Abstract.

Air pollution harms human health and the environment. Several regulatory efforts and different actions have been taken in the last decades by authorities. Air quality trend analysis represents a valid tool in assessing the impact of these actions taken both at national and local levels. This paper presents for the first time the capability of the Italian national chemical transport model, AMS-MINNI, in capturing the observed concentration trends of three air pollutants, NO₂, inhalable particles having diameter less than 10 micrometres (PM10) and O₃, in Italy over the period 2003-2010. We firstly analyse the model performance finding it in line with the state of the art of regional ~~models applications~~ air quality modelling. The modelled trends result in a general significant downward trend for the three pollutants and, in comparison with observations, the values of the simulated ~~slopes trends show the~~ were of a same-similar magnitude for NO₂ (in the range -3.0 ~~÷~~ -0.5 μg m⁻³ yr⁻¹), while a smaller range of trends was found than those observed ~~variability is detected~~ for PM10 (-1.5 ~~÷~~ -0.5 μg m⁻³ yr⁻¹) and O₃-maximum daily 8-hour average concentration (-2.0 ~~÷~~ -0.5 μg m⁻³ yr⁻¹). As a general result, we find a good agreement between modelled and observed trends; moreover, the model provides a greater spatial coverage and statistical significance ~~of pollutant concentration trends allowed to extend both the spatial coverage and the statistical significance of pollutants' concentrations trends~~ with respect to observations, in particular for NO₂. We also conduct a qualitative attempt to correlate the temporal concentration trends to meteorological and emission variability. Since no clear tendency in yearly meteorological anomalies (temperature, precipitation, geopotential height) was observed for the period investigated, we focus the discussion of concentrations trends on emissions variations. We point out that, due to the complex links between precursors emissions and air pollutants concentrations, emission reductions do not always result in a corresponding decrease in atmospheric concentrations, especially for those pollutants that are formed in the atmosphere such as O₃ and the major fraction of PM10. These complex phenomena are still uncertain and their understanding is of the utmost importance in planning future policies for reducing air pollution and its impacts on health and ecosystems.

1 Introduction

30 Air pollution represents one of the main environmental challenges of modern society. Numerous studies have already demonstrated the adverse effects on health (Pope III et al., 2020; WHO, 2019; Pope III and Dockery, 2006; Cohen et al., 2017) and environment (EEA, 2020; Feng et al., 2019), as well as on climate (Watts et al., 2019; Fuzzi et al., 2015), society and economy (Lanzi and Dellink, 2019; OECD, 2016). The adverse impact on health of fine particulate matter results in premature deaths due to ischemic heart disease, strokes, lung cancer, chronic obstructive pulmonary disease and respiratory
35 infections (Apte et al., 2018; Rajagopalan et al., 2018).

Efforts aimed at reducing air pollution have been ongoing for decades, namely in the framework of the Convention on Long-Range Transboundary Air Pollution drawn up under the United Nations Economic Commission for Europe, ~~bringing-leading~~ to a general decrease of ~~air pollutant concentrations measured concentrations of air pollutants~~ in Europe (Maas and Grennfelt, 2016). The trends in concentrations are useful to verify if and ~~how much to what degree~~ environmental regulations
40 establishing ~~limitations~~ for pollutants' emissions, e.g. the Gothenburg protocol (UNECE, 1979) and the European Directive on National Emission Ceilings (EC, 2016), have been effective and efficient in improving air quality at national and local level. Several European studies addressed this topic, focussing on the entire continent (Colette et al., 2011, 2016, 2017a; Wilson et al., 2012; Guerreiro et al., 2014; Yan et al., 2018) and on single countries (Sicard et al., 2009; Cattani et al., 2014; Querol et al., 2014; Carnell et al., 2019; Velders et al., 2020). The studies were carried out using observed and/or modelled
45 concentrations. The best approach should be the one which integrates both of these sources of information. Indeed, the observed concentrations provide an actual air quality evaluation, though at sparse locations and sometimes with poor temporal coverage, while the modelled concentrations offer a comprehensive spatial and temporal coverage, ~~although they have even if with~~ intrinsic uncertainties in describing the complex processes of atmospheric chemistry and physics (Iversen, 1993).

50 ~~On-For~~ Europe, Colette et al. (2011) performed an assessment of nitrogen dioxide (NO₂), particulate matter with diameter of 10 µm or less (PM₁₀) and ozone (O₃) concentrations trends over the 1998-2007 decade, using 6 regional and global chemical transport models (CTMs). The simulated trends were evaluated against observed ones at background monitoring stations located in major anthropogenic emission hotspots. This comparison showed that the primary pollutants trends were generally well reproduced by simulations, with lower performance for O₃ which is a secondary pollutant produced in the
55 atmosphere. Wilson et al. (2012) also investigated the O₃ trends over Europe using the CHIMERE model between 1996 and 2005. The data collected in 158 rural background stations showed that the model reproduces well the European-averaged O₃ trend of the annual 5th percentiles but ~~failed to reproduce it is missing~~ the positive trend in the observed 95th percentiles. Another European-wide study was conducted by Yan et al. (2018) for the period 1995-2012 using the global chemical transport model EMAC. The results showed that the model successfully captured the observed temporal variability in O₃
60 mean concentrations at EMEP background stations, as well as the contrast in the trends of 95th percentile (decreasing) and 5th percentile (increasing). Solberg et al. (2015) and Colette et al. (2017b) provided reviews of scientific papers which

compare modelled to observed trends in Europe. In the EURODELTA-Trends multi-model exercise at European scale, (Colette et al., (2017a); ~~they~~ investigated the period 1990-2010 with 8 chemical transport models (including the AMS-MINNI, Atmospheric Modelling System of the Italian National Integrated Model to support the international negotiation on atmospheric pollution, Mircea et al., 2014; Vitali et al., 2019). The authors showed the time variability of PM10, PM2.5 (Tsyro et al., 2017), organic aerosols and precursor gases (Ciarelli et al., 2019) and O₃ (Mar et al., 2016; Colette et al., 2017b). In particular, the EURODELTA-Trends study, by analysing emissions, intercontinental inflow and meteorological variability, confirmed that the reduction of European anthropogenic emissions plays a fundamental role in the modelled net reduction of ambient air pollution.

Italy is affected by air pollution at the highest levels recorded in Europe (EEA, 2020). Despite this evidence, even if the above mentioned studies over the European area include Italy in their investigations of long-term air quality trends, few analyses focussing on the Italian territory are available. Most of the available trends analyses rely on measured concentrations of single pollutants at single monitoring stations (Casale et al., 2000; Cristofanelli et al., 2015; Gilardoni et al., 2020) or in distinct urban areas (Cadum et al., 1999; Cattani et al., 2010; Gualtieri et al., 2014; Pozzer et al., 2019) and administrative regions (Carugno et al., 2017; Masiol et al., 2017; Lonati and Cernuschi, 2020). Some works cover the whole Po Valley, in Northern Italy, which is a well-known regional hot-spot for air pollution (Putaud et al., 2014; Bigi and Ghermandi, 2016). Currently, the studies by Cattani et al. (2014; 2018) are the only Italian-wide analyses and they are based on measured concentrations available from the National Air Quality database (BRACE, 2013). In particular, Cattani et al. (2014) show significant reduction trends in concentrations of carbon monoxide (CO) and benzene (C₆H₆), linearly related with emission reductions, a large ~~prevalence number~~ of stations measuring PM10 and NO₂ decreasing trends and low statistical significance in O₃ trends, which indicates that no clear trend exists in measured ozone concentrations. So far, to the authors' knowledge, there is not a modelling study exploring concentration trends and their relations with emission changes over time covering the whole Italian territory.

This paper evaluates the trends of three air pollutants (NO₂, PM10, O₃) in Italy, over the period 2003-2010, using the AMS-MINNI air quality model. The evaluation of CTM capabilities to reproduce the trends of pollutants increases the reliability of their application in assessing air quality and supporting air quality plans, especially for models regularly used in national regulatory assessments, as requested by Air Quality (EC, 2008) and National Emission Ceilings (EC, 2016) directives but also for other scientific studies. The analysis is based on statistical methods widely used in literature, for the sake of comparability with other investigations on air quality trends. The ability of the model to reproduce the concentration trends is evaluated through the comparison with independent data available from the National Air Quality database (BRACE).

