Abstract

Himalayan glaciers are melting due to atmospheric warming with the potential to limit access to water for more than 25% of the global population that reside in these glacier meltwater catchments. Black carbon has been implicated as a factor that is contributing to Himalayan glacier melt, but its sources and mechanisms of delivery to the Himalayas remain controversial. Here, we provide a 211-year ice core record spanning 1781 – 1992 CE for refractory black carbon (rBC) deposition from the Dasuopu glacier ice core, that has to date provided the highest elevation ice core record (7200 m). We report an average rBC concentration of 1.5 µg/L (SD = 5.0, n = 1628) over the 211-year period. An increase in the frequency and magnitude of rBC deposition occurs after 1877 CE, accompanied by decreased snow accumulation associated with a shift in the North Atlantic Oscillation Index to a positive phase. Typically, rBC is deposited onto Dasuopu glacier during the non-monsoon season, and short-lived increases in rBC concentration are associated with periods of drought within neighboring regions in north-west India, Afghanistan and Pakistan. Using a combination of spectral and back trajectory analyses, and comparison with a concurrent analysis of trace metals at equivalent depths in the same ice core, we show that biomass burning resulting from dry

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

conditions is a source of rBC to the central Himalaya, and is responsible for deposition that is up to 60 times higher than the average rBC concentration over the time period analyzed. We suggest that biomass burning is a significant source of rBC to the central Himalaya, and that the rBC record can be used to identify periods of drought in nearby regions that are up-wind of Dasuopu glacier.

1 Introduction

Although the rate and extent of glacier melt differs geographically, the overall trend of glacier mass loss globally, and particularly in mountain glaciers, is well documented (IPCC, 2013). While warming summer temperatures resulting in increased glacier mass loss and decreasing precipitation as snow are important factors contributing to glacier mass wastage (Sakai and Fujita, 2017), the deposition of atmospheric aerosols that darken the glacier surface also contribute to melt (Flanner et al., 2007; Xu et al., 2009). The most efficient of these aerosols is black carbon (BC) which is produced by a variety of combustion processes (Bond et al., 2004, 2013), most commonly by the incomplete combustion of fossil fuels and biomass (Jacobson, 2004; Hammes et al., 2007). BC is also the dominant absorber of visible light in the atmosphere (Lindberg et al., 1999) and exerts a positive radiative forcing globally, second only to CO_2 (+1.1 W m^{-2} and +1.6 W m^{-2} respectively; Ramanathan and Carmichael, 2008). BC continues to absorb radiation upon deposition from the atmosphere onto glacier surfaces, reducing ice and snow albedo, leading to melt (Hansen and Nazarenko, 2004; Forster and Ramaswamy, 2007; Xu et al., 2009; Doherty et al., 2013).

A significant source of BC emitted to the atmosphere results from anthropogenic activity (Ramanathan and Carmichael, 2008; Bond et al., 2013). The BC flux to the atmosphere has increased by a factor of 2.5 since the European Industrial Revolution, resulting in an increase of the global atmospheric BC burden by a factor of 2.5 - 3 (Lee et al., 2013). BC's relatively short atmospheric residence time influences its distribution globally, with the highest concentrations being proximal to BC emission sources (Bond et al., 2007; Xu et al., 2009; Bond et al., 2013). Asian regions surrounding the Himalaya are major sources of atmospheric BC (Novakov et al., 2003; Bond et al., 2007; Ramanathan et al.,

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

2007; Bond et al., 2013) and southern Himalayan glaciers are particularly influenced by BC emissions from India (Kopacz et al., 2011; Gertler et al., 2016) and more local emission sources that may add to the broader-scale regional flux (Kaspari et al., 2011).

Atmospheric aerosols, including BC, are warming the cryosphere and accelerating snow melt in the western Tibetan Plateau and Himalayas (Lau et al., 2010) and altering the regional hydrologic cycle (Immerzeel et al., 2010). This is a concern because Hindu Kush Himalayan (HKH) glacier melt affects the water security, particularly during the early- and post-monsoon season (Hill et al., 2020), of densely populated regions of south-east Asia. Meltwater from HKH glaciers are the source of ten major rivers that provide water for irrigation, hydropower, and ecosystem services for two billion people across Asia (Scott et al., 2019); over 25% of the global population.

Research into BC's interaction with the HKH cryosphere has increased in recent years. Several studies have documented the magnitude and timing of BC deposition using short-term BC records preserved in surface snow that span 1 - 2 years (e.g. Xu et al., 2009; Ming et al., 2008; Ming et al., 2012; Kaspari et al., 2014; Zhang et al., 2018; Thind et al., 2019). More recently, continuous surface measurements of near-surface aerosols, including BC, have been reported for the HKH region (e.g. Marinoni et al., 2010; Bonasoni et al., 2010; Cao et al., 2010; Babu et al., 2011; Chaubey et al., 2011; Marinoni et al., 2013; Niu et al., 2017; Negi et al., 2019). While useful for tracking the evolution of atmospheric BC at high temporal resolution, these studies do not provide a longer-term historical context against which current levels of BC can be compared. Records of BC deposition preserved in ice cores are useful as longer-term environmental archives for reconstructing atmospheric aerosol composition that span decades (Liu et al., 2008; Ming et al., 2008; Ginot et al., 2014). In the HKH region, these archives are essential for identifying trends in BC deposition onto HKH glaciers in response to increasing BC emissions in surrounding regions. For example, Ming et al. (2008) report an increasing trend in BC deposition onto East Rongbuk Glacier (Mt. Everest; 6500 m above sea level (asl)) during a 10 year period beginning in 1965, and then another increase beginning in 1995 to the end of the record in 2001. Xu et al.

Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

(2009) report a period of relatively high concentrations in the 1950s and 1960s in 4 Himalayan and Tibetan Plateau glaciers (Muztagh Ata, Guoqu glacier, Noijin Kangsang glacier, East Rongbuk glacier, and Tanggula glacier) and suggest a European source of BC to these sites. They also note an increase in BC on the eastern-most site (Zuoqiupu glacier) beginning in the 1990s and suggest an Indian source of BC for the region. Similarly, Liu et al. (2008) report high elemental carbon (a form of BC) at Muztagh Ata from 1955 - 1965. Ginot et al. (2014) report BC concentrations at Mera Glacier from 1999 - 2010, and suggest that variations in BC over this period respond primarily to monsoonal rather than anthropogenic forcing.

