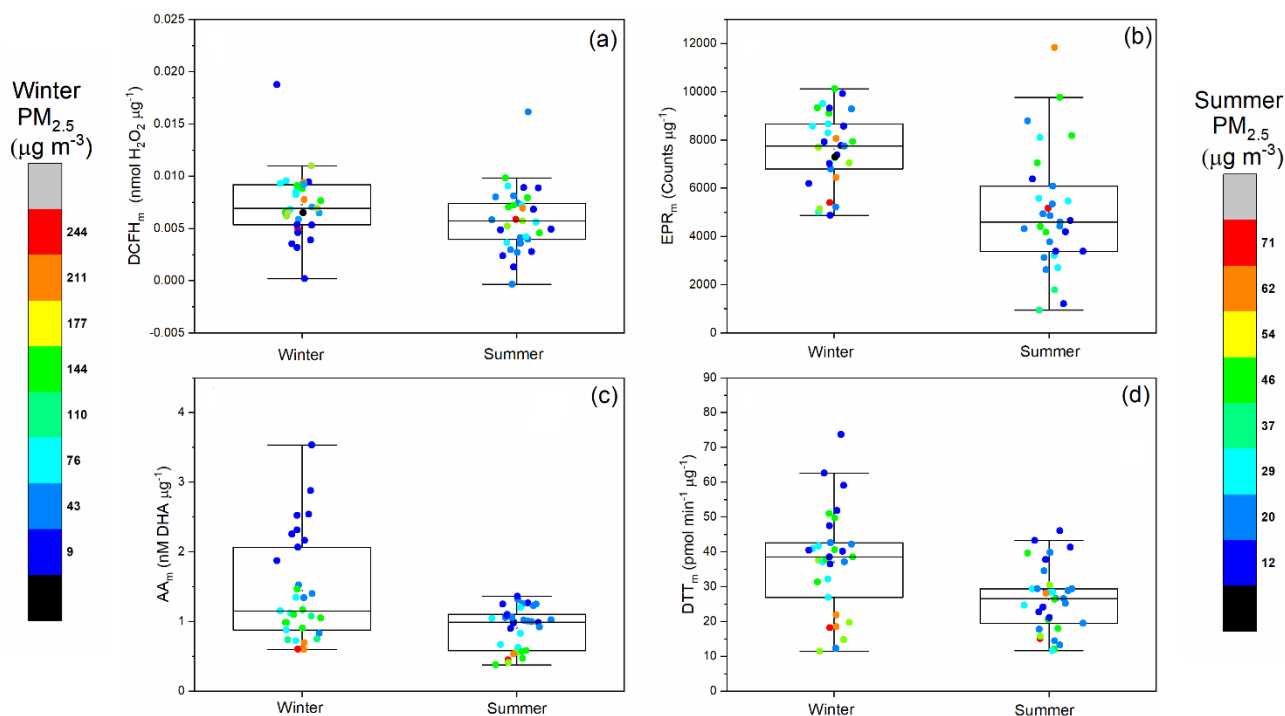
315   values, which has also been observed previously (Wang et al., 2020b). The DTT_m response is also not correlated with Cu and Mn concentrations, despite the non-linear but monotonic relationship between these components being demonstrated in other studies (Charrier et al., 2016). These results indicate that on high-pollution days a large fraction of the PM mass might be OP-inactive, resulting in low intrinsic OP_m values. In general, smaller particles have been observed to have higher DTT_m values compared to larger particles (Bates et al., 2019; Janssen et al., 2014), an effect which may also play a role here. Another

320   possibility is that on higher $PM_{2.5}$ mass days, selected chemical species interact with or deactivate redox-active components present in $PM_{2.5}$ (e.g. interaction of organics with metals (Tapparo et al., 2020), therefore reducing the observed OP_m signal. It is also possible that components present in $PM_{2.5}$ on higher $PM_{2.5}$ mass concentration days interfere with the assay response. It is currently unclear which chemical components are responsible for the observed inverse relationship between $PM_{2.5}$ mass with AA_m and DTT_m. However, statistically significant inverse correlations are observed between AA_m and DTT_m in both the

325   winter and summer with the chemically undetermined "unknown" fraction of $PM_{2.5}$ for DTT_m (R_s = -0.81) and AA_m (R_s = -0.75), implying that $PM_{2.5}$ chemical components unaccounted for in this study are likely responsible for the lower intrinsic AA_m and DTT_m values on high $PM_{2.5}$ mass days (See **Section 3.2** "Univariate analysis of PM OP and additional measurements", **Figure S11** and **Figure S12**).

In contrast, higher $DCFH_m$ responses are observed on days with greater $PM_{2.5}$ mass concentrations in both winter and summer.

330   Increased $DCFH_m$ responses on more polluted days could indicate that the mass fraction of particle-bound ROS (e.g. organic peroxides from SOA) increases with increasing $PM_{2.5}$ mass concentration, or that the capacity of PM components to produce H_2O_2 upon extraction, as measured by DCFH, is enhanced. Despite the significant seasonal difference in EPR_m, no obvious relationship between EPR_m and $PM_{2.5}$ mass was observed in our study. There is potential to underestimate PM OP and particle-bound ROS using offline filter-based analysis, as short-lived components which contribute to particle-bound ROS and OP may

335   undergo degradation prior to analysis. However, using an offline based method allows the opportunity to correlate with a wide range of additional composition measurements, allowing a more explicit characterisation of the chemical components of PM that contribute to observed acellular assay responses.


340 **Figure 3.** Summer and winter 24-hour averaged mass-normalised OP_m (a) AA_m (μM DHA μg^{-1}), (b) $DCFH_m$ (nmol H_2O_2 μg^{-1}), (c) EPR_m (counts μg^{-1}) and (d) DTT_m. Box plots indicate the median, 25% and 75% percentiles, and the data range. Data points are colour coded with respect to the 24-hour average $PM_{2.5}$ mass (μg m^{-3}), with a separate colour scale for winter and summer $PM_{2.5}$ masses given the difference in total $PM_{2.5}$ masses observed between the seasons.

Spearman rank correlations (R_s) between the four assays, for mass-normalised OP_m and volume-normalised OP_v are presented

345 in **Table 1**. In terms of OP_v, all four assays show significantly strong correlations with each other in the winter season (R_s 0.72 – 0.89), but weaker correlations are observed between assays in the summer (R_s 0.01-0.58), a seasonal difference observed previously by Calas et al. (2018). In contrast, the only statistically significant correlation observed for OP_m is between AA_m and DTT_m in the winter season only ($R_s = 0.58$).

Seasonality of both OP_v and OP_m observed in the assays could be driven by changes in PM sources influencing overall OP, or

350 a number of physical and chemical factors directly affecting particle composition. For instance, lower ambient temperatures in the winter may increase the partitioning of semi-volatile organic compounds, such as small quinones (e.g. anthracenequinone and 2,3-dimethylanthraquionone (Delgado-Saborit et al., 2013)) and nitro-PAHs, which have been shown to influence DTT activity (Ntziachristos et al., 2007; Verma et al., 2011), observations which are supported by lab-based studies showing decreasing aerosol OP at higher temperatures (Biswas et al., 2009; Verma et al., 2011). Changing boundary

355 layer height between the seasons may also contribute to higher concentrations of species which correlate with $PM_{2.5}$ mass responsible for increasing aerosol OP during the winter, compared to summer, especially affecting OP_v seasonality (Wang et al., 2020a). Furthermore, air mass history may play an important role in the observed seasonality of OP. For instance, it was

observed that winter days with high $PM_{2.5}$ mass concentrations typically originate from regional sources south of Beijing, which is widely industrialised, whereas high mass days in the summer typically have more varied air mass histories (Panagi et al., 2020; Steimer et al., 2020). There are likely varying contributions between different sources in different seasons, e.g. more photochemistry in the summer driving oxidation and biogenic sources, and more contributions from residential heating combustion in the winter (Xu et al., 2020a). In order to gain further insight into what causes the observed variability of OP, relationships between particle chemical composition and aerosol OP will be explored in detail below.