Moreover, in order to identify the potential efficacy of mitigation policies in reducing air pollution, concentrations trends were qualitatively compared with variations in meteorology and anthropogenic emissions~~to meteorological and anthropogenic emissions variability~~.

2 Data and methods

95 2.1 Air quality measurements

The air quality monitoring data considered in the present work derive from BRACE ~~where-in which~~ data from regional/local monitoring networks were collected for the formal submission to the European Environment Agency (EEA), in the framework of the reciprocal exchange of information and data from networks and individual stations measuring ambient air pollution within the Member States (EC, 1997). BRACE fed the European database Airbase (Airbase, 2020) with data from 100 2002 to 2012, thus covering the period investigated in this study.

Several processing steps were applied to the raw BRACE database in order to adapt the database to model validation requirements and to verify station reported metadata, in particular concerning geographical coordinates (Piersanti et al., 2012).

In the present work, in order to analyse the concentration trends, we selected only stations covering the 100% of the 105 investigated years with at least 75% of valid data per year. The two thresholds for time coverage were chosen according to the legal requirements on yearly time series stated in the Air Quality Directive (EC, 2008) and also widely adopted in scientific literature (Colette et al., 2011; Colette et al., 2016), for a robust analysis. The threshold of 100% of the investigated years is a more stringent criterion with respect to other studies, generally adopting a less stringent criterion (e.g. 75% is set in Colette et al. (2011), corresponding in same cases to 8 years). Our choice guarantees that the trend analysis is always based on an 8-year period, which can be considered quite robust. Indeed, several studies are available in literature, presenting trend analysis over similar or shorter periods (Zhai et al., 2019; Dufour et al., 2018; Sheng et al., 2018). Of course, data covering a longer period would strengthen our findings. Anyway, in this first study over Italy, the choice of the period to investigate was determined by the availability of coherent model results that have the same model setup for the years 2003 to 2010. More specifically, in the following years, AMS-MINNI simulations adopted a different setup (spatial domain, chemical mechanism, boundary conditions), that clearly affects time series homogeneity. The pollutants considered 115 are NO₂, PM₁₀ and O₃ due to their large monitoring coverage in the period of interest. Particulate matter with diameter less than 2.5 μm (PM_{2.5}) could not be included in the analysis, as the data coverage from BRACE started in 2007 (Uccelli et al., 2017). Time resolution is given in hours (for NO₂ and O₃) and days (for PM₁₀).

The number of the air quality monitoring stations that satisfied the chosen criteria is reported in Table 2. In Appendix S1 of 120 the Supplementary Material (SM), Figure S1 represents the 20 Italian administrative regions and Figures S2-S4 the locations of all sites that passed the selection criteria, ~~by station type divided by type~~ (background - BKG, traffic - TRA, industrial - IND) and the background ~~sites by zone type ones divided by zone~~ (rural, suburban, urban). The model spatial resolution of 4 km is not sufficient to describe TRA and IND stations with the same skills of BKG stations, nevertheless for the sake of completeness we chose to include them in the validation.

125

2.2 Model simulations

The air quality modelling system used for our simulations is AMS-MINNI (Mircea et al., 2014, 2016; D’Elia et al., 2009, 2018; Ciucci et al., 2016) which includes a meteorological prognostic model (RAMS), a chemical transport model (FARM),
 130 an emission processor model (EMMA) and a meteorological diagnostic processor (SURFPRO).

The three-dimensional Eulerian chemical transport model FARM (Flexible Air Quality Regional Model, <http://www.farm-model.org>; Gariazzo et al., 2007; Silibello et al., 2008; Kukkonen et al., 2012) describes the transport, turbulent dispersion, formation and destruction of the pollutants in the atmosphere. The mesoscale non-hydrostatic meteorological model RAMS (Regional Atmospheric Modelling System; Cotton et al., 2003) generates the required input meteorological fields. Another
 135 fundamental AMS-MINNI component is the emission processor, the Emission Manager EMMA (Arianet, 2014), which prepares the hourly gridded emissions by breaking down annual data from emission inventories in space and time. Moreover, the diagnostic module SURFPRO (Arianet, 2011), computes the Planetary Boundary Layer (PBL) scale parameters, horizontal and vertical diffusivity coefficients, deposition velocities for different chemical compounds and natural emissions, using meteorological fields ~~in input~~ from RAMS ~~and~~ orographic and land use data.

140 The main features of the AMS-MINNI simulation setup used to carry out the simulations are synthetized in Table 1.

Table 1. Main features of the AMS-MINNI simulation setup.

Chemical Transport Model Simulation	
Model and version	FARM version 4.7
Horizontal resolution	4 km
Vertical layers	16 terrain-following layers
Vertical extent	10000 m
First layer depth	40 m
Gas-phase chemistry	SAPRC99 (Carter, 2000)
SIA module	ISORROPIA v1.7 (Fountoukis et al., 2007)
SOA module	SORGAM module (Schell et al., 2001)
Aerosol model	AERO3 (Binkowski and Roselle, 2003)
In-cloud sulphate chemistry	Simplified S(IV) to S(VI) formation (Seinfeld and Pandis, 1998)
Boundary Conditions	Eurodelta (Colette et al., 2017a)
Meteorological Simulation	
Model and version	RAMS version 6.0
Horizontal resolution	12 km and 4 km (two way nesting)
Vertical	32 levels (sigma coordinate) from 30 m above ground level to lower stratosphere
Radiation	Chen and Cotton (1983) long/shortwave model – cloud processes considering all condensate as liquid
Convection	Modified Kuo scheme (Tremback, 1990)
Lower Boundary	LEAF-2, Land Ecosystem–Atmosphere Feedback model (Walko et al., 2000)
Turbulence Closure	Mellor-Yamada level 2.5 scheme – ensemble–averaged TKE (Mellor and Yamada, 1982)

Cloud Microphysics	Bulk microphysics parameterization: cloud water, rain, pristine ice, snow, aggregates, graupel, and hail, or certain subsets of these (Walko et al., 1995)
Boundary conditions	GFS analyses at 0.5° horizontal resolution (https://wwdata/model-datasets/global-forecastw.ncdc.noaa.gov/data-access/model--system-gfs)
Data Assimilation	Nudging on pre-analysed fields
Emission Processing	
Anthropogenic Emissions Software and version	EMMA version 6.0
Anthropogenic emissions Inventories	National Emission Inventories of Italy and neighbouring countries reported to the European Monitoring and Evaluation Programme of the UNECE Convention on Long-range Transboundary Air Pollution
Biogenic model e Soil-NO	MEGAN v2.04 (Guenther et al., 2006)
Saharan dust	None
Sea salt	Zhang et al. (2005)
Windblown dust	Vautard et al. (2005)
Dust traffic suspension	Amato et al. (2012); Padoan et al. (2018)

More details about the anthropogenic emissions and the meteorological data are reported in paragraph 2.3 and 2.4, respectively.

A complete description of the standard configuration of the modelling system can be found in Vitali et al. (2019).

2.3 Anthropogenic emissions

Emission data used as input for AMS-MINNI simulations derive from the national emission inventories covering the period from 1990 to 2015, elaborated by ISPRA (Italian Institute for Environmental Protection and Research, Taurino et al., 2017) available in 2017. Figure 1 shows the emission variation for SO_x (sulphur oxides), NO_x (nitrogen oxides), PM_{2.5}, PM₁₀, NMVOC (non-methane volatile organic compounds) and NH₃ (ammonia) for the period 2003-2010 considered in the present work. The variation over the whole period, 1990-2015, by SNAP nomenclature (Selective Nomenclature for Air Pollution, see Table S1 of Appendix S2 in the SM) for the selected pollutants is reported in the SM (Appendix S2, Figs. S5-S7).