Kaspari et al. (2011) were the first to present a BC record that extended back to the pre-industrial period (1860-2000) in an ice core from East Rongbuk glacier (6518 m asl) and reported a threefold increase in BC deposition since 1975, indicating that anthropogenic BC is contributing to the BC flux to the southern Himalaya. Jenkins et al. (2016) report an increase in BC deposition in the central Tibetan Plateau beginning in 1975 from the Guoqu glacier ice core record spanning 1843-1982. These deep ice core records are valuable for evaluating long-term trends in BC spanning the Industrial Revolution to the present and the concomitant increase in anthropogenically-sourced BC emissions. Additional ice core-derived BC records that span the period of industrialization in Asia are required to both corroborate existing historical records of BC deposition onto HKH glaciers and to establish a regional baseline record for BC fluxes onto the region. These records are currently lacking for the HKH and are essential for identifying regional-scale trends in BC deposition.

The highest elevation ice core record ever obtained is the Dasuopu ice core (C3; Thompson et al., 2000), which was retrieved from the Dasuopu Glacier in the Central Himalaya (28.38 °N, 85.72 °E; Fig. 1) in 1997 at an elevation of 7200 m asl. Thompson et al. (2000) determined that monsoonal precipitation is responsible for the net accumulation of snow onto the glacier surface, in the order of 1000 mm water equivalent per year (in 1996), permitting an annually resolved environmental record spanning 1440 - 1997 CE (Thompson et al., 2000). The remote location and high

Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

125 elevation of the Dasuopu ice core drill site suggests that any local influence on the
126 deposition of atmospheric aerosols onto the glacier surface is minimal, and that
127 accumulation is representative of mixed free tropospheric composition (Kumar et al.,
128 2015). Evidence suggesting that the Dasuopu glacier differs from lower-elevation
129 glaciers in the region with respect to seasonal meteorology supports the hypothesis that
130 the flux of aerosols onto the glacier surface may be more representative of free
131 tropospheric composition rather than being affected by local (valley-scale)
132 meteorological conditions (Li et al, 2011).
133
134 Here, we quantify refractory BC (rBC; a subset of the broader BC descriptor of
135 carbonaceous particles that it is measured by laser induced incandescence specifically;
136 Lack et al., 2014) in a section of the Dasuopu ice core from 1781-1992 CE at annual to
137 sub-annual resolution in the glacier ice portion. We employ spectral analysis of the rBC
138 ice core time series to identify trends in rBC deposited onto Dasuopu glacier across
139 several temporal scales and to avoid “peak-picking” that might lead to subjectively
140 identifying episodes of increased rBC in the ice core time series. The rBC record is
141 compared to trace-element analysis of samples from equivalent depths along the same
142 ice core, as described by Gabrielli et al. (2020), and an atmospheric back trajectory
143 analysis to elucidate the broader-scale trends of deposition and potential rBC sources to
144 the southern Himalaya.
145
146 **2 Methods**
147 **2.1 The Dasuopu Ice Core**
148 Dasuopu glacier descends to the north from Mt. Xixiabangma in the Central Himalaya
149 (Fig. 1). The ice core examined here was drilled from the Dasuopu glacier surface to
150 bedrock (145.4 m) with an electromechanical drill, without using drilling fluid, and
151 provides a continuous record of deposition onto the glacier surface from 1010 to 1997
152 CE (Thompson et al. 2000). Here, we examine the upper section of the C3 ice core
153 (hereafter referred to as the “Dasuopu core”), from 8.4 - 120.3 m depth from the
154 surface, corresponding to the period 1781 - 1992 CE. Sections of the Dasuopu core
155 outside of this interval were not available for analysis. We use the Thompson et al.

Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

(2000) chronology that was established using $\delta^{18}O$, dust, and NO_3^- measurements, as well as annual layer counting confirmation using the location of the 1963 CE beta radioactivity peak from thermonuclear tests at a depth of 42.2 m to determine the core's age-depth relationship. Thompson et al. (2000) also used two major monsoon failures (1790-1796 and 1876-1877) as age/depth benchmarks that are reflected in the dust and Cl^- records to validate the ice core dating chronology. The chronology is accurate to ±3 years (Thompson et al., 2000).

2.2 Sample Preparation

A portion of the Dasuopu core has been housed in the Ice Core Storage Facility (Byrd Polar and Climate Research Center (BPCRC)) at -30 °C since the original analysis by Thompson et al. (2000). The portion of the Dasuopu core analyzed here is characterized by consolidated firn from 8.4 m - 56.4 m and glacier ice from 56.4 - 120.3 m depth. Ice was sampled continuously (with the exception of intervals noted in Suppl. Info. Table 1) in a cold room (-5 °C) at sub-annual resolution (2.5 - 10 cm sample interval) with a band saw along the length of the ice section. Each ice sample was divided in half to permit the analysis of BC and trace elements from identical depths throughout the core (n = 1572). Prior to rBC analysis, each ice sample was rinsed with MQ water at room temperature in a class 100 laboratory to remove any contaminants from the outer edges of the core, placed in a sealable polyethylene bag and immediately stored frozen (-34 °C) to ensure that the sample did not melt prior to analysis.

Due to sample volume limitations resulting from previous studies of the Dasuopu core (e.g. Thompson et al., 2000; Davis et al., 2005), 56 firn samples (5.5 - 10 cm length) were collected at discontinuous intervals (where sufficient sample volume was available) from 8.4 - 56.4 m depth in the cold room (-5 °C) using a band saw. The outer 2 cm of each sample (n = 56) was removed using clean stainless-steel knives (soaked in HNO_3^- and rinsed with MQ water) under laminar flow conditions in the cold room to remove surface contaminants. Clean firn samples were stored frozen (-30 °C) in double Ziploc bags until analysis.

Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

187

188 **2.3 BC analysis**

189 rBC was quantified by laser induced incandescence using a Single Particle Soot
190 Photometer (SP2; Droplet Measurement Technologies, Longmont, U.S.A.; Schwarz et
191 al., 2006; Wendl et al., 2014) at Central Washington University (Ellensburg, WA, USA).
192 Frozen samples were melted at room temperature, transferred from storage bags into
193 50 ml polypropylene centrifuge tubes, and sonicated for 20 minutes immediately prior to
194 analysis. Each liquid sample was stirred with a magnetic bar as water was routed into a
195 CETAC U-5000AT+ ultrasonic nebulizer (Teledyne CETAC Technologies, Omaha,
196 U.S.A.) using a peristaltic pump. The resultant aerosols flowed to the SP2 inlet at a
197 known rate using carbon-free air carrier gas. The peak intensity of light emitted by an
198 incandescing rBC particle is linearly proportional to its mass (Schwarz et al., 2006), and
199 the SP2 detects this emitted light using the amplified output from 2 photodetectors
200 (broadband and narrowband) to provide a detection range of ~70 – 500 nm volume-
201 equivalent-diameter (VED; Kaspari et al., 2014). A 5-point calibration curve using
202 Aquadag standards and MQ water was performed daily to correct for BC loss during
203 nebulization (Wendl et al., 2014). MQ water was analyzed every 5 samples as a blank
204 to monitor instrument baseline conditions. If the baseline was above background levels,
205 then MQ water would be run through the system until stability was achieved. Baseline
206 instability was not observed throughout the course of the analysis. The SP2 data output
207 was processed using the PSI SP2 Toolkit ver. 4.100a (Paul Scherrer Institut, CH) and
208 the IGOR Pro software platform (WaveMetrics Inc., Portland, U.S.A.).