Table 1. Correlation of volume-normalised (OP_v, top panel) and mass-normalised (OP_m, bottom panel) assay responses in the winter (blue) and summer (orange) campaign. It should be noted that assay responses expressed as mass-normalised (OP per µg) are correlated with mass-normalised additional particle phase composition measurements (i.e. µg or ng per µg $PM_{2.5}$).

OP_v R_s	AA_v	$DCFH_v$	EPR_v	DTT_v
AA_v		0.89***	0.86***	0.83***
$DCFH_v$	0.35*		0.86***	0.72***
EPR_v	0.19	0.01		0.88***

3.2 Univariate analysis of PM OP_m and additional measurements

Spearman rank correlations between OP_m of the four assays and 107 additional measurements conducted during the APHH campaign (see **Section 2.1.2** "$PM_{2.5}$ composition, gas phase composition and meteorological data"), were calculated for both the winter ($n = 31$) and summer ($n = 33$). We focus on OP_m in the forthcoming discussion; as mentioned previously, as we consider it a particularly informative metric when determining the role of chemical composition on OP (Bates et al., 2019; Puthussery et al., 2020) (all univariate statistical summaries are presented in **Section S8**).

The majority of additional particle phase composition, gas phase composition and meteorological measurements differed significantly by season. Exceptions included Al, V, Zn, Pb, Ca^{2+}, Na^+, NH_4^+, acetaldehyde, acetonitrile, methanol, methyl ethyl ketone, methyl vinyl ketone/methacrolein, trans-2-methyl-1,3,4-trihydroxy-1-butene, β-caryophyllinic acid, 3-hydroxyglutaric

acid, C5-alkene triols, cholesterol, LOOOA and MOOOA. Stacked bar plots illustrating the total daily concentrations for both mass-normalised and volume-normalised data are shown in **Figure 4** and **Figure S13**. Total concentrations of individual PM components (excluding all composite measures) account for approximately 0.3-0.8 µg/µg, i.e. 30 – 80% of the total PM mass (data not shown). Interestingly there were no marked or characteristic changes in mass composition associated with haze days; however, haze events were generally correlated with increased biomass burning marker concentration and total organic carbon in winter for the mass-normalised data (also observed during recent later winter haze events in Beijing (Li et al., 2019)), and small inorganic ion concentrations in both seasons in the volume-normalised data (Figure S13).

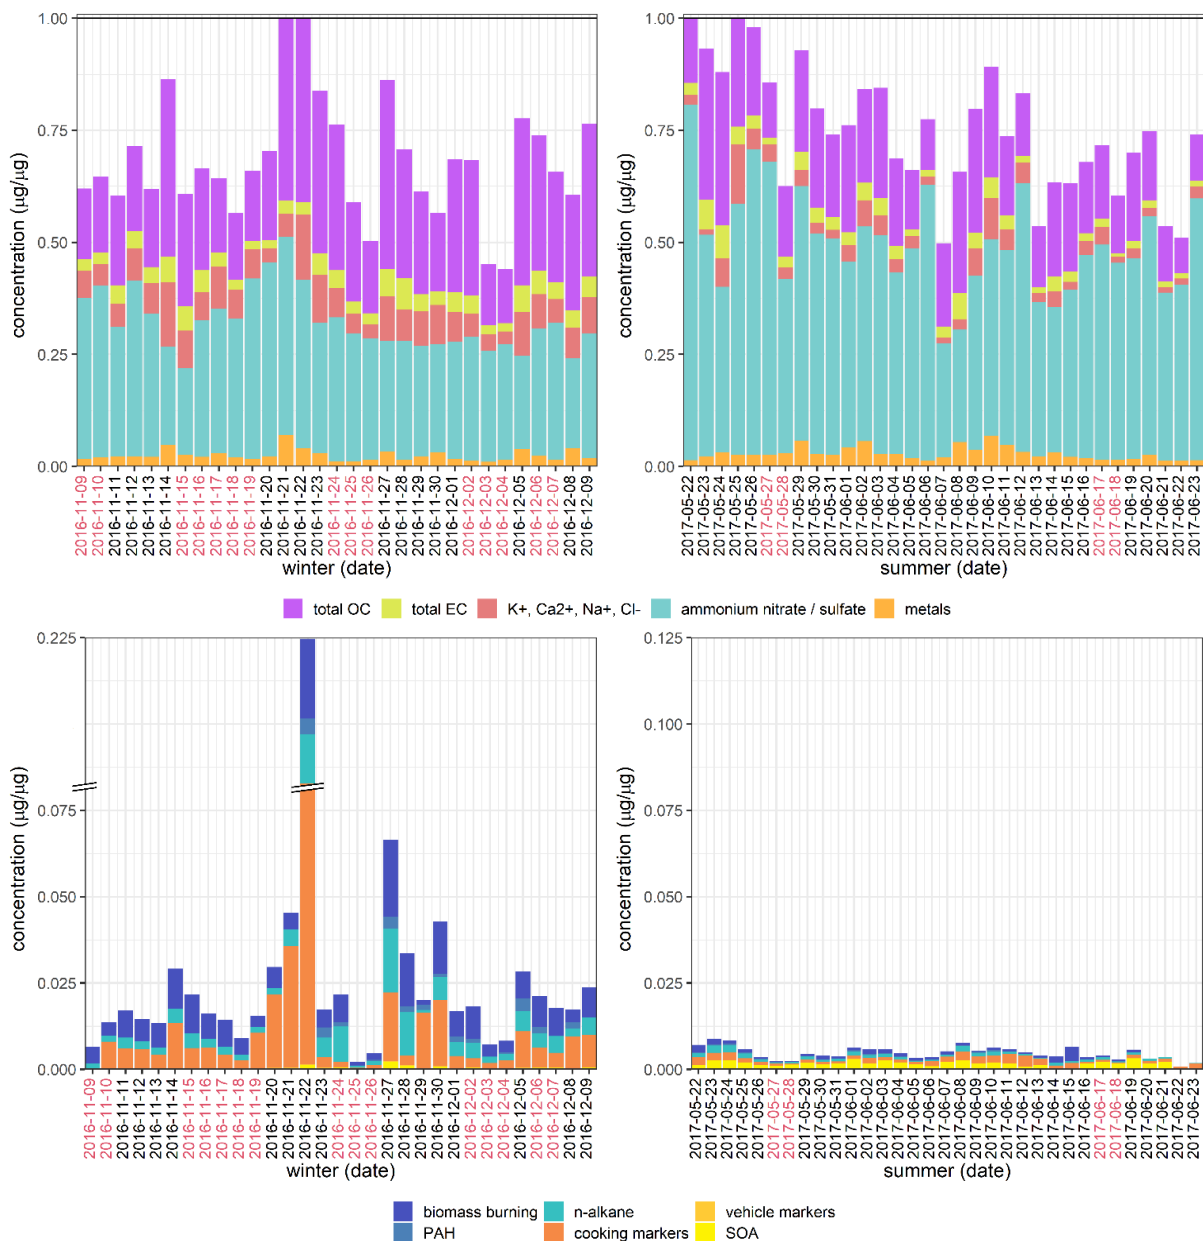
IC measurements (K^+, Na^+, Ca^{2+}, NH_4^+ NO_3^- and SO_4^{2-}) account for the greatest proportion of total particle mass in both seasons, all of which are major components of secondary inorganic PM mass (NH_4^+, NO_3^-, SO_4^{2-}), mineral dust (Ca^{2+}, K^+,), and marine aerosols (Na^+, Cl^-). These species were present at higher daily concentrations in summer than in winter. Summer compositions for each category were generally consistent for the whole sampling period, with a larger total proportion of SOA markers, whereas winter compositions were more variable, with greater contributions from elemental carbon, PAHs, n-alkanes and cooking-related compounds than for summer samples. Although PAHs are not redox-active (Charrier and Anastasio, 2012), they are precursors to redox-active oxy-PAHs (quinones) and nitro-PAHs (Atkinson and Arey, 2007), and have well-established intrinsic cellular toxicity (reviewed in Moorthy et al., 2015), mediated by their conversion to hydroxy-PAHs, which exert mutagenic and teratogenic effects, and also inducing transcriptional modifications and oxidative stress. EC and n-alkanes are also non-redox-active and the exact mechanism of their toxicities is unclear (Levy et al., 2012); however, SOA derived from the interaction of n-alkanes with NO_x with photo-oxidation (Lim and Ziemann, 2005; Presto et al., 2010) is likely both to contribute to the redox activity of samples (Tuet et al., 2017), and to have more toxic properties than its precursors (Xu et al., 2020b). The sample from 22 November 2016 has a particularly high concentration of cooking markers (palmitic acid, stearic acid and cholesterol). This could reflect the fact that the traditional Chinese winter solar term Xiao Xue (小雪,"Light Snow"), begins on this date (Li, 2006), a period associated with the preparation of warm foods as the ambient temperatures in northern China drop; a similar elevation of palmitic acid and stearic acid has been observed around the same week in a more recent study in Shanghai (Wang et al., 2020c).