SO_x emissions show the highest reduction, -58% in the period 2003-2010, followed by NO_x (-29%) due to a large decrease in combustion from energy and road transport sectors, respectively. NMVOC emission reduction is driven by the road transport and solvent use sectors, while NH₃ emissions show a very slight decrease. PM_{2.5} and PM₁₀ emissions increase from 2006 to 2008 onwards due to an increase in biomass combustion in the residential sector (SNAP code 02) (IIR, 2021).

The estimated emissions at national level need to be further disaggregated in space, before being assigned to the AMS-MINNI grid at 4 km spatial resolution. A provincial distribution (NUTS3 level, where NUTS stands for Nomenclature of territorial units for statistics, the hierarchical system for dividing up the territory of the European Union, <https://ec.europa.eu/eurostat/web/nuts/background>) is provided by ISPRA every 5 years; hence it was available for both the years 2005 and 2010. For the purposes of this work, the 2005 NUTS3 disaggregation was used for the years 2003, 2004, 2005, 2006 and 2007, while the 2010 NUTS3 disaggregation for 2008, 2009 and 2010. Finally, hourly and speciated gridded

emissions on the AMS-MINNI grid were produced by means of EMMA processor. The spatial allocation of NUTS3 emissions to the 4 km grid of the MINNI model relied for point sources on geographic coordinates of each facility (for example, large combustion plants) and for diffuse/linear sources on spatial layer used as proxy variables, like population density (for residential heating and urban traffic), georeferenced road networks (for rural and highway traffic), land-use (for agriculture).

2.4 Meteorological simulations

The meteorological simulations required by AMS-MINNI were elaborated making use of the RAMS model whose main features are summarized in Table 1. The hourly meteorological fields produced by RAMS, such as temperature, wind speed, relative humidity and precipitation play an important role in determining the level of air pollution concentrations. In trend analysis, it is important to establish the role of the emissions and the meteorology in influencing air pollutant concentration ~~tendency~~trends. It is out of the scope of the present paper to attribute a relative weight to these factors in determining the analysed concentration trends, but, as a first approximation, we can consider that it could be reasonably attributed to emission trends rather than to a clear tendency in meteorology. In fact, looking at the anomalies (referred to 1981-2010 climatology) of some meteorological fields for the considered years (2003-2010) computed from NCEP/NCAR reanalyses (National Centers for Environmental Prediction/National Center for Atmospheric Research, Kalnay et al., 1996), it is worth noting that no clear tendency is shown. In Appendix S3 of the SM, yearly maps for temperature at 850hPa (T850), precipitation and 500hPa geopotential height (Z500) anomalies are reported, together with the near surface temperature trend computed from the Copernicus Climate Data Store (CDS, <http://climate.copernicus.eu/climate-data-store>).

~~Figures S8 to S10 in Appendix S3 of the SM show that the year 2004 can be considered an “average” year as it presents no anomalies for T850, Z500 and precipitation rate in the Northern area, while in the Southern area a higher precipitation rate is observed; lower values of T850 are present in 2005 while higher values are recorded in the years 2003, 2007 and 2009; lower values of Z500 are registered in the years 2005, 2009 and 2010, while higher values in the years 2003, 2006 and 2007 are recorded. A higher variability is observed for the precipitation rate with higher values in 2009 and 2010; lower values in 2006 and 2007 over Northern Italy, while almost no anomaly is observed in 2008 in Southern Italy. Moreover, no clear signal is present over Italy for near surface temperature tendency (Fig. S11): almost no trend in temperature or slightly negative in the North Western area is observed.~~

2.5 Trend methodology

The detection and calculation of trends in measured and simulated concentrations were performed using the “openair” package (Carslaw and Ropkins, 2012), specifically designed for air pollution data analysis developed for the open source R software (version used v.3.6.1, <http://www.R-project.org>). The presence of a monotonic increasing or decreasing trend was estimated using the non-parametric Mann-Kendall trend test together with the Theil-Sen’s method for estimating the slope of a linear trend (as a concentration variation per year) (Mann, 1945; Theil, 1950; Sen, 1968; Kendall, 1975), adopting the

deseasonalisation option ~~before time trend estimates~~. The calculated trends were considered as statistically significant if the significance level (i.e., the p-value of the Mann-Kendall test) is lower than 0.05 ($p < 0.05$). This method does not require assumptions about the data ~~statistical~~ distribution, ~~it is not sensitive to it does not care about~~ outliers and it has been used in several ~~works~~ studies, for example in the EMEP Task Force on Measurements and Modelling during the Eurodelta experiment (Colette et al., 2016) and in the EEA air quality trend reports (EEA, 2009; 2020). Temporal trends were calculated considering monthly averages of the pollutant concentrations at each monitoring stations. Table 2 summarizes the number of stations, grouped per type, with significant and non-significant trends both for observations and ~~modelled~~ ~~estimates~~ ~~simulations~~ analyses.

Table 2. Number of all the stations considered in the trend analysis for the period 2003-2010 divided in separated into background (BKG), traffic (TRA), industrial (IND) and classified as statistically significant ($p < 0.05$) for observed, simulated and both observed and simulated trends.

Pollutant	Number of stations				Observations: number of stations with $p < 0.05$				Simulations: number of stations with $p < 0.05$				Number of stations where both obs and sim with $p < 0.05$			
	BKG	TRA	IND	Tot	BKG	TRA	IND	Tot	BKG	TRA	IND	Tot	BKG	TRA	IND	Tot

3 Results and discussion

3.1 Model validation results

Before inspecting the ~~AMS-MINNI~~ capability ~~of AMS-MINNI~~ to capture the trends of pollutants concentration, a comprehensive evaluation of the model results was carried out.

Comparisons between time series of observed and modelled values were performed on the same set of monitoring stations satisfying the selection criteria used for the trends analysis (i.e. with at least 75% of valid data per year covering all the 8 years from 2003 to 2010, see Table 2).

215 For all the pollutants included in the trends analysis, annual time series of daily values were used for the comparison, ~~being~~ this metric ~~being~~ considered the most appropriate one for model performances assessment (Colette et al., 2011). ~~For O₃, in addition to daily values~~ Anyway, ~~in addition to daily values and concerning only O₃ evaluation~~, the MDA8 metric (maximum daily 8-hour average concentration), calculated for the period from April to September, was considered as well, since it turned out to be the most suitable metric for O₃ trends analysis within the context of this study (see Section 3.2.3).

220 As recommended by literature on model validation (Chang and Hanna, 2004), a comprehensive set of statistical ~~indices~~ ~~indexes~~ was computed in order to quantify, from different points of view, the agreement between modelled and observed values.

~~Here, for the sake of brevity~~ Therefore, ~~only~~ three ~~out of all the computed~~ statistical metrics are presented: *Mean Bias (MB)*, *Root Mean Square Error (RMSE)* and the *correlation coefficient (corr)*; see Appendix S4 in the SM for their formulations. 225 These ~~indices~~ ~~indexes~~ were chosen because they globally capture several features of model performance in terms of amplitude, phase and bias. Moreover, such indicators are frequently used in model evaluation studies (Simon et al., 2012), namely those previously cited on ~~time-temporal trends, including~~ ~~Indeed, in~~ Colette et al. (2011), which we consider as a reference for the present evaluation, ~~model validation is based on the same subset of these three statistical indices~~. Values of *MB*, *RMSE* and *corr* for each pollutant are presented here as an average over the 8 years period and over all the available stations, ~~being them~~ 230 classified according to their type (BKG, TRA, IND) and, ~~concerning for~~ BKG stations, ~~for by zone type~~ (rural, suburban, urban).

Results are shown in Fig. 2 for daily values of NO₂ (upper left panel), PM10 (upper right panel), O₃ (lower left panel) and for MDA8 of O₃ (lower right panel).