209

210 **2.4 Spectral analysis**

211 The record of rBC concentration with depth through the Dasuopu ice core provides a
212 time series of rBC deposition onto Dasuopu glacier over time. The decomposition of the
213 time series into time-frequency space using spectral analysis (wavelet analysis) permits
214 the identification of dominant modes of variability and their variance with time (Torrence
215 and Compo, 1998). Wavelet analysis is well suited to the analysis of time series data
216 where frequency and/or magnitude is non-stationary through the signal (Debret et al.,
217 2007). For example, wavelet analyses have been used to identify Himalayan climatic

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

oscillations related to orbital forcing, Dansgaard-Oeschger cycles, and Heinrich events in the 1992 Guliya ice core (Yang et al., 2006), characterize the increased role of ENSO climate forcing on Antarctic temperature since ~1850 from ice core records from East and West Antarctica (Rahaman et al., 2019), and a switch from external forcing to internal forcing mechanisms on global climate during the mid-Holocene (Debret et al., 2009).

The ice core sampling strategy employed here may influence the results of the spectral analysis because the uppermost firn section was not sampled continuously and there are occasional sampling gaps in the glacier ice section (Suppl. Info. Table 1). The discontinuous sampling of the firn section likely resulted in an incomplete characterization of rBC deposition onto the Dasuopu glacier since 1944 (56.4 m depth). Further, the number of samples per year is not consistent throughout the record because of interannual differences in snow accumulation (Suppl. Info. Fig. 1). It is important to note that the spectral analysis treats the rBC time series as a linear depth-time function. However, because the depth-time relationship in the ice core is not linear, data is treated here as a function of the sample number of progression with depth in the ice core, while the dates of the individual features detected relative to sample number are specified using the Thompson et al. (2000) depth-age model. Therefore, the spectral decomposition of the time series into time-frequency space is achieved while minimizing the influence of data gaps and non-linear accumulation rate.

The wavelet analysis of the Dasuopu rBC record was performed using the Wavelet Toolbox in Matlab (ver. R2020a; Mathworks). A continuous 1-D wavelet transform was generated to identify modes of variability and the characteristics of that variability with time throughout the rBC record. The Mexican Hat (or Rickler) mother wavelet was chosen because it is similar to the shape of the annual variability in the rBC concentration signal across the time series (Suppl. Info. Fig. 2).

2.5 Trace element analysis

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

Trace element quantification at equivalent depths as the rBC was only possible for the glacier ice section of the Dasuopu ice core due to lack of sampling volume in the corresponding overlying firn sections. Trace element concentration was determined by Inductively Coupled Plasma Sector Field Mass Spectrometry (ICP-SFMS) at BPCRC. Twenty three trace elements were measured (Al, As, Ba, Bi, Cd, Co, Cr, Cs, Fe, Ga, Mg, Mn, Mo, Nb, Ni, Pb, Rb, Sb, Ti, Tl, U, V, and Zn) using methods described in Uglietti et al. (2014). The trace element crustal enrichment factor (EF) is used to identify trace element contributions exceeding natural background levels, and was calculated relative to Fe and elemental ratios of dust from the Tibetan Plateau following Gabrielli et al. (2020) as an additional variable to be compared with rBC.

2.6 Back trajectory analysis

While the complex geomorphology of the Himalayas affects local wind patterns, back trajectory modeling permits the characterization of the broader regional catchment from which rBC may be derived. Atmospheric circulation capable of delivering rBC to Dasuopu glacier was identified using the Hybrid Single Particle Lagrangian Trajectory Model (HSYPLIT; NOAA Air Resources Laboratory, 2018). A 7-day back trajectory was chosen as a conservative estimate of rBC atmospheric residence time given the range reported in the literature (e.g. Ogren and Charlson, 1983; Reddy and Boucher, 2004, 2007; Samset et al., 2014; Lund et al., 2018). Back trajectories from the Dasuopu drill site were calculated at 6 hour intervals from 1948-1991 for January (winter/non-monsoon) and July (summer/monsoon) using the NCEP/NCAR (National Centers for Environmental Prediction/National Center for Atmospheric Research) reanalysis from 1948 (the limit of the NCEP/NCAR dataset) to 1991.

3 Results

3.1 The rBC record

Figure 2a shows the 211-year rBC record from the Dasuopu ice core. The mean rBC concentration is 1.5 μg/L (SD = 5.0, n = 1628) from 1781 (± 3 years) to 1992 CE. The mean rBC concentration in the glacier ice section from 1781 to 1944 and the discontinuously sampled firn section from 1944 to 1992 is 1.4 μg/L (SD = 4.4, n = 1572)

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

and 6.0 µg/L (SD = 13.2, n = 56), respectively. Note that the median values for the same time periods are less influenced by outliers with high concentrations (median 1781 to 1944 = 0.2 µg/L, 1944 to 1992 = 0.6 µg/L). Even though the rBC concentration in the ice and firn described here is significantly different (two tailed Mann-Whitney U test, $p<0.05$), the effect of discontinuously sampling the firn section and its accurate characterization of rBC since 1944 is unknown. It is possible that the firn section is biased towards higher rBC concentrations because only 26% (14 of 54) of the firn samples correspond to snow deposited during monsoon conditions, as indicated by depleted $\delta^{18}O$ (data not shown), that is a period associated with lower atmospheric aerosol loading (Lelieveld et al., 2018). In general, rBC deposition corresponds to $\delta^{18}O$ enrichment (Fig. 3) and increased dust in glacier ice, indicating that rBC is deposited during the non-monsoonal dry season (Fig. 3; Kaspari et al., 2014). Occasional exceptions occur, for example in 1824 CE, when a period of high rBC deposition corresponds to a relatively low dust concentration and a low $\delta^{18}O$ value (Fig. 3a).

The smoothed (5 year median) rBC concentration and flux (the product of mean annual rBC concentration and snow accumulation) records show an increase beginning in ~1870 and again in ~1940 (Fig. 2a, b). The discontinuous firn section of the core has elevated concentrations during the late 1960s - 1970s, consistent with observations from East Rongbuk glacier by Ming et al. (2008) and Kaspari et al. (2011), and for Tanggula glacier by Xu et al. (2009).