Figure 4. Stacked bar plots of total concentrations for mass-normalised data. **Abbreviations:** OC: organic carbon; EC: elemental carbon; PAH: polycyclic aromatic hydrocarbon; SOA: secondary organic aerosol "Metals" is the summed concentrations of Al, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Sb, Ba, Pb; "biomass burning" is the summed concentrations of palmitic acid, stearic acid and cholesterol; "PAH" is the summed concentrations of naphthalene, acenaphthylne, acenaphthene, fluorene, phenanthrene, fluoranthene, pyrene, benzo(a)anthracene, chrysene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(a)pyrene, indeno(1,2,3-cd)pyrene, dibenzo(a,h)anthracene and benzo(ghi)perylene; "*n*-alkane" is the summed concentrations of C24, C25, C26, C27, C28, C29, C30, C31, C32, C33, C34; "cooking markers" is the summed concentrations of palmitic acid, stearic acid, cholesterol; "vehicle markers" is the summed concentrations of 17a(H)-22,29,30-trisnorhopane (C27a) and 17b(H),21a(H)-norhopane (C30ba); "SOA" is the summed concentrations of 2-methylthreitol, 2-methylerythritol, 2-methylglyceric acid, cis-2-methyl-1,3,4-trihydroxy-1-butene, -methyl-2,3,4-trihydroxy-1-butene, trans-2-methyl-1,3,4-trihydroxy-1-butene, C5-alkene triols, 2-methyltetrols, 3-hydroxyglutaric acid, cis-pinonic acid, acid, MBTCA, beta-caryophyllinic acid,

glutaric acid derivative, 3-acetylpentanedioic acid, 3-acetylhexanedioic acid, 3-isopropylpentanedioic acid and 2,3-dihydroxy-4-oxopentanoic acid. Dates marked in red indicate partial or total day haze events as described in Shi et al. (2019). Measurement uncertainty values were unavailable for most data types, and for selected dates in the upper plots, the sum of the total mass measurements is slightly more than 1 (i.e. more than 1µg per µg); for these dates, the data has been proportionately scaled. It should be noted that the OC measurement in the upper plots incorporates the variety of organic carbon species represented in the lower plots.