Overall, model performance ~~is quite good and statistical indexes are~~ ~~is~~ in line with the results obtained by analogous 235 modelling systems (e.g. Solazzo et al., 2012; Pirovano et al., 2012; Badia and Jorba, 2015; Bessagnet et al., 2016), especially when applied at similar spatial resolution (e.g. Chemel et al., 2010; Pay et al., 2014). ~~More specifically, in Table S2 of Appendix S4 in the SM, the statistical scores values are reported together with the outcomes of Colette et al. (2011), used hereafter as a reference for an explicit comparison of the performances.~~

As far as NO₂ daily values are concerned (upper left panel of Fig. 2), ~~AMS-MINNI turns out to perform well. More specifically in detail,~~ *RMSE* and *corr* values, ranging from 10.8 to 28.6 $\mu\text{g m}^{-3}$ and from 0.578 to 0.689, respectively, with BKG stations scoring best, are in line with Colette et al. (2011). According to *MB*, ~~AMS-MINNI performs even better.~~ ~~Negative values~~ *MB*, between -22.4 and -4.2 $\mu\text{g m}^{-3}$, are obtained for all station types, stressing a general underestimation of NO₂ concentration values. ~~Anyway, underestimation is generally lower than in Colette et al. (2011) at BKG stations, getting worse at TRA sites.~~ This feature is commonly expected in chemical transport model applications at regional scale and it can 245 be ascribed to the intrinsic difficulties of regional models in capturing, at their resolution, high gradients in spatial

concentration variability (Schaap et al., 2015). This hypothesis is confirmed by the evidence that model performance (according to both **RMSE** and **MB**) deteriorates with decreasing spatial representativeness of monitoring sites; in particular, absolute values of **MB** (i.e. underestimations) increase passing from rural to urban environments and even more at TRA stations.

250 AMS-MINNI tends to underestimate PM10 daily values too, ~~which is common for as commonly in regional models, as shown. This is highlighted~~ by negative values of **MB** in the upper right panel of Fig. 2. ~~Anyway, in this case the~~ **However**, underestimation does not seem to increase with decreasing spatial representativeness of sites, and can be attributable to the well-known difficulties of air quality models to take into account all the contributions to PM10 concentration (Solazzo et al., 2012; Im et al., 2015). In particular, it is worth noting that, in the present AMS-MINNI simulations, ~~the contribution of Saharan dust~~ **Saharan dust contribution** was not included and this could be the main reason for the underestimation at rural sites. ~~As far as MB and corr are concerned, simulated PM10 concentrations are overall in agreement with observations, with values ranging from -12.8 to -3.9 $\mu\text{g m}^{-3}$ and from 0.453 to 0.630, respectively. Anyway, compared to Colette et al. (2011), simulated PM10 concentrations are overall in agreement with observations, especially as far as MB and corr are concerned, with values ranging from -12.8 to -3.9 $\mu\text{g m}^{-3}$ and from 0.453 to 0.630, respectively.~~

260 AMS-MINNI O₃ daily values (lower left panel of Fig. 2), are in line with the findings of Colette et al. (2011) concerning both the general overestimation of O₃ concentration levels and the range of values of the statistical ~~indices~~ **indexes** (21.7 \div 25.7 $\mu\text{g m}^{-3}$ for **RMSE**, 2.2 \div 18.6 $\mu\text{g m}^{-3}$ for **MB** and 0.757-0.83 \div 0.822 for **corr**). **More specifically, Table S2 shows that, for More in detail, considering results at** background stations, similar **RMSE** values are obtained, together with generally lower **MB** values and better correlation ~~skills~~ **values**. Similarly to ~~the NO₂ performance~~ **for NO₂, the MB of O₃ concentrations changes the MB in reproducing O₃ levels changes** with ~~the~~ spatial representativeness of monitoring sites, i.e. as NO₂ underestimation increases passing from rural to urban environments, O₃ overestimation increases, since close to NO₂ sources the titration process ~~plays acts~~ as **an** O₃ sink (Seinfeld and Pandis, 1998).

Model performance in reproducing MDA8 of O₃ for the period from April to September (lower right panel of Fig. 2) is similar ~~to that for daily concentrations to daily one~~, evaluated throughout the whole year, apart from the negative (albeit small) **MB** value obtained at rural stations. ~~With respect to daily values, correlation for MDA8 (0.712 - 0.853) is generally better, as is MB (lower absolute values). With regards to RMSE (24.4 - 25.1 $\mu\text{g m}^{-3}$) the values are worse at BKG stations and slightly better at IND and TRA sites."With respect to daily values, MDA8 correlation skill (0.712 \div 0.853) is globally better, whereas no clear tendency can be inferred concerning concentration biases: according to MB (-1.9 \div 14.8 $\mu\text{g m}^{-3}$), MDA8 results to be always better (lower absolute values); according to RMSE (24.4 \div 25.1 $\mu\text{g m}^{-3}$), it is worse at BKG stations and slightly better at IND and TRA ones.~~ Nevertheless, it is worth noting that, when assessing O₃ performance, higher biases in concentration estimates could be expected when using the MDA8 metric, instead of daily average, since concentration levels are higher too. Indeed, higher MDA8 concentration values are ~~expected when compared with daily values forexpected if compared to daily ones, due to~~ two reasons: i) maximum values are taken into account instead of average ones; ii) only the warm period (April-September) is considered here, when higher O₃ values are generally observed.

280 Globally, AMS-MINNI ~~performs quite well, with the results being~~ turns out to perform quite well being the results in line with ~~the performances of state of the art of air quality models~~the state of the art of air quality model performances, when operating at the regional scale, ~~when considering concerning~~ both the values of the statistical ~~indices~~indexes used for the comparison and the general tendency to overestimate O₃ and to underestimate NO₂ and PM10.

3.2 Trend analysis

285 From the concentration fields provided by AMS-MINNI simulations, data were extracted at each monitoring station to ~~make a comparison between~~compare observed trends (OT) and simulated trends (ST).

In the following paragraphs, for each of the pollutants considered and for the whole set of stations described in Table 2, an analysis of observed and simulated trends is discussed examining different parameters. For each pollutant, we present:

- the overall distribution of stations with statistically significant/not significant trends, with their sign, for both observations (OT) and simulated (ST) values, in order to ~~synthetically~~evaluate model performance in reproducing ~~time-temporal~~ trends in measured concentrations (Figs. 3, 7, 11);
- ~~the time series of observed and simulated monthly average concentrations (averaged over all stations for each station type) the time series of observed and simulated monthly average concentration values, detailing model performance in the considered multiannual period~~(Figs. 4 (a), 5 (a), 8 (a), 9 (a), 12 (a), 13 (a));
- scatter plots of observed/simulated slopes, by station type (Figs. 4 (b), 5 (b), 8 (b), 9 (b), 12 (b), 13 (b));
- ~~maps of simulated the map of the simulated~~ slopes at each grid point, in comparison with ~~the~~ spatial distribution of observed slopes ~~split up according to by~~ station type, in order to provide a more detailed description of the results, since observed and simulated slopes are presented according to their spatial distribution and geographical context. Moreover, simulated quantities are provided not only at monitoring sites but at every grid point of the computational domain, to fully exploit model capabilities at their best in terms of both spatial coverage and variability ~~description~~(Figs. 6, 10, 14).

295

300

In Appendix S5 of the SM the observed and simulated slopes (both in terms of $\mu\text{g m}^{-3} \text{yr}^{-1}$ and $\% \text{yr}^{-1}$) are reported for each pollutant and for each station with a significant trend ($p < 0.05$).

3.2.1 NO₂

305 Out of 73 monitoring stations, 47(68) ~~show~~have a statistically significant OT(ST) whereas 42 result to have both significant observed and simulated trends. ~~Figure 3 shows that all STs are negative (93% significant), whereas 79% of the OTs were negative (58% significant; 21% non-significant) and 21% were positive (7% significant; 14% non-significant). Figure 3 shows that, concerning simulations, the 93% of the sites has a significant decreasing trend while the rest exhibits a not significant tendency. Observation based trend analysis shows a lower fraction (58%) of points with significant decreasing trends, a higher fraction (36%) of cases with not significant trends and also some cases of significant increasing trends.~~

310

Figures 4 (a) and 5 (a) show that the model ~~reproduces monthly values better~~ ~~better reproduces monthly values~~ at BKG sites than at TRA and IND stations, while the intra-annual variability is well reproduced for all types of stations. This result confirms the good model performance for daily values at BKG stations (Fig. 2).