3.2 Spectral Analysis

The spectral analysis of the rBC record identifies three modes of variability (Fig. 4b):

First, the mode at a = 6 (a = 0.5 x frequency) indicates high frequency, and generally, relatively low amplitude variability in spectral coefficients (81% of rBC concentrations are < 1 µg/L) occurring at ~ annual (12 data points/year; SD = 4.3, n = 112) resolution with isolated relatively higher amplitude events dispersed throughout the record (Fig. 4c). The frequency of these higher amplitude events increases from ~1877 until 1992 CE (Fig. 4a, c).

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

Second, a lower frequency mode (a = 27; ~4.5 years) captures periodic peaks in rBC concentrations centered at 1825, 1877, 1888, 1908, 1920, 1930, and 1977 CE if peaks that are >25% of the largest peak's amplitude in the time series (1977 CE) are considered (Fig. 4d). Dips in the a = 27 spectral coefficients indicating periods of low amplitude (defined here as >25% of the amplitude of the lowest dip at 1937 CE), occur at 1818, 1868, 1875, 1880 - 1884, 1893, 1914, 1924, and 1937 CE (Fig. 4d).

Third, the a = 512 (~85 year) mode identifies a shift from samples with negative spectral coefficients to those with positive spectral coefficients at 1877 CE (Fig. 4e). All three modes identify a period early in the rBC record characterized as a quiescent period (1781 - 1877 CE) where rBC concentrations do not exceed 19.3 µg/L (mean = 0.8, SD = 3.0, n = 880), except for the isolated peak (63.3 µg/L) at 1825 CE (Fig. 4a, c, d)). Prior to 1877 the rBC concentration in the ice core is significantly lower (Mann-Whitney U test, $p < 0.05$) and less variable (mean = 0.8, SD = 3.03, n = 898) than the post 1877 period (mean = 2.3, SD = 6.6, n = 732; Fig. 4). While the ~85 year mode identifies a shift from negative to positive spectral coefficients in 1877, the 5 year median of the rBC record identifies an increase occurring at ~1870. This suggests that the wavelet analysis may be sensitive to individual or tightly clustered peaks in the rBC record, such as those that occur between 1875 and 1880 (Fig. 3a, 4a).

3.3 Comparison of the rBC record with the trace element record

When considering the full record (n = 857 to 916 depending on the element; Table 1), all of the trace element concentrations analyzed are significantly correlated with rBC (range of 0.15 (Zn; n = 915) to 0.27 (Rb; n = 914); Table 1; $\alpha = 0.01$; Spearman correlation test is used instead of Pearson correlation test because the rBC and trace element data are not normally distributed). If the low-rBC pre-1877 period, as indicated by the spectral analysis, is considered independently, then the correlation between trace element and rBC are still statistically correlated (range of 0.26 (Zn, n = 915) to 0.44 (Mg and Mn, n = 915). In contrast, the post 1877 period shows a statistically insignificant slightly negative correlation between the trace elements and rBC ranging from -0.04 (Cs and Nb, n = 913 and 915, respectively) to -0.10 (Bi and Mn, n = 857 and 915, respectively).

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

The crustal enrichment factor (EF) for all of the trace elements were significantly weakly to moderately negatively correlated with rBC for all trace elements, ranging from -0.21 for Mg to -0.57 for Ga, except for Mn which was insignificantly positively correlated (0.02). The trace element EFs were more negatively correlated to rBC during the post 1877 period than the pre-1877 period (excluding Mn because it was insignificantly correlated; SD = 0.14), although this difference is not statistically significant, $t(22) = 1.88$, $p = 0.07$ ($p < 0.05$).

3.4 Back trajectory

Figure 5a shows the results of the July back trajectory showing that aerosols are primarily derived from areas to the south-west of the Dasuopu drill site, from the Arabian Sea and across western and northern India during the monsoon. A secondary source is located to the west and draws atmospheric aerosols from the eastern Mediterranean Sea and Arabian Peninsula. January (non-monsoon) circulation is derived from the westerly circulation across north-eastern Africa, Central Europe, the Arabian Peninsula and north-west India (Fig. 5b).

4 Discussion

4.1 rBC concentrations

The mean rBC concentration in the Dasuopu ice core, from 1781 to 1992 CE is 1.5 µg/L (SD=5.0, n=1628); 6 times higher than the average rBC reported by Kaspari et al. (2011) for the period 1860-1992 and ~2 times lower than BC reported by Ming et al. (2008) and Xu et al. (2008) for the East Rongbuk ice core record over similar time periods (Fig. 1). Note that while Kaspari et al. (2011) measured BC from the East Rongbuk core using the same incandescence method used here, samples were stored as liquid and measured concentrations are likely underestimated due to rBC particle adherence onto the walls of the storage container and/or agglomeration of BC particles above the detected particle size range (Wendl et al., 2014; Kaspari et al., 2014). In contrast, Ming et al. (2008) and Xu et al. (2009) measured BC concentration by thermo-optical methods, which may result in an overestimation of reported BC due to organic

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

matter pyrolysis during analysis (Gilardoni and Fuzzi, 2017), and a larger fraction of the carbonaceous particles being classified as BC.

4.2 rBC seasonality

Seasonally, peaks in rBC concentration correspond to intervals of increased dust concentration and enriched $\delta^{18}O$ over the entire ice core record (see examples in Fig. 3), indicating most BC deposition occurs during the non-monsoonal season when drier westerly air masses dominate atmospheric circulation (Fig. 5). Weather station measurements and previous snow/ice studies in the region confirm that rBC concentrations are lower in near-surface air at the Nepal Climate Observatory-Pyramid (NCO-P; 5079 m a.s.l.) during the monsoon (Bonasoni et al., 2010; Marinoni et al., 2010, 2013) and higher during the pre-monsoon period (Babu et al., 2011; Nair et al., 2013; Ginot et al., 2014; Kaspari et al., 2014; Chen et al., 2018).

4.3 Temporal variations in rBC deposition and regional climate

The pre-1877 CE period differs from the post-1877 CE period in the frequency and amplitude of variability in rBC deposition (Fig. 2a and 4e). The high BC deposition event in ~1825 CE (Fig. 4c) occurs during an otherwise quiescent pre-1877 CE period coinciding with a time of severe regional moisture stress/droughts as reflected in suppressed tree ring growth across Nepal, peaking in 1817 CE (Figs. 6 and 7 in Thapa et al., 2017). This period of abnormally dry conditions occurs after 2 large volcanic events; the Tambora eruption of 1815 (Stothers, 1984) and an eruption of unknown origin in 1809 CE (Cole-Dai et al., 2009). Anchukaitis et al. (2010) argue that major explosive eruptions in the tropics can disrupt the Asian monsoon system and result in drier conditions in central Asia for up to 8 years afterward. Dry conditions are typically associated with an increase in the frequency and severity of biomass burning in south-east Asia (Baker and Bunyavejchewin, 2009) and the association between dry conditions and increases in rBC deposition suggests that biomass burning may be a source of high rBC deposition events onto Dasuopu glacier.