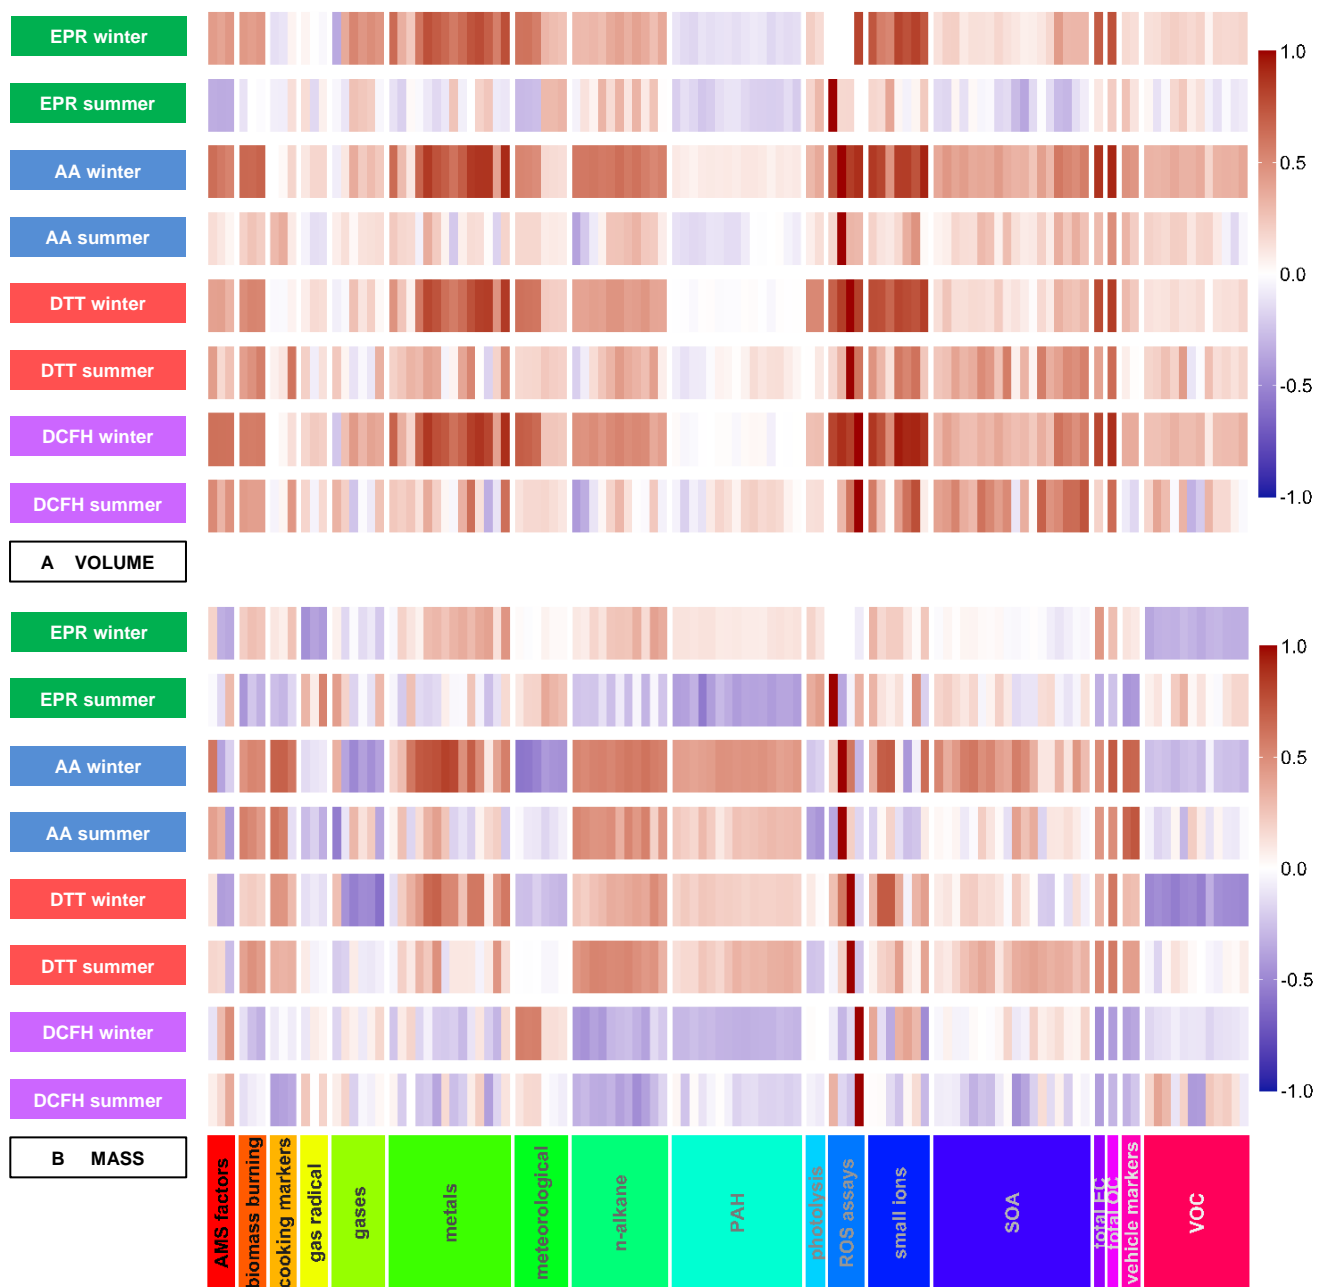
R_s calculated for OP_v and OP_m with the individual compositional measurements have strikingly different univariate correlations, as illustrated in correlation heatmaps (**Figure 5**). Cumulative scores, referring to the number of R_s correlations $\geq$ 0.5 for OP_m and OP_v (Table S3), demonstrate that for all assays, considerably more significant correlations are observed for OP_v in the winter compared to OP_m. For both OP_v and OP_m, all assays show more statistically significant correlations in winter compared to summer, particularly for the AA response (AA_m, $n = 54$ winter, $n = 15$ summer, AA_v $n = 67$ winter, $n = 4$ summer). Volume-based correlation analysis (**Figure 5A**) indicates that a very large number of the 107 atmospheric components measured in this study correlate statistically significantly with all four assays. The large number of correlations in the volume-normalised data indicate strong collinearity between concentrations of chemical components in $PM_{2.5}$ and overall $PM_{2.5}$ mass concentrations likely due to meteorological processes, complicating analysis of the sources and processes contributing to OP variability in particles. However, the mass-based analysis (**Figure 5B**) reveals that the mass fractions of chemical components and sources to which the four assays are sensitive to differ significantly (further illustrated by the weaker inter-assay correlations shown in Table 1), which demonstrates that mass-based analysis of OP data is also important to elucidate atmospheric processes and particle sources responsible for the different OP metrics.


Figure 5. Heatmaps demonstrating the correlation of OP, expressed as volume-normalised OP_m (A) and mass-normalised OP_v (B) vs a range of additional measurements conducted during the APHH campaign. Red indicates positive correlation; blue indicates inverse correlation. For OP_m, particle-phase components are also mass normalised (µg per µg $PM_{2.5}$ and for OP_v, volume-normalised (µg or ng per m^3).

A range of transition metals were all positively correlated with AA_m and DTT_m, including V, Cr, Mn, Fe, Co, Ni, Zn, Cd and Pb (all $R_s \geq 0.5$, $p < 0.05$). This reinforces the importance of their contribution to urban $PM_{2.5}$ and potential to substantially

450   influence $PM_{2.5}$ OP, particularly Fe, Cr, V and Co which are commonly major components of vehicle emissions, and which can undergo redox-cycling reactions producing ROS (Charrier et al., 2014; Shen and Anastasio, 2012; Valko et al., 2005) contributing to higher AA_m and DTT_m in the winter compared to the summer. Stronger correlations between Fe and AA_m are observed in the winter (R_s 0.73) compared to summer (R_s 0.48) despite Fe concentrations ($\mu g/\mu g$) being lower in winter samples than summer samples, again highlighting the enhanced role of redox-active transition metals in winter. It is not established

455   whether this seasonal difference is related to the chemical availability (i.e. redox state, solubility, speciation) of Fe, to the variability of emission sources of Fe between the seasons, or to some other important unknown additional contribution of Fe to AA_m in the summer; complexation of Fe in PM may differ between seasons, and the ligands directly influence the redox state and thus the bioavailability of the metal (Ghio et al., 1999). Ultimately, the direct correlation of transition metals measured only by ICP-MS with OP does not adequately reflect the nuances in redox behaviour of these species when they are complexed

460   with organic ligands (Calas et al., 2017), as well as their range of oxidation states; this represents further gaps in the standard chemical (and particularly the transition metal) characterisation of PM. The epidemiological effects related to bioavailability of the metal when complexed (Costa and Dreher, 1997) in humans are also still not fully explored, although it is clear from multiple atmospheric and clinical studies that complexation affects both transition metal uptake in both the atmosphere and in the body. Interestingly, a mild inverse correlation of Fe with $DCFH_m$ is observed (**Table S8**), which may be linked to the

465   destruction of particle-bound organic peroxides by Fe *via* Fenton-type chemistry (Charrier et al., 2014), a process which the DCFH assay is specifically sensitive to (Gallimore et al., 2017; Wragg et al., 2016), and which has been observed in other recent studies (Paulson et al., 2019). No significant positive correlation between any metals measured in this study and $DCFH_m$ and EPR_m was observed. Few EPR studies have looked specifically at superoxide formation, as is the case here, but those conducted so far show that EPR specifically detecting O_2^- is less sensitive to transition metal chemistry compared to traditional

470   EPR methods focussing on OH formation.

In the summer, from the measured transition metals, only Fe correlated significantly positively (Spearman correlation p-value < 0.05) with DTT_m and AA_m response ($R_s = 0.48, 0.51$ respectively), whereas in the winter, DTT_m and AA_m correlated with a number of transition metals including V, Cr, Mn, Fe, Co, Ni, Zn, Cd. Of particular note, AA_m is mildly correlated with Cu in winter samples (R_s 0.48), whereas no correlation is observed between DTT_m and Cu in either winter or summer, in agreement

475   with a recent online DTT study also (Puthussery et al., 2020). In contrast, previous reports from other locations have implicated Cu as a dominant contributor to DTT oxidation, considering volume normalised and mass normalised data (Calas et al., 2018; Charrier et al., 2015). Interestingly, in contrast with OP_m, strong correlations ($R_s > 0.6$) are observed in this study between AA_v, EPR_v, $DCFH_v$ and DTT_v and Cu in the winter, but poorer correlations are observed in the summer for all assays ($R_s < 0.39$). Higher average Cu concentrations in winter compared to summer (winter = 17.7 ng m^{-3}, summer = 4.9 ng m^{-3}) may

480   explain the higher R_s observed for Cu vs. OP_v in winter compared to summer, whereas mass normalised concentrations of Cu are more similar between the seasons. Poor correlation of Cu concentrations with AA_m and DTT_m response in winter may hint

at more insoluble Cu complex formation observed at this site in Beijing, as predominantly water-soluble Cu participates in redox reactions, therefore the sensitivity of AA and DTT towards Cu probably depends on the soluble fraction of Cu (Bates et al., 2019; Charrier and Anastasio, 2012; Fang et al., 2016). Furthermore, the presence of organic chelating ligands in PM may reduce the redox-activity of Cu and Fe (Charrier et al., 2014; Charrier and Anastasio, 2011; Shen and Anastasio, 2012).