The scatter plots of Figs. 4 (b) and 5 (b) show an overall good agreement for BKG sites with statistically significant trends, while, as expected, performance ~~worsen-is worse~~ at TRA sites where the absolute values of the simulated slopes are ~~usually~~ mostly lower than the observed ones.

Figure 6 shows that model simulations provide coverage and information ~~in parts of the domain also in some portion of the territory~~ where observations are completely absent in the considered period, i.e. in the Southern part of Italy. Overall, at BKG stations the model ~~better~~ captures both the sign and the variability of the slopes better, while its ~~is worse performances~~ decline at TRA stations. The map of the simulated slopes not only has a wider coverage but also shows a greater area with significant trends compared with observations.

~~More in general, the map of the simulated slopes shows not only a wider coverage but also a greater area of significant trends compared with observations.~~

3.2.2 PM10

The well-known underestimation of PM10 concentrations when simulated by regional models, already discussed in Section 3.1, and the poor quality of the observation network, ~~proven-also~~ shown by the low number of stations fulfilling the selection criteria, greatly influenced the trend estimates. Out of 32 monitoring stations, 27(14) ~~show~~ have a statistically significant OT(ST) while 11 have both observed and modelled significant trends. The fraction of all the sites with statistically significant observed ~~statistically significant~~ trends, shown in Fig. 7, is 84% compared with only 44% for the ST, ~~reaches a percentage of 84% but decreases to 44% when simulated data are taken into account.~~ The simulated monthly mean time series illustrated in panel (a) of both Figs. 8 and 9 for BKG and TRA/IND stations, respectively, show a general underestimation of observed concentrations, with performances ~~slightly~~ improving slightly from 2007 onwards. Focussing on sites where both observed and simulated trends are statistically significant, Figures 8 (b) and 9 (b) show that the model succeeds in capturing not only the sign of all the observed trends, but also the slopes ~~in-at~~ many sites, even if the absolute values are ~~slightly~~ underestimated, especially at the industrial site. This result is confirmed by the maps ~~represented~~ in Fig. 10, which show depicting a general agreement at most of the available monitoring stations. Although to a lesser extent ~~if~~ when compared ~~to-with~~ NO₂ and O₃, the simulated statistically significant trends for PM10 ~~also for PM10 the simulated statistically significant trends~~ cover a wider area with respect to observations especially in the Northern area and in the Sardegna island where no observations are available at all. A poor coverage of significant trends in both model and observations ~~A poor coverage by both model and observations~~ occurs in some areas of Centreal and Southern Italy, where the model estimates ~~where anyway the model shows~~ larger areas of significant ~~trends~~ ST, especially for the Puglia region and Sicilia island.

3.2.3 O₃

As underlined in Lefohn et al. (2017; 2018) and Colette et al. (2017b), the choice of the O₃ metrics is of the utmost importance since each indicator could show a different trend. In our analysis, both effect-based indicators (AOT40 and SOMO35) and process-based indicators (MDA8) were computed and analysed. The different metrics explored are: the mean O₃ concentration (O₃ avg); the maximum daily 8-hour average concentration (MDA8); the accumulated amount of ozone over the threshold value of 40 ppb (AOT40) calculated from April to September (~~Apr/Sep~~Apr-Sep) and the sum of the daily maxima of 8-hour running average over 35 ppb (SOMO35) for the whole year. Concerning O₃ avg and MDA8 metrics, analyses were carried out ~~on-for~~ both the entire year and from April to September. The number of stations with increasing and decreasing trends and their significance depends on the metric used (Table 2 and Fig. 11). ~~Both absolute (Table 2) and relative (Fig. 11) figures of statistical significance depend on the metric.~~ The fraction of stations with significant trends also varies between the observed and modelled ~~trends~~datasets. Annual metrics (O₃ avg, MDA8 and SOMO35) ~~show~~have a lower fraction of significant trends than the metrics calculated in ~~Apr/Sep~~Apr-Sep. For the purpose of our analysis, i.e. to show the capacity of the AMS-MINNI in capturing the air pollution trends through a comparison of observations and simulations, we preferred to focus on the MDA8 indicator calculated in the warm period (~~Apr/Sep~~Apr-Sep), when higher O₃ values are generally recorded. Indeed, the MDA8 calculated in the period ~~Apr/Sep~~Apr-Sep ~~shows~~has the highest number of stations with significant trend among all indicators.

The fraction of stations with significant trend is comparable between observations and simulations, 66% and 68% respectively, but when looking at the sign of the trend, we found out that all significant simulated trends are decreasing, while the 39% of significant observed trends are increasing. The monthly mean shows a good agreement for BKG stations (Fig. 12 (a)) and a slight overestimation for both IND and TRA stations (Fig. 13 (a)). The scatter plots (panel (b) of both Figs. 12 and 13) show a higher variability for observed trends than for those simulated~~in observed trend than simulated ones~~. When looking at the spatial distribution, Figure 14 shows a large area of significant simulated slopes~~a wide area of significant simulated trend~~, ranging from -2.0 µg m⁻³ yr⁻¹ to -0.5 µg m⁻³ yr⁻¹ with an area of non-significant ST in the North-Eastern area~~with no significant ST covering especially the North Eastern area~~. The comparison with observations is particularly interesting for BKG stations, for which there are more stations available~~where a higher sample is available~~. As already pointed out, the ~~simulated trend~~model does not reproduce the ~~observed positive trends~~observed trend where positive, but the model has a good agreement with the significant decreasing OT, ~~although with a lower variability~~when significant decreasing OT are calculated the model shows a good agreement, even though with a lower variability range than observations. Moreover, there are some areas, especially in ~~are different areas, especially in the~~ Central and Southern Italy, where the model shows a significant trend, whereas monitoring sites are not available at all or the OT is not significant~~without significant OT~~.

3.3. Discussion

375 ~~Our analysis shows that AMS-MINNI is capable of reproducing observed trends albeit with some differences between the~~
~~pollutants studied. Our analysis shows the good capability of the AMS-MINNI in reproducing observed trends widening the~~
~~spatial coverage of the significant modelled trends respect to observations albeit with some distinctions among the different~~
~~pollutants. Although a quantitative analysis of the influence of variations in emissions and meteorology on concentration~~
~~trends was not performed, we present a preliminary qualitative attempt to compare the temporal concentration trends to~~
380 ~~variation in emissions, having already observed (see Section 2.4) that there is no clear tendency in the meteorology. Although~~
~~being out of the scope of the present paper to quantitatively establish the role of emissions and meteorology in determining~~
~~the analysed concentration trends, we try to carry out a preliminary qualitative attempt to compare the temporal~~
~~concentrations trend to emission variations, having already observed (see Section 2.4) that there is not a clear tendency in~~
~~meteorology.~~

385 ~~The nitrogen oxides (NO_x) that are most relevant for air pollution (namely NO and NO₂) are mostly emitted NO_x (i.e.,~~
~~nitrogen oxides that are most relevant for air pollution, namely NO and NO₂) are mostly emitted during fossil fuel~~
combustion processes, and in particular by road transport. In our analysis, the road transport sector represents almost the
50% of all the total emitted NO_x (see Fig. S5 of Appendix S2 of the SM). The decrease of NO₂ concentrations is almost
consistent with the decrease in NO_x emissions, ~~being since~~ NO₂ concentrations ~~are~~ directly linked to primary emissions
390 (Colette et al., 2011; Henschel et al., 2015) and mainly driven, in our case, by a reduction in emissions from the road
transport sector. Despite the underestimation of absolute values of background concentrations, AMS-MINNI ~~adequately~~
reproduces ~~adequately~~ the observed trends at ~~a~~ national scale (Fig. 4 (b)), ~~demonstrating its potential for supporting showing~~
~~robustness in potential support to~~ reduction policies of background pollution. On the other hand, besides underestimating
concentrations at traffic stations like many state of the art CTMs, the ~~decreasing concentrations trends observed decreasing~~
395 ~~tendency of concentrations measured~~ at traffic stations is underestimated (Fig. 5 (b)). This indicates that the model is either
misrepresenting the decrease of emissions, ~~or the model is not responding correctly to the changes in emissions or producing~~
~~concentrations not fully responsive to correct trends of emissions.~~ Moreover, the spatial resolution can limit the ~~model's~~
~~ability to capture large concentration gradients~~ ~~model capacity in capturing high gradients in concentration features~~, typical of
the urban environment, and this may be the reason for ~~failure of the model to capture the positive trends~~ ~~the model failure in~~
400 ~~catching positive slopes.~~ As an interesting example, from Fig. 6 (lower right panel) it turns out that the traffic station
~~exhibiting with~~ the highest positive observed slope (as showed ~~by in~~ Fig. 5 (b)) is located in Florence, Toscana region. The
comparison of lower right and upper left panels of Fig. 6 ~~points out shows~~ that this traffic monitoring site, (airbase code
IT0861A, see Table ~~S2-S3~~ of Appendix S5 in the SM), is located between two urban BKG ~~sites that have non-significant~~
~~OT sites exhibiting not significant OT.~~ The three monitoring points are located within about 4 km (i.e. in the same cell of the
405 computational domain). This is a feature that the model is not able to capture; indeed, in this area ~~simulated trends are not~~
~~significant or decreasing~~ ~~simulated concentrations show no significant or decreasing trends.~~ Something ~~similar occurs in like~~