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

From ~1877 CE until the end of the rBC record in 1992, rBC concentrations are significantly higher and the amplitude of rBC deposition increases, as indicated by the shift from negative to positive spectral coefficients at a = 512 (Fig. 4e). This suggests a change in either the magnitude of rBC emission source(s) or in the atmospheric mechanism that delivers rBC to Dasuopu glacier after ~1877 CE. The post ~1877 increase in rBC corresponds to a decrease in snow accumulation onto Dasuopu glacier (Fig. 2c; Davis et al., 2005) and an increase in the rBC flux from the atmosphere beginning in ~1880 (Fig. 2b). This decrease in snow accumulation has been linked to a strengthening of the Icelandic Low pressure system as temperatures in the Northern Hemisphere warmed at the termination of the Little Ice Age (LIA). This resulted in a shift in the North Atlantic Oscillation Index (NAO) from a negative mode to a positive mode, contributing less moisture to the southern Himalaya during winter (Davis et al., 2005). Less winter snow accumulation post ~1877 would be associated with drier winter (non-monsoon) conditions generally, when rBC deposition onto Dasuopu glacier is highest.

4.4 The influence of drought and biomass burning on the rBC record

Biomass burning, and associated rBC emissions result from dry conditions and drought that lowers the water table and dries biomass fuel (Baker and Bunyavejchewin, 2009; Tosca et al., 2010). Further, aerosols produced during fires may contribute to a positive feedback cycle where smoke plume shading decreases sea surface temperature, while increased concentrations of atmospheric BC warm and stabilize the troposphere, suppressing convection and precipitation and intensifying drought conditions on land (Tosca et al., 2010). High BC aerosol levels in ambient air corresponding to agricultural burning beginning in late April and forest fire activity during the non-monsoon season was reported by Negi and others (2019) from ambient air measurements at Chirbasa, India (Gangotri glacier valley) during 2016. The spectral coefficients calculated here identify trends in rBC deposition onto Dasuopu glacier and can be compared to regional rainfall data from a network of rain gauge stations that are distributed across India to identify periods of dryness (e.g., Parthasarathy et al. 1987) associated with rBC deposition.

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

Continuous regional instrumental rainfall records within the atmospheric catchment for atmospheric aerosols to Dasuopu glacier prior to the early 1900s CE are rare, and biomass burning records are non-existent. However, continuous tree ring-based reconstructions of precipitation conditions for Europe, North Africa, and the Middle East is provided by the Old World Drought Atlas (OWDA; Cook et al., 2015) and includes areas identified by the back trajectory analysis as being potential source regions for rBC to Dasuopu glacier (Fig. 5b). The Monsoon Asia Drought Atlas (MADA; Cook et al., 2010) provides a similar dataset for regions in East Asia, including Pakistan and Afghanistan, which may contribute rBC to Dasuopu glacier (Fig. 5b). An instrumental record for both the OWDA and MADA begins in 1901 (Fig. 6). Comparing the peaks in rBC deposition identified by the spectral coefficients (a = 27, ~4.5 year frequency) centered at 1825, 1877, 1888, 1898, 1908, 1920, 1930, and 1977 CE (Fig. 4d) to the reconstructed and instrumental self-calibrating Palmer Drought Severity Index (scPDSI) for the summer season (where positive and negative scPDSI indicate wet and dry conditions respectively; Fig. 6), it is possible to identify periods of dryness that might contribute to the production of rBC by biomass burning.

rBC wavelet coefficient peaks in 1825 and 1877 CE occur at the end of a decade-long period of negative scPDSI in the OWDA and MADA reconstructions, respectively (Fig. 6). Similarly, 1888, 1898, and 1930 follow years of negative scPDSI in either the OWDA or MADA reconstructions, indicating periods of dryness preceding episodes of rBC deposition onto Dasuopu glacier (Fig. 6). The 1908 and 1920 CE peaks do not follow periods of negative scPDSI in the OWDA or MADA reconstructions, but follows periods of negative scPDSI in the MADA instrumental record (Fig. 6) indicating that dryness is associated with these rBC deposition peaks as well. The peak centered at 1977 CE follows periods of positive scPDSI in the OWDA and MADA reconstructions and instrumental records and does not appear to be related to abnormally dry conditions, and may indicate an unidentified source of rBC. Conversely, dips in the spectral coefficients at a ~4.5 year frequency (a = 27) indicate periods of low rBC deposition occurring at 1818, 1868, 1875, 1880-1884, 1893, 1914, 1924, and 1936 CE. With the exception of the dip centered at 1875 and 1936 CE, dips in the spectral coefficient

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

record follow periods of positive scPDSI in either or both the OWDA and MADA tree ring reconstruction. While dips centered at 1914 and 1924 CE follow periods of positive scPDSI in both the OWDA and MADA instrumental record, 1936 CE follows a period of positive scPDSI in the MADA instrumental record only (Fig. 6).

In addition to the scPDSI from OWDA and MADA tree ring reconstructions and the instrumental record (since 1900 CE), an independent historical record for rainfall is available for India that was compiled by Mooley et al. (1981) and has since been reported in terms of drought/flood severity by Parthasarathy et al. (1987; Suppl. Table 1a, b). As mentioned, several periods of high rBC concentration are identified by the spectral coefficients at a = 27 (~4.5 year frequency) centered at 1825, 1877, 1888, 1898, 1908, 1920, 1930, and 1977 CE (Fig. 4d). These periods of high rBC deposition coincide with periods of drought reported for India, particularly in western/northwestern meteorological subdivisions (Parthasarathy et al., 1987) within the ±3 years dating error of the ice core chronology (Fig. 7; Suppl. Fig. 3 a). For example, from 1876 – 1878, India experienced widespread moderate to severe drought conditions (Parthasarathy et al., 1987; Fig. 7a) and soil moisture deficits (Mishra et al., 2019) that resulted in the "Madras Famine" (Cook et al., 2010; Mishra et al., 2019). In 1888 (and 1891 which is within the ±3 year ice core dating uncertainty), regions in western and northwestern India experienced moderate and severe drought conditions (Fig. 7b). In 1899 (corresponding to 1898 in the rBC record, ±3 years), northwest and western meteorological subdivisions (among others) experienced severe drought while moderate drought was experienced by most of India (Fig. 7c), resulting in famine that affected 59.5 million people (Mishra et al., 2019). In 1911 (1908 ± 3 years) there was extreme drought reported in the northwest and moderate drought reported in the north-central and southwest meteorological districts (Fig. 7d). In 1918 (1920 ± 3 years), there was severe drought reported in the north and central-west and moderate drought reported throughout the south and north-central regions of the continent (Fig. 7e). From 1927-1929 (1930 ± 3 years), moderate drought was reported in the northern region of India (Fig. 7f). Similar to observations from the OWDA and MADA comparisons, the ~1977 period does not stand out in the climate record as being exceptional (Suppl. Fig.