Correlations between AA_m and DTT_m with total OC are observed in both summer and winter (**Tables S6** and **S7**), and with total EC in the winter season, whereas $DCFH_m$ is negatively correlated with total OC (**Table S8**). In contrast, $DCFH_m$ is positively correlated with MOOOA and LOOOA, whereas DTT_m and AA_m show no correlation and even exhibit slight negative correlations with MOOOA and LOOOA in both summer and winter. This potentially indicates that the MOOOA and LOOOA AMS fractions, typically associated with water-soluble organic carbon content (Verma et al., 2015b), may contain higher concentrations of particle-bound ROS (i.e. organic peroxides) as measured by $DCFH_m$, but on a per-mass basis these species may contribute less significantly to AA_m and DTT_m compared to redox-active transition metals and other organic components. Total OC and EC correlations with AA_m and DTT_m may relate to concentrations of redox-active organic components such as oxidised PAHs and quinones, which may not be represented by MOOOA and LOOOA factors and which have been shown to significantly contribute to DTT_m (Chung et al., 2006; McWhinney et al., 2013b).

Significant correlations are also observed between AA_m and a range of *n*-alkanes and hopanes (17a(H)-22, 29,30-trisnorhopane (C27a) and 17b(H)-21a-norhopane (C30ba), **Table S6**), markers of primary organic aerosol emitted from vehicles (Schauer et al., 1999; Subramanian et al., 2006). Although these species are not redox-active, they are co-emitted with redox-active transition metals such as Fe, V and Cu from vehicle activity, either directly (Bates et al., 2019) or *via* dust resuspension, and other organics contributing to SOA (Platt et al., 2014) and highlight the potential importance of vehicular emissions on AA_m. Vehicular emissions and dust-resuspension have been previously shown to be the dominant sources of Cu and Fe in Beijing (Gao et al., 2014). EPR_m, DTT_m and $DCFH_m$ responses do not show any significant correlations with these organic traffic markers.

Notably, AA_m correlates well with cis-pinonic acid, pinic acid and 3-methyl-2,3,4-butanetricarboxylic acid (MBTCA) in both seasons, all of which are biogenic SOA markers and products of α-pinene oxidation, with MBTCA a marker for OH-initiated ageing of first generation α-pinene oxidation products (Müller et al., 2012). AA sensitivity towards α-pinene SOA has been demonstrated previously (Campbell et al., 2019a). Although these three carboxylic acids are also not redox-active, they may correlate with the formation of particle-bound ROS such as peroxides or peroxy acids in SOA (Steimer et al., 2018), or with species that decompose liberate ROS upon extraction (e.g. (Tong et al., 2017)); these processes are highly likely to contribute to AA_m, highlighting the assay's potential sensitivity to redox-active particle phase components and particle-bound ROS. Generally, DTT_m has been previously shown to be relatively insensitive to SOA as observed here (Bates et al., 2015; Verma et al., 2015b), and both DTT_m and $DCFH_m$ correlate poorly with the SOA markers analysed in the present study (**Tables S7** and **S8**).

Compared to the three other assays, few significant correlations are observed between EPR_m and additional measurements, despite the much better correlations with the EPR_v data, particularly for the summer samples. However, seasonality in the

EPR$_m$ response is still observed, with substantial variability in the mass-normalised EPR$_m$ response ($\approx$ factor of 10 in the summer, factor of 2 in the winter, **Figure 3**). Therefore, we observe differences in aerosol composition influencing EPR$_m$, but with the current comprehensive measurements (i.e., 107 parameters) are unable to determine the specific PM$_{2.5}$ components responsible for the observed EPR$_m$ variation.

520 The univariate analysis presented here clearly shows that OP$_m$ enables a more nuanced identification of aerosol components influencing the oxidising properties of PM$_{2.5}$ as compared to OP$_v$. Many more correlations are observed when considering volume-normalised OP$_v$, likely related to collinearity of species with overall PM$_{2.5}$ mass concentration due to meteorological effects. Metal and organic tracers of traffic emissions (exhaust and non-exhaust) such as Fe, Cu and hopanes and SOA markers show especially strong correlations with AA$_m$, whereas the other three OP$_m$ metrics (DTT$_m$, DCFH$_m$ and EPR$_m$) provide a less

525 clear picture.

3.3 Multivariate modelling of OP from measured components

To assess potential latent influences from the individual components on assay response and hence on OP, a systematic multivariate analysis was undertaken. Initially, principal components analysis was applied to the whole set of independent measurements excluding the OP assay responses (i.e. the values to be predicted by the models), to investigate which contributed

530 most to the variation in the data, whether there were relationships between measurements which characterised OP, and if the OP$_m$ response could be predicted from the individual component measurements.

In the PCA model, the seasonal variation within the samples was clearly apparent (**Figure 6**). The first four principal components (PC) accounted for 68.2% of the observed variation in the dataset (R^2 or goodness-of-fit), of which 50.5% was stable through 7-fold cross-validation (Q^2, or model variation accounted for through cross-validation), indicating about half of

535 the variation in the model was robust with respect to sample score prediction. The loadings plot (**Figure 7**) indicated that seasonality in the first principal component was related to increased PAHs (Feng et al., 2019), *n*-alkanes (He et al., 2006) and biomass burning markers (He et al., 2006) in winter, and increased ozone (Zhao et al., 2018), ambient temperature and selected SOA markers (including 2-methylerythritol (Liang et al., 2012) and 2-methylglyceric acid (Ding et al., 2016; Shen et al., 2018)) in summer, findings which are consistent with existing volume-based studies. When scores were coloured by OP,

540 the AA$_m$ (**Figure 6A**), DTT$_m$ (**Figure 6C**) and DCFH$_m$ (**Figure 6D**) assay responses could be observed in the second and sometimes also the first principal components (although the EPR$_m$ response demonstrated no specific trend, **Figure 6B**). When loadings plots were examined by general measurement category (**Figure 7**), it was observed some categories of measurements cluster together (e.g. PAH, *n*-alkanes, NO$_x$, temperature, relative humidity), but this was related to strong correlation of these species with the OP$_m$ measurement and known compound behaviour rather than to measurement bias, as other categories