410 ~~this happens in~~ most of the cases ~~with positive OT~~ where positive slopes occur, being they obtained only from measurement analysis. Most of these points are very close to other monitoring sites where the opposite behaviour (negative slopes) ~~are found~~ is observed; see for example the couple of BKG sites in Lombardia surrounded by other BKG sites where the opposite sign is found, or the IND site located in Eastern Liguria very close to a TRA site ~~showing with~~ a decreasing trend. Therefore, when designing mitigation scenarios at local urban scale, ~~these results suggest it is confirmed~~ that a regional scale CTM like AMS-MINNI needs to be integrated with high resolution models.

Concerning PM and O₃, given their secondary nature, a direct link between emissions and atmospheric concentrations ~~reductions~~ is not expected (Guerreiro et al., 2014).

415 PM₁₀ is both primarily emitted and secondarily generated in the atmosphere from reactions of chemical precursors (NO_x, SO_x, NH₃, NMVOC) ~~reactions~~. Therefore, observed concentrations reflect these and other contributions, like long-range transport, including Saharan dust, in ~~quantitatively~~ variable fractions depending on the sites. The national emissions of primary PM₁₀ (Fig. 1) are stable for the first four years (apart from 2004), then grow for ~~two-four~~ years and diminish in the last period, resulting in a final increase of 13% from 2003 to 2010. On the other hand, the emissions of all four mentioned
420 ~~precursors decrease at different rates. These contrasting trends in emissions could partly explain the large areas of non-significant trends shown in~~ of not significant trend illustrated in Fig. 10, whereas the areas with the higher simulated decrease correspond mainly to industrial and traffic areas, underlying the significant efforts in reducing emissions from the industrial and road transport sectors. The few stations available for the comparison show a nice model skill in reproducing observed negative trends, even on TRA stations. This could be a preliminary confirmation of the fitness of AMS-MINNI for the
425 purpose of supporting emission reduction planning, even though further evaluations of model trends are needed, especially ~~on for~~ more recent time intervals. Moreover, the observed biases in concentrations, especially at the beginning of the time series (Figs. 8 (a) and 9 (a)), suggest that further insights are needed to investigate how the change of model performances could affect the trend estimates.

O₃ is a ~~totally~~ secondary pollutant produced in the troposphere by the chemical reactions of its precursors, such as NO_x and
430 NMVOC, while CH₄ and CO become more important at a wider scale (Guerreiro et al., 2014).

The number of cited studies focussing on O₃ indicates how critical this pollutant is when exploring relations between ~~temporal trends of emissions and concentration~~ emission and concentration time trends, given the complex photochemistry ~~complex generation chain~~, showing sometimes a discrepancy between the emission decrease of O₃ precursors and the variation of O₃ concentrations (Colette et al., 2011; Guerreiro et al., 2014; Querol et al., 2014). This is particularly important in Mediterranean areas, which are susceptible to ozone-related impacts (De Marco et al., 2019) due to climatological conditions that are more favourable for O₃ formation ~~This is even more important in the particularly susceptible to ozone related impacts Mediterranean area (De Marco et al., 2019) whose climatological conditions are more favourable for its formation (Guerreiro et al., 2014).~~ The national emissions of the main ozone precursors follow a similar descending gradient trend in the 8 years considered, thus there has been little change in the ratio between them, which is the
435 main driver of the chemical equilibrium for O₃ formation (Seinfeld and Pandis, 1998; Sillman, 1999) ~~considered, so not~~
440

modifying the national scale ratio between the two, which is the main driver of the chemical equilibrium in the generation of O_3 - (Seinfeld and Pandis, 1998; Sillman, 1999). This could partly explain (Fig. 14) why the model gives not significant or close to zero trends in Northern Italy, especially in the Po Valley, a well-known air pollution hot spot, densely populated and with high anthropogenic emissions. In the same region, where most of the monitoring stations are concentrated, different behaviours of OT are observed ~~in for some scattered stations~~: negative slopes (especially in the Western part), not significant trends and positive slopes: in some stations, mainly located in complex orographic contexts or near to the coastline, where the transport of O_3 from the sea, caused by sea breeze circulation (Monteiro et al., 2016), together with precursor emission by nearby harbours, could lead to local peculiar features ~~These stations are mainly located in complex orographic contexts or near to the coastline, where the transport of O_3 from the sea, caused by sea breeze circulation (Monteiro et al., 2016), together with precursors' emissions by nearby harbours, could be additional causes of local peculiar features.~~ Similar findings can be found in the ~~were already noticed in~~ literature, as for example in Guerreiro et al. (2014) or in Colette et al. (2011), who noticed in particular that different models had different behaviours. On a national level, Cattani et al. (2014), focussed on observations ~~throughout all over~~ the Italian territory in the period 2003-2012, showed that it is not possible to estimate a general significant statistical trend (although with even if on a different reference metric, i.e. SOMO0 calculated ~~in the half summer period from April to September~~), regardless of the type or the area of the stations, and that there are discrepancies in significant trend among-between adjacent stations. Moreover, as already mentioned, the choice of the O_3 metrics can influence the trend estimate. Overall, in our analysis, ~~the~~ AMS-MINNI underestimates the absolute value of the descending OT at background stations. This result is driven by North-Western monitoring locations, where further work is needed to analyse the quality of local emission ~~values-estimates~~ and external contributions to ozone concentrations.

460 4 Conclusions

The present work ~~describes-aims to assess for~~ the first ~~assessment-time~~ of the capability of the Italian chemical transport model AMS-MINNI ~~of~~ capturing the trends of three pollutants, namely NO_2 , PM_{10} and O_3 . The analysis ~~on-for~~ O_3 was carried out using different metrics, both for observations and simulations. We firstly conducted a thorough analysis of the model skill considering some statistical score parameters most commonly used in the literature. This analysis confirms that the model performance is in line with the state of the art ~~of-for~~ regional models applications. Statistical indicators ~~turned-out to be~~ as good as other CTMs in literature and a similar behaviour to that of most regional models and the same behaviour of most of the regional models was observed concerning the general tendency to overestimate O_3 and to underestimate NO_2 and PM_{10} . The trend evaluation was performed using the non-parametric Mann-Kendall trend test together with the Theil-Sen's method for the estimation of the slopes and an in-depth comparison between observed and AMS-MINNI modelled trends was carried out. Comparing the sign of modelled and observed trends we found ~~out~~ a good agreement for almost all sites. Our main result is a general downward simulated trend for the three pollutants. With respect to observations, modelled slopes show the same magnitude for NO_2 (in the range $-3.0 \div -0.5 \mu g m^{-3} yr^{-1}$), while a smaller variability is detected for

PM10 ($-1.5 \div -0.5 \mu\text{g m}^{-3} \text{ yr}^{-1}$) and O₃-MDA8 ($-2.0 \div -0.5 \mu\text{g m}^{-3} \text{ yr}^{-1}$). ~~The reason for the discrepancy for PM10 concerning PM10, the reason for this discrepancy~~ could be attributed to the well-known underestimation of ~~modelled PM10 modelled~~ concentrations. ~~The results for O₃ results~~ could be influenced by the poor quality of the monitoring network ~~data~~ in the period we considered, together with the well-documented difficulties of models in ~~capturing catching~~ O₃ concentration trends, given its non-linear dependence on precursors emissions.