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

3), and it does not correspond to anomalously high rBC values (Fig. 2a) yet it corresponds with a period of highly positive spectral coefficients (Fig. 4c, d). Finite-length signal border effects (so called edge effects) have been well documented, where a wavelet transform (such as that used here) yield abnormal coefficients as the wavelet extends into the "shoulder areas" of the record that don't have data (Su et al., 2011, Montanari et al., 2015). It is possible that the peak identified here at a = 6 and a = 27 is a result of wavelet transform edge effects. Alternatively, sources other than biomass burning, that have not been identified here, may contribute to high rBC values observed in the Dasuopu ice core ~1977 CE.

Dips in the a = 27 spectral coefficient record correspond to periods of flooding in India. For example, the trough at 1875 CE corresponds to reports of extreme flooding in the north-west and moderate flooding in western India (Fig. 8a). It should be noted that moderate drought was reported in the far west and south, but these conditions did not result in a rBC peak in the a = 27 coefficients (Fig. 4d). For the period ~1880 to 1886 CE, severe and moderate flooding is reported in the west in 1884 CE, with moderate drought to the south and east that did not result in an rBC peak in the a = 27 coefficients (Fig. 8b). From 1880 – 1882 CE, the continent experienced relatively stable conditions with moderate flooding in some western and north-western districts (Suppl. Info. Fig. 3). Western India experienced severe and moderate flooding in the west and northwest in 1893 (Fig. 8c), corresponding to a dip in the a = 27 coefficients (Fig. 4d). 1914 and 1917 (1914 $\pm$ 3 years), 1926 (1924 $\pm$ 3 years) and 1933 (1936 $\pm$ 3 years) all saw severe and/or moderate flooding in western meteorological districts, with no drought conditions reported in the rest of India, corresponding to dips in the a = 27 coefficients (Fig. 8d, e, f respectively).

4.5 rBC and trace metals

Recent work by Gabrielli and others (2020) suggested that atmospheric trace metals preserved in the Dasuopu ice core, likely linked to the long-range transport of fine fly ash, were indicative of emissions from coal combustion and fires used to clear forested areas to the west of the Himalayas since the beginning of the Industrial Revolution

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

(~1780 CE). Fly ash is composed of alumino-silicate and iron-rich byproducts of coal combustion and biomass burning and is enriched in trace metals (Ross et al., 2002). Fly ash is not detected by the SP2 as configured here.

We observe a general negative correlation between BC and the crustal enrichment factor (EF; indicative of element concentrations above the natural background derived from crustal material) of trace metals in the Dasuopu core, particularly after 1877 CE (Table 1) when rBC spectral coefficients are positive at a = 512 (Fig. 4e). This illustrates that the deposition of the non-crustal fraction of trace metals (as indicated by a positive EF), and fly ash, occurred out of phase from rBC.

rBC deposition resulting from biomass burning may be expected to correlate with trace elements associated with the biomass source material (K, Cl, Zn, and Br; Echalar et al., 1995). Of these, only Zn was analyzed here. Zn concentration is only weakly correlated with rBC (0.15), although more strongly (0.26) in the pre-1877 period than in the post-1877 period (-0.06), and Zn's EF is moderately negatively correlated, particularly in the post 1877 period (-0.63). While the lack of correlation between potential biomass burning-derived trace elements such as Zn and rBC might suggest a non-biomass burning source for rBC, one should be cautious in attributing specific trace elements to biomass burning events. For example, trace elements emitted during partial combustion can vary depending on fire intensity (flaming vs. smoldering), fuel source (savanna vs. forest) (Echalar et al., 1995), and size-dependent particle adhesion (Samsonov et al., 2012). Further, biomass burning remobilizes soil-derived particles which would lower the individual trace element's EF (Gaudichet et al., 1995) causing a negative correlation between rBC and EFc. There is a statistically significant negative correlation with rBC to all of the trace EFs (except for Mn), suggesting that rBC deposition is not associated with non-crustal trace element deposition, interpreted as an indicator of fly ash deposition (Gabrielli et al., 2020), that is enriched above the natural dust input. Of importance is that the discontinuous sampling of firn in the Dasuopu ice core record presented here does not capture a continuous record of rBC deposition during the post

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

1970s; a period when rBC is reported to have increased in the southern Himalaya (Kaspari et al., 2011) and Tibetan Plateau (Jenkins et al., 2016; Wang et al., 2015).

5 Conclusions

Here, we present the highest elevation (7200 m asl) record of rBC deposition ever reported. This record is unique in its high elevation and represents conditions in the free troposphere, away from local sources of BC. The Dasuopu record also contributes to the limited number of proxy records of BC deposition in the HKH region where glacier melt, and therefore factors such as BC that affect glacier melt, influence the water security of one of the most densely populated regions of the planet. While the Dasuopu rBC record presented here is not well resolved during the period after the 1970s, the record does indicate elevated BC during 1970-1980, consistent with the Everest ice core BC record that showed elevated BC post 1970 (Kaspari et al., 2011).

rBC deposition at the Dasuopu site is highest during the winter (non-monsoon) season when westerly circulation is dominant. Back trajectory analyses indicate that this westerly circulation predominantly includes areas of west/northwest India, Afghanistan, Pakistan, northern Africa, central Europe and the Mediterranean. Dry conditions increase the production of rBC through biomass burning and we suggest that regional biomass burning contributes to periods of high rBC deposition onto the Dasuopu glacier during periods of dryness as indicated by historical records of precipitation within the atmospheric catchment of Dasuopu glacier. The continuous historical record of precipitation for India, in particular, suggests an association between moderate to severe drought conditions in west/north-west India and rBC concentration in the Dasuopu ice core. Upwind industrial sources of rBC, such as coal combustion, appear to be of minor influence during these periods of increased rBC deposition as indicated by the absence of correlation between rBC concentration in the Dasuopu core and the crustal enrichment of industrially-sourced trace elements at equivalent depths in the ice core. It should be noted that the Dasuopu ice core rBC record is discontinuous during the period of increased regional industrial activity thus the available data cannot address the importance of this regional industrialization to rBC deposition onto Dasuopu

https://doi.org/10.5194/acp-2020-1052
Preprint. Discussion started: 20 October 2020

glacier. Together, evidence presented here indicates that while rBC transport in the free troposphere is influenced by large scale synoptic circulation, regional sources of rBC strongly influence rBC deposition onto Dasuopu glacier, particularly after ~1877, and that the rBC record from Dasuopu glacier may provide a proxy record for drought and resultant biomass burning within its catchment of atmospheric circulation.