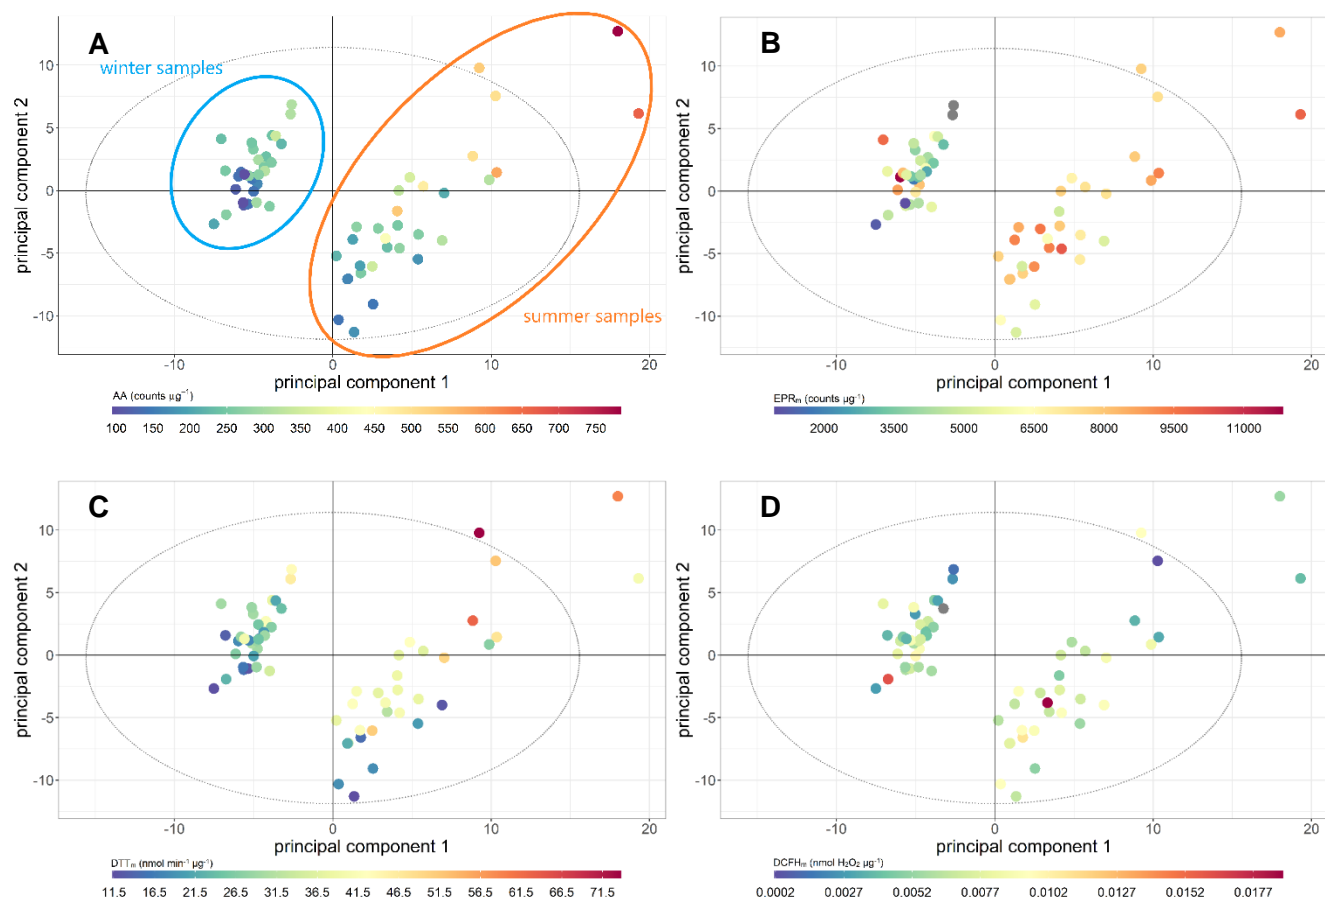
545 showed broader variation (e.g. inorganic and small organic ions, gases, metals and SOA markers).


Figure 6. Principal components analysis scores plot of all data. A: coloured by AA_m response; B: coloured by EPR_m response; C: coloured by DTT_m response; D: coloured by $DCFH_m$ response. Both principal component 1 and principal component 2 demonstrate variance associated with AA and DTT response, and there is greater variation associated with the winter response than the summer response (highlighted in A). PC 1 R^2X 35.90%, Q^2 29.28%; PC 2 R^2X 19.34%, Q^2 23.73%; the model included six principal components, with a cumulative R^2X of 68.2% and Q^2 of 50.5%.
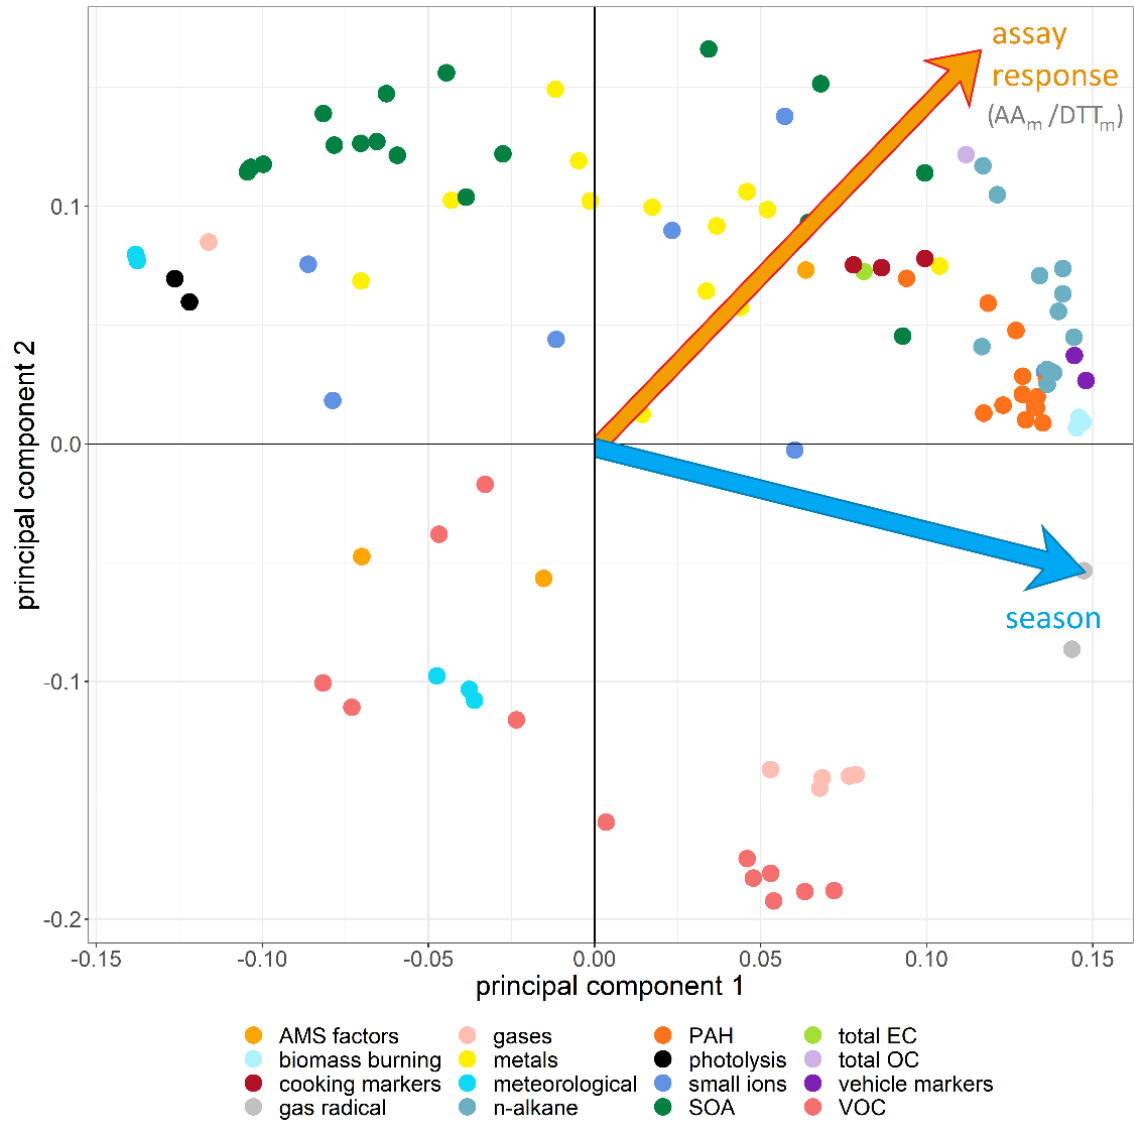