Model capabilities in terms of both spatial coverage and ~~variability are illustrated variability description were illustrated~~ by the maps ~~generated for all~~ the three pollutants, showing ~~larger area for significant a wider significant area for~~ simulated trends compared ~~to observed ones with those observed~~, with a ~~higher larger~~ coverage for NO₂ and O₃-MDA8 and a ~~lower smaller~~ one for PM10. ~~For all pollutants, For almost all almost the entire domain of~~ Northern Italy ~~and for all pollutants, it is possible to estimate an has area with~~ significant simulated trends. Even for Southern Italy, where in general a low coverage of ~~significant modelled PM10 trends PM10 significant modelled trends~~ is obtained, ~~it is possible to catch somewhere are~~ areas with ~~significant simulated significant trends where there are no observations, where no observed data are present at all. It is also worth More in detail, it is worth~~ noting that in the major islands, Sardegna and Sicilia, the simulated trends give useful information, filling the gap ~~due to a sparse or absent monitoring network due to the absence of significant observed trends~~.

Moreover, a qualitative comparison between the temporal concentration trends and the meteorological and emission variations was carried out too. Since we do not observe a clear tendency in meteorological anomalies, concentrations trends were discussed in connection with emissions variations. Indeed, it was pointed out that, due to the complex links between precursors emissions and air pollutants concentrations, emission reductions do not always result in a corresponding decrease in atmospheric concentrations, especially for secondary pollutants like PM10 and O₃. Studies on air pollutant trends are relevant to evaluate the impact of the actions taken to reduce emissions in different environmental policies both at national and local levels. ~~The evaluation of the AMS-MINNI capability to reproduce the trends of pollutants increases the reliability of its application in assessing air quality and supporting air quality plans, especially for its use in national regulatory assessments. Indeed, Our~~ analysis demonstrates the good agreement between modelled and observed trends and the added value of the model in ~~widening increasing~~ both the coverage and the significance of air concentration trends with respect to observations. Model performance ~~turned out to be better is best~~ for NO₂, while for the others, especially O₃, the issue is more challenging. Moreover, the capability to interpret past air quality trends is fundamental in understanding the efficacy of already applied air quality policies and measures and in planning further actions. As demonstrated, the understanding of complex interactions is still uncertain and represents a gap to be filled since it is of the utmost importance in planning future policies aimed at reducing air pollution and its impacts on health and ecosystems.

~~The present analysis may be applied to other pollutants, especially substances of potential concerns for health (e.g. PM2.5). Moreover, it can be considered a reference for other studies in complex geographical conditions such as the Italian territory, that represents an interesting environmental framework, due to its complex orography, resulting in peculiar meteorological conditions, the great variety of natural and anthropogenic contexts, and the presence of the Po Valley, a well-known air pollution hot spot.~~

Figure 1: Italian anthropogenic emissions, as a percentage from 2003 to 2010 relative to 2003, from 2003 to 2010, elaborated from ISPRA emission data set described in Taurino et al. (2017).

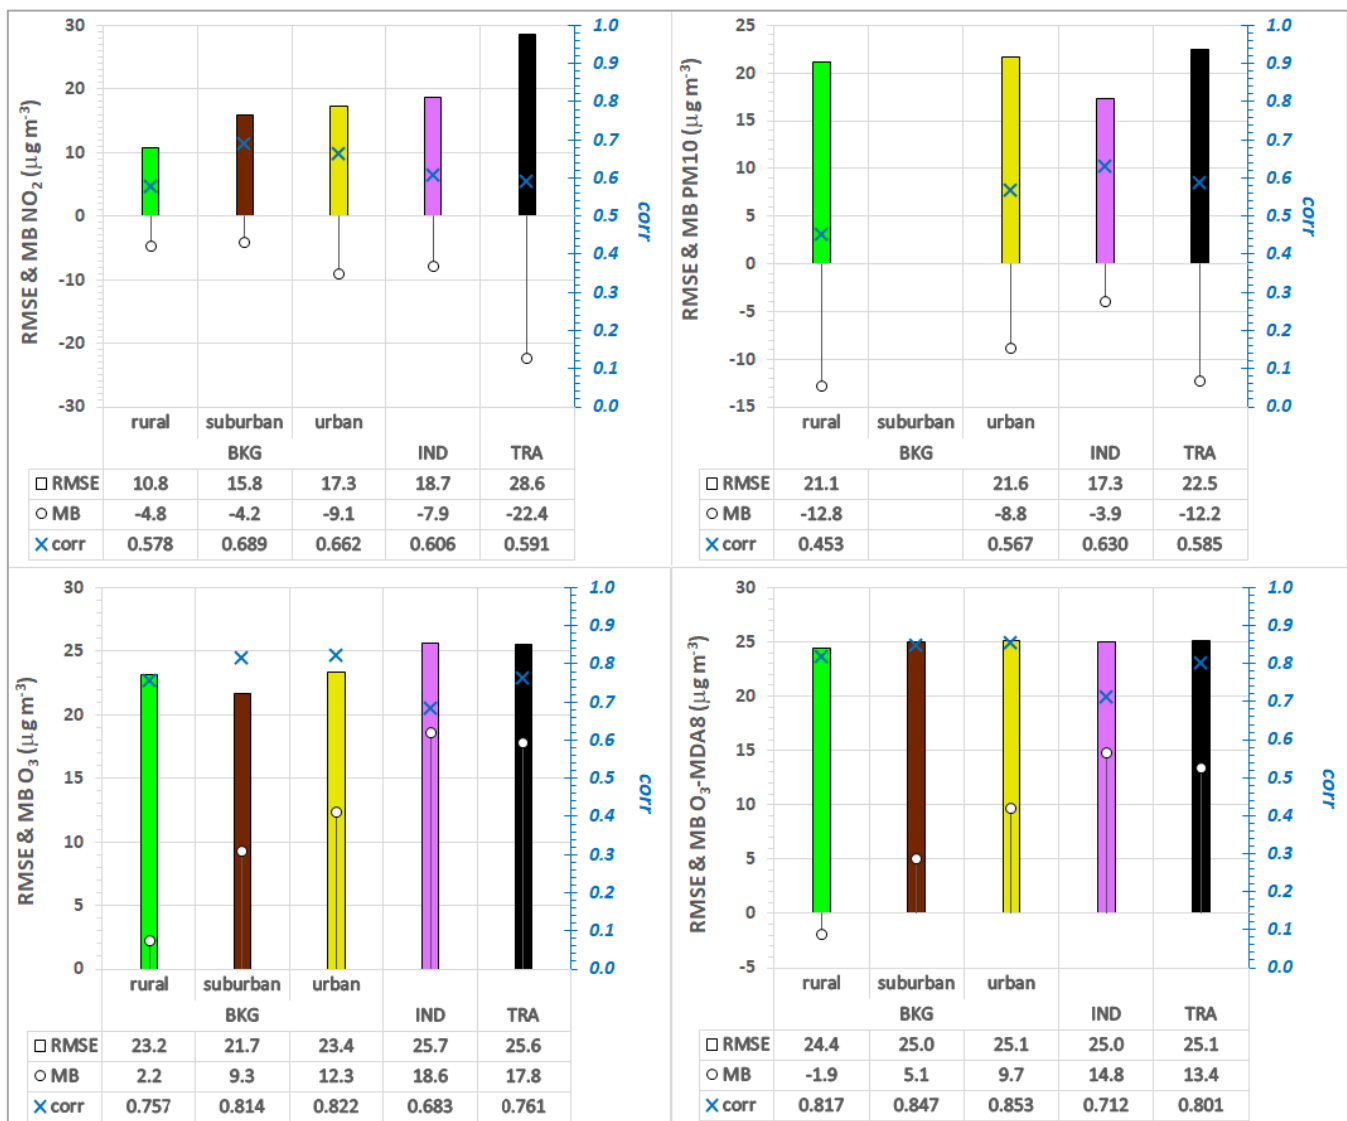

Figure 2: Summary of model performance evaluated at all valid Italian monitoring stations during 2003-2010. The statistical scores are based on annual time series of daily average values of NO₂ (upper left panel), PM10 (upper right panel) and O₃ (lower left panel) and on MDA8 of O₃, calculated in-for the period Apr-Sep (lower right panel).