Acknowledgments

This work was funded by the NSF Atmospheric Chemistry Program (award # 1149239) and the by the NSF-ESH program, The Ohio State University, the Ohio State Committee of Science and Technology, and the National Natural Science Foundation of China. We thank the many scientists, engineers, technicians, and graduate students from the Byrd Polar and Climate Research Center and the Lanzhou Institute of Glaciology and Geocryology (China) that contributed to the collection and previous analysis of the Dasuopu ice core. We are grateful to Julien Nicolas for performing the graphic display of the back trajectories. This is BPCRC contribution no. xxxx.

Data availability

The data presented in this work are archived at the National Oceanic and Atmospheric Administration World Data Center-A for Paleoclimatology at xxxx.

Author contribution

Barker performed the sample preparation, BC analysis and interpretation, and was the primary author of the manuscript. Kaspari assisted with the BC analysis and interpretation of the BC record. Gabrielli designed the overall project, performed the trace element analysis with Wegner. Wegner, Beaudon, and Sierra-Hernández cut the samples from the ice core and performed the trace element analysis. Thompson retrieved the Dasuopu ice core. All authors contributed to manuscript preparation.

Competing interests

The authors declare that they have no conflict of interest.

Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

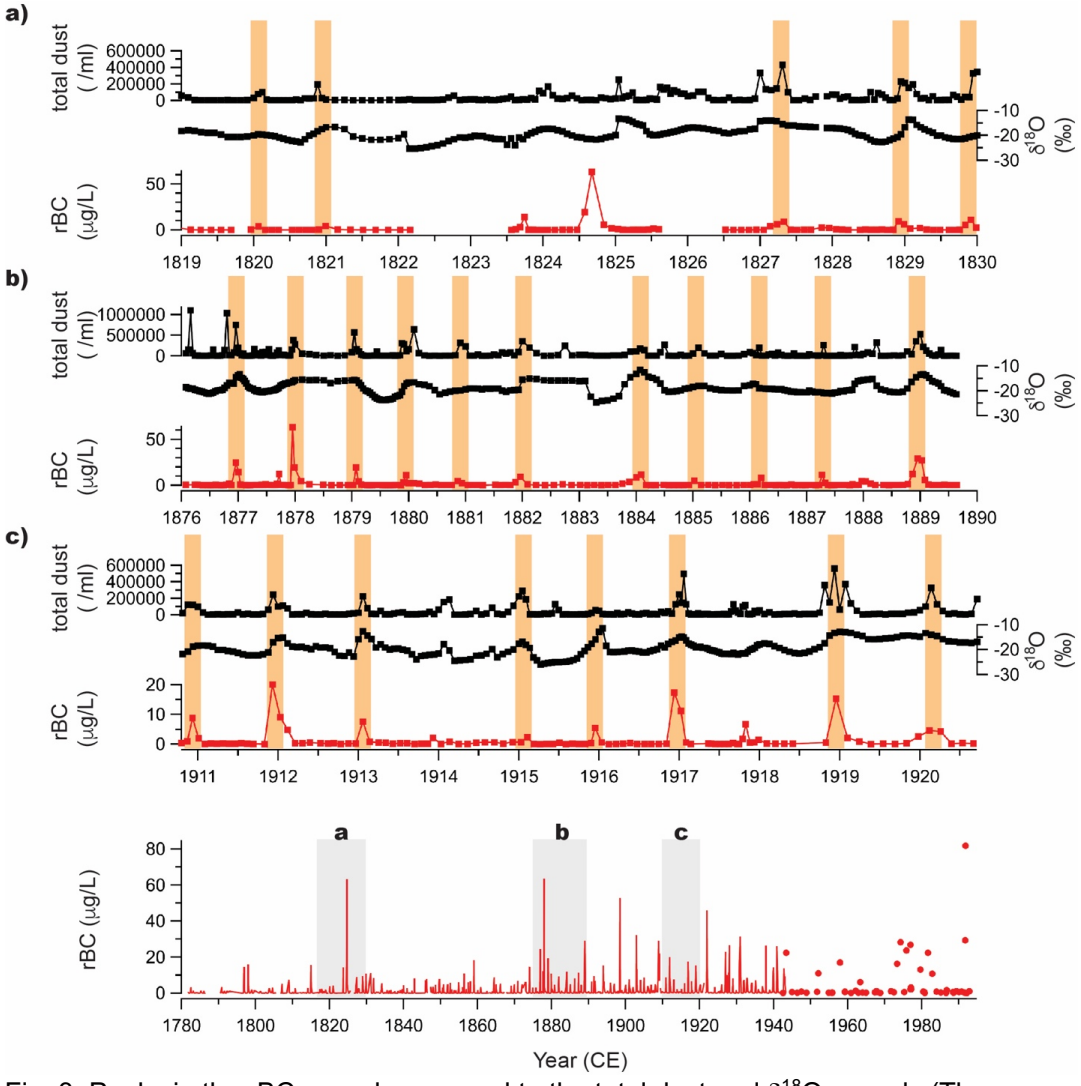
956 Figure 3:



957
958 Fig. 3: Peaks in the rBC record compared to the total dust and $\delta^{18}O$ records (Thompson
959 et al., 2000) over 3 time intervals (a: 1819 - 1830, b: 1876 - 1890, c: 1911 - 1921 CE) in
960 the Dasuopu ice core. Note that peaks in the rBC record are associated with depleted
961 $\delta^{18}O$ and increased dust deposition.
962