Figure 7. Principal components analysis loading plot for all data points. Points are coloured by measurement category; fully labelled loadings are provided in **Figure S14**. The plot is annotated with the same orientation as the scores plot, to indicate the direction of visualised trends for selected assays and for season from the latent variable origin as shown in **Figure 6**. In PC 1, the winter classification is driven by increased gas radicals, *n*-alkanes, PAH, vehicle markers, biomass burning markers, total OC and selected metals and SOA markers; the summer classification is driven by increased temperature and photolysis, ozone (the single gas species in this section of the plot), selected SOA markers and metals, and selected VOCs. In PC 2, high AA_m and DTT_m response is associated with increased SOA, transition metals, cooking markers, *n*-alkanes and PAH concentrations in samples; low AA_m and DTT_m response associated with low VOCs, gases and selected meteorological parameters (relative humidity).

Partial least squares regression (PLSR) is a supervised regression extension of PCA, which models the variation in the data associated with a defined sample classification (Eriksson et al., 2013). PLSR models were constructed for each individual OP

assay and season, to examine the most specific markers associated with assay response. **Table 2** provides the model performances for all PLSR assay models, and example PLSR scores plots for AA_m and DTT_m models (both seasons) are illustrated in **Figures 8** and **9** (analogous plots for other assays provided in **Figures S18** and **S19**). The performance indicators
570 show that while the mass-normalised measurement data can be used to explain and predict a large majority of the variation associated with AA_m summer/winter and DTT_m winter assay response, the other assay responses were less consistent; R^2 and Q^2 values for these models indicated that less than 70% of the variance in response can be predicted from the individual component measurements, and the predictions were much less stable through cross-validation. These results could suggest either that assay responses are not as adequately sensitive at µg/µg concentrations as for the total PM per sample, or that a
575 proportion of the OP_m response is contributed to by species not measured directly in this campaign and which cannot also be inferred from total organic carbon measurements. As total OC is estimated from combustion properties of the sample rather than from a sum of individually validated component measurements, and as multiple organic and transition metal-organic complexed species contribute to the total OC measurements with unknown redox properties, these observations reiterate the need for more comprehensive chemical characterisation of PM composition. Similarly to the univariate correlations, the
580 summer samples were less well modelled in both mass-normalised and volume-normalised data, indicating either reduced assay sensitivity (which may also be compounded by the reduced collected filter PM mass in summer) or the influence of unmeasured components.

Table 2. Performance assessment of PLSR models for all assays, for both mass-normalised (left) and volume-normalised (right) data. Models are considered to perform well when both cumulative (i.e. across all latent variables included in the model) R^2 and Q^2 values are high, or at
585 a minimum where Q^2 values are within 10% of the R^2 value, indicating that the variance is well accounted for in model cross-validation. Permutation tests were rejected for robustness if any single random permutation model performance surpassed the performance of the real cross-validated model; on this basis, the winter $DCFH_m$ and summer DTT_v models were rejected (highlighted with *), although fewer than three random models outperformed the real model, and none of the permuted model Q^2 values outperformed those of the real model.

assay	season	mass (µg/µg)				volume (µg/m³)

Table 3 shows the top ten features in the variable importance in projection (VIP) for the PLSR loadings, which enable a ranking of the features which contribute most to the model (Naes and Martens, 1988). It is evident from these data that the features which best model the OP_m seasonal response are derived from multiple particle sources and atmospheric aging processes. For example, the AA_m and DTT_m responses show similar trends in the multivariate models, but the main contributors to their responses have little overlap, with AA_m responses being more strongly associated with SOA tracers, PAHs and general measures of organic carbon, and the DTT_m more characterised by combustion and vehicle emissions markers (**Figures S19-S22**; Figures S17-S24 list the top 50 contributors to each assay model response). Notably, compounds which are not generally recognised as being redox-active were frequently observed to be important in PLSR classification, and though they do not directly contribute to the OP_m response, they are likely co-emitted with or are secondary products of redox-active particle components.

3.4 Multiple Linear Regression (MLR) modelling to predict OP_m associated with specific sources

While multivariate model loadings highlighted the measurements most associated with assay response, multivariate models are not always amenable to variable selection, which is important to characterise the chemical profiles contributing to each assay OP response. Multiple linear regression modelling has been used in previous studies (Calas et al., 2018) to establish contributors to total OP response, rather than looking at source apportionment in relation to OP, and only simple forward variable selection was used for model refinement. In the present study, relevant measurements were grouped into six categories of known contributors to Beijing PM (biogenic SOA, biomass burning, coal and fossil power generation, cooking, dust and vehicle emissions). The full method description, references, model formulae and performance parameters for the mass-normalised data models are presented in the Methods (**Section 2.3** "Statistical analysis") and in **Section S10**. Briefly, literature sources (**Table S13**, Section S10) and the SPECIEUROPE database (Pernigotti et al., 2016) were used to establish which individual chemical measurements were likely to be characteristic of each source, with several measurements appearing in multiple categories (e.g. total EC). All proxy and composite measurements (except total EC, as multiple organic carbon species are represented in the dataset, but elemental carbon should be independent of the majority of these), AMS measurements, and general atmospheric measurements including temperature, relative humidity and actinic flux measurements were excluded from models entirely. Composite measures duplicate selected individual measurements; atmospheric measurements complicate model interpretation, and are more likely to be useful as random effects terms in a mixed effects model approach (not pursued in the present study due to the complexity of model parameterisation and measurement uncertainties). Multiple linear regression models were then constructed for each assay and season for each category, using both mass-normalised and volume-normalised data.

MLR models further reinforced that not all putative sources and components of $PM_{2.5}$ contribute equally to OP_m response (

Table 4). OP_m assay response models based on measurements characteristic of vehicle emissions, coal/fossil fuel combustion and biomass burning gave accurate and robust predictions of OP_m, and these are important contributors to PM (reported as

mass per volume) in Beijing urban background sites (Yu et al., 2013; Zheng et al., 2005). As expected, OP_v models also gave very good predictions for these source profiles, but additionally gave improved models of OP_v for biogenic SOA and dust compared with the OP_m data. Although the same base sets of predictors for each source were used for each model (season, OP assay and PM normalisation), there was only partial overlap of the final selected predictors between models from the same

640 source and season, again illustrating the complex dynamic between OP and overall mass/volume composition. As with the PLSR models, the most important contributors to regression models were often not redox-active species, indicating that they are probably influencing or contributing to the oxidation state of the redox-active PM components. As with the univariate and multivariate analyses, the summer samples gave less robust linear regression models (and thus OP predictions) from both mass- and volume-normalised data. However, AA and DTT measurements produced the best models for all source

645 contributions, indicating that these assays might be most optimal for measuring OP in an urban environment, as they appear to reflect the variety and composition of PM sources well.