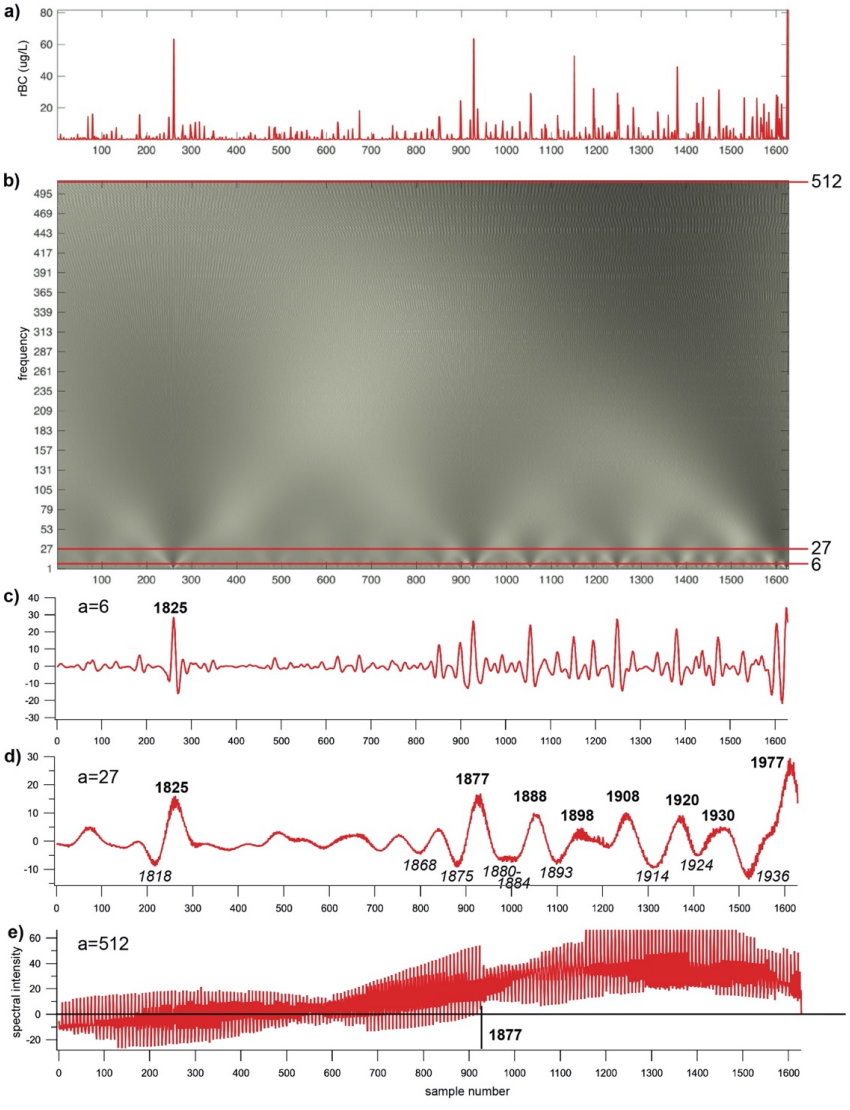
Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

963 Figure 4:



964

965 Fig. 4: The spectral analysis of the Dasuopu rBC concentration record. Sample number
966 1 is located at the bottom of the ice core (1781 CE) and sample number 1628 is at the
967 top of the firn section (1992 CE). a) is the rBC record plotted relative to sample number;
968 b) is the spectral analysis showing variance across all frequency scales relative to
969 sample number ranging from a = 2 to a = 512. Darker shades indicate relatively
970 stronger (more positive) coherence between the wavelet and the rBC record, as
971 indicated in the spectral coefficients; c, d, e) are the spectral coefficients relative to
972 sample number for frequency scales a = 6, 27, and 512 respectively.

Preprint. Discussion started: 20 October 2020

Atmospheric Chemistry and Physics Discussions

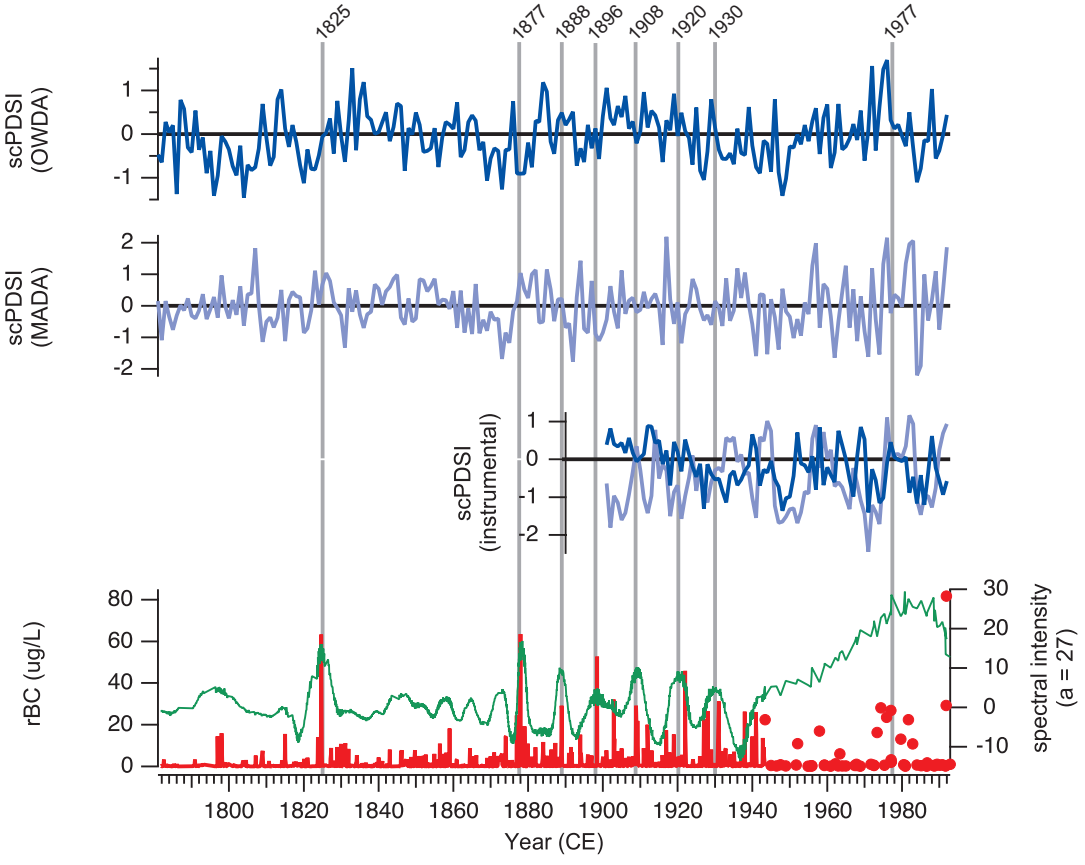
981 Figure 6:



982

983 Fig. 6: The Dasuopu rBC record (in red) compared to regional reconstructed and
984 instrumental climate records from the Old World Drought Atlas (OWDA; dark blue) and
985 the Monsoon Asia Drought Atlas (MADA; light blue). Note the correspondence between
986 negative self-calibrating Palmer Drought Severity Index (scPDSI) and periods of high
987 rBC deposition. Data for both the reconstructed and instrumental climate records are
988 obtained from; OWDA (drought.memphis.edu/OWDA/) and MADA
989 (drought.memphis.edu/MADA).