Vehicle emissions, biogenic SOA and winter biomass burning contributions to AA and DTT response (as measured by the model R^2 value) were generally comparable across both assays, contrasting with the findings of Fang et al. (2016), who observed greater OP response in positive matrix factorisation-chemical mass balance (PMF-CMB) models associated with

650 traffic emissions for AA_v over DTT_v, and biomass burning for DTT_v over AA_v in multiple locations in the southeastern US. However, a more recent study conducted in the coastal areas adjacent to Beijing (Liu et al., 2018) observed similar seasonality to the present study in the DTT OP_m response. Vehicle emissions (Wang et al., 2016; Yu et al., 2019), coal combustion (Ma et al., 2018; Yu et al., 2019), biomass burning (Ma et al., 2018) and dust (Yu et al., 2019) sources have been shown in other studies using PMF models to contribute to OP_v in Beijing, all using the DTT assay. Cooking markers (palmitic acid, stearic

655 acid and cholesterol) contributed a substantial proportion of the known organic fraction of the PM mass and volume concentrations (see **Figure 4**), but did not contribute robustly to the modelled OP response for either normalisation type, suggesting they are either not strongly contributing to or affected by oxidative conditions in PM, or that their variation over the sampling period cannot be linearly modelled. Similarly, biomass burning markers contribute a comparable number of variables in the model base sets, but appear to contribute much more significantly to the OP_v than to the OP_m response. Biogenic

660 SOA and dust models (which incorporate K^+, Na^+, Ca^{2+}, Cl^-, Al, Ti, Mn, Fe and Zn) explained a significant proportion of winter OP_v responses, but were only strongly correlated with winter AA and DTT for mass-normalised models. These observations suggest these sources contribute to PM OP_v by total quantity rather than through their particularly high intrinsic OP, i.e. their mass as a proportion of the PM mass is smaller, but their concentration per volume is high, and the AA and DTT assays have a notable selectivity for these species over the EPR and DCFH assays.

665 It should be noted that the MLR models represent a sub-optimal prediction of the OP response from measured components, as numerous species which are known source components (e.g. PAHs from combustion processes and those which distinguish gasoline from diesel vehicle emissions, or VOCs relevant to biomass burning such as methanol or acrolein) could not be included in models. Not all measurements which were associated in the literature with a particular assay response passed the stages of variable selection for mass-normalised models, which could reflect a lower limit of detection in either the OP_m assay

670 responses, or in the individual component measurements. Synergistic effects between individual measured components (e.g. transition metals with organic components such as quinones or carboxylic acids (Wang et al., 2018)) cannot be interpreted from linear models when the complexation and oxidation states of the contributing compounds are essentially unknown. MLR models do not fully account for the proportion of each measurement which may originate from multiple emissions sources, and PMF-CMB or mixed effects models can address this issue more adequately. Validation of both the multivariate and MLR

675 models using secondary datasets (both from Beijing and other locations) is also needed prior to their future implementation.

Table 4. R^2 values for optimised subset multiple linear regression models of relevant source contributions. R^2 values greater than 0.7 are highlighted in bold. Full model performance indicators are provided in **Section S11** of the SI, including all model terms, residuals, coefficients and p-values.

4 Conclusions

This study presents a detailed and comprehensive analysis of PM$_{2.5}$ oxidative potential and particle-bound ROS concentrations measured in winter 2016 and summer 2017 during the APHH-Beijing campaign at a central site in Beijing, China. Four acellular methods for measuring OP were applied, providing a broad assessment of the oxidative properties of particles

685 including particle-bound ROS concentrations, superoxide radical production and catalytic redox activity. We correlated the acellular assay responses with an extensive and comprehensive dataset including 107 additional atmospheric measurements (particle components, trace gases, meteorological parameters) to delineate chemical particle components and atmospheric processes and sources responsible for driving PM$_{2.5}$ OP. Higher volume-normalised and mass-normalised OP values across all assays were observed in the winter compared to the summer. An inverse correlation was observed between AA$_m$ and DTT$_m$

690 with overall PM$_{2.5}$ mass concentrations, i.e. days with higher PM$_{2.5}$ mass concentrations have lower intrinsic OP values. This

is likely due to an increase in OP-inactive material in high $PM_{2.5}$ mass days, and/or a mass fraction that is at present undetermined and highlights that a focus on total PM exposure only does not necessarily capture accurately the oxidising properties and therefore certain toxicological effects of PM.

Univariate analysis with the additional 107 measurement parameters acquired during the APHH-Beijing campaign highlight

695   significant assay-specific responses to chemical components of $PM_{2.5}$, as well as a seasonal difference in what components drive aerosol OP. It also highlights the importance of considering both volume-normalised and mass-normalised OP metrics when drawing conclusions on the role of chemical composition on OP, as assay correlations vary significantly between the two metrics. The data presented in this study illustrate that mass-normalised OP_m values provide a more nuanced picture of specific chemical components and sources that influence intrinsic OP, whereas many more correlations with OP_v values are

700   observed, likely due to collinearity of many chemical components with overall $PM_{2.5}$ mass concentrations driven by changes in meteorological conditions. Both metrics, mass-normalised OP_m as well as volume-normalised OP_v, are important to consider with OP_v a more relevant metric with respect to exposure and epidemiological studies, whereas OP_m provides more insight into what sources and what composition drives OP concentrations in particles. Furthermore, OP_m may allow easier study and site inter-comparisons.

705   The multivariate statistical analyses encapsulated the observations from the univariate analyses into comprehensive single models of OP relating to PM composition, and the inference from the univariate analyses that OP_m measured by each assay is related to different compounds present in the particle was confirmed. It is clear from these differences that assay chemistry must contribute directly to its chemical selectivity, as the independent chemical measurements were given equal analytical weight with respect to each assay. The relationship between each assay and the independent measurements also confirmed that

710   while there may exist a correlative relationship between an assay and non-redox active compounds such as *n*-alkanes or PAHs, the assay is more likely to be measuring either secondary oxidation products of these primary compounds or species co-emitted that contribute to particle OP. This represents a gap in the chemical analysis of these samples, and more detailed redox active compound speciation is required, especially for functionalised organics. Furthermore, variable selection of measurements and evaluation through multiple linear regression models indicated that OP_m is well predicted by measurement panels characteristic

715   of combustion sources, particularly (exhaust and non-exhaust) vehicle emissions, and biogenic SOA. This study demonstrates further that these commonly applied acellular assays are sensitive to a wide and differing range of chemical components, highlighting the advantage of using these assays as a they encompass multiple chemical components and sources of aerosol into an integrated measurement. Further comprehensive work is needed to identify the direct links between these OP assays and biological and toxicology data.

Author Contributions. SJC collated data, analysed filters for AA and DCFH, performed data analysis and interpretation and wrote the manuscript. KW performed univariate and multivariate statistical analysis, data interpretation and wrote the manuscript. BU, JW, ST and NS analysed filters for AA, DCFH, DTT and EPR respectively. TV provided XRF and additional

data. AMS data were provided by YS. PAH data was provided by AE and AL. SOA tracer data was provided by DL, LL and PF. All other authors contributed to data analysis, interpretation and writing of the manuscript.

Competing Interests. The authors declare that they have no conflict of interest

Special Issue Statement. This article is part of the special issue "In-depth study of air pollution sources and processes within Beijing and its surrounding region (APHH-Beijing) (ACP/AMT inter-journal SI)