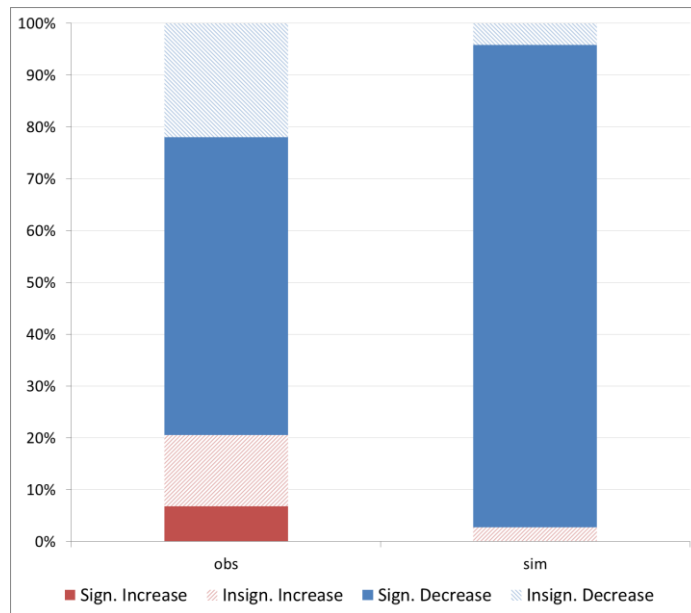

Figure 3: Percentage of sites where statistically significant upward trends (dark red), not significant upward trends (dashed hashed dark red), significant downward trends (dark blue) and not significant downward trends (dashed hashed dark blue) were obtained for NO₂ observations and simulated data.

905

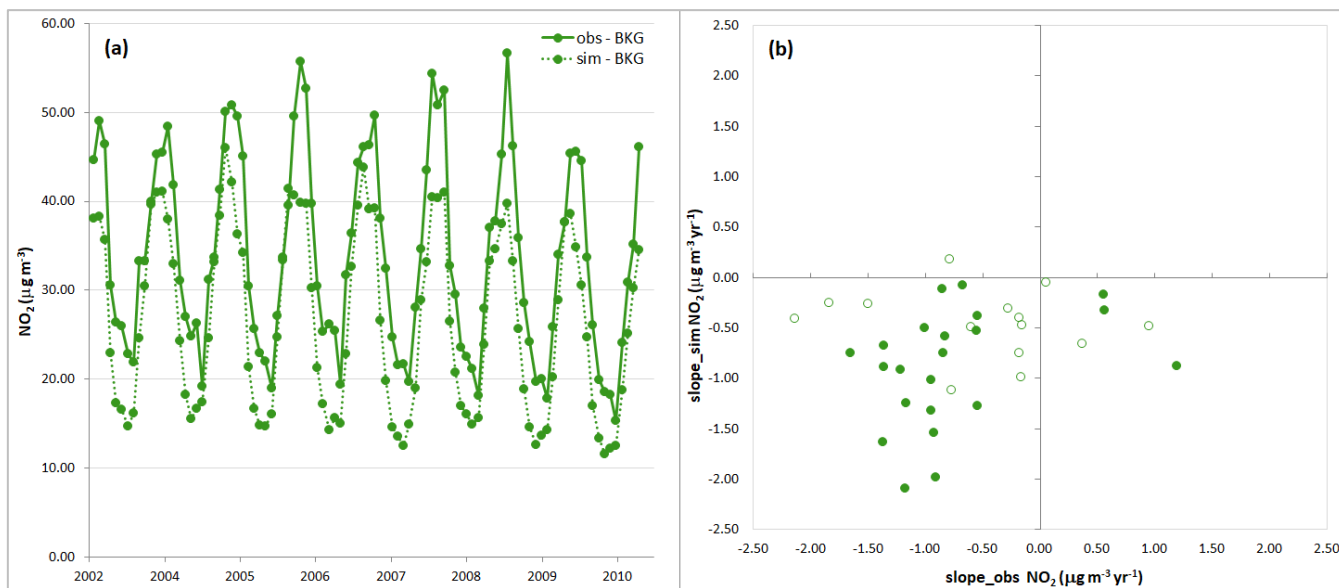

Figure 4: (a) Observed (solid line) and simulated (dashed line) monthly means of NO₂ concentrations (in µg m⁻³) for all the background monitoring stations. (b) Scatter plot of observed and simulated slopes (in µg m⁻³ yr⁻¹) at each individual stations. Sites where significant slopes are estimated for both observations and simulated data are indicated with a filled symbol.

910

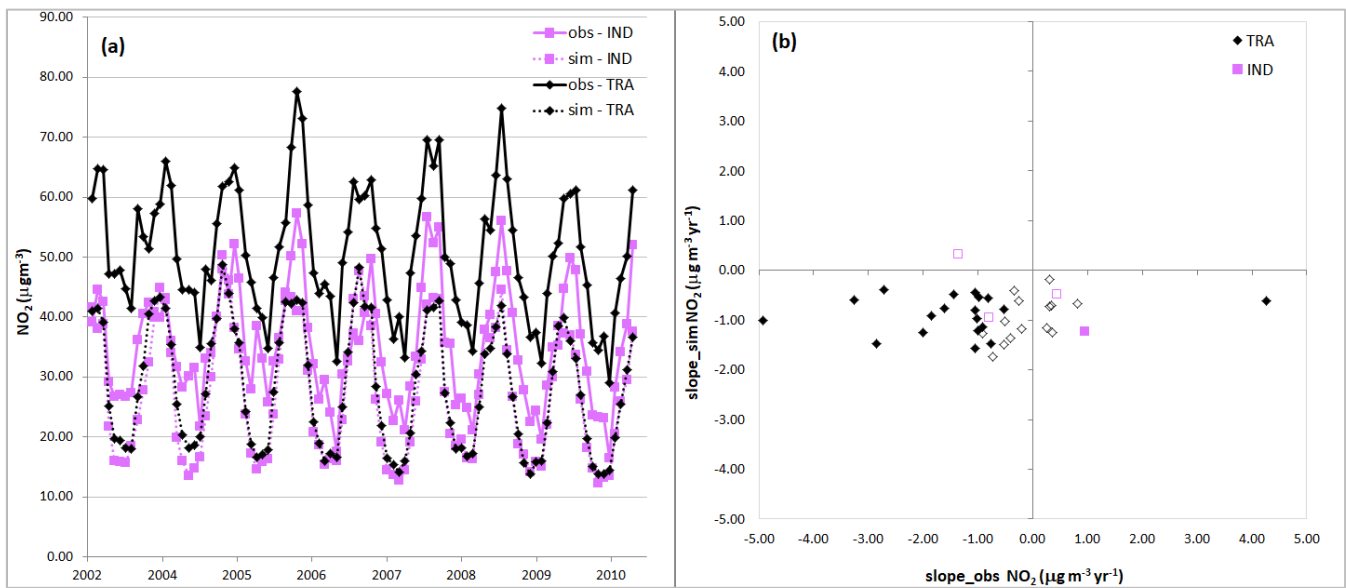

Figure 5: (a) Observed (solid line) and simulated (dashed line) monthly means of NO₂ concentrations (in $\mu\text{g m}^{-3}$) for all the traffic (black diamond) and industrial (magenta square) monitoring stations. (b) Scatter plot of observed and simulated slopes (in $\mu\text{g m}^{-3} \text{ yr}^{-1}$) at each individual stations. Sites where significant slopes are estimated for both observations and simulated data are indicated with a filled symbol.

915

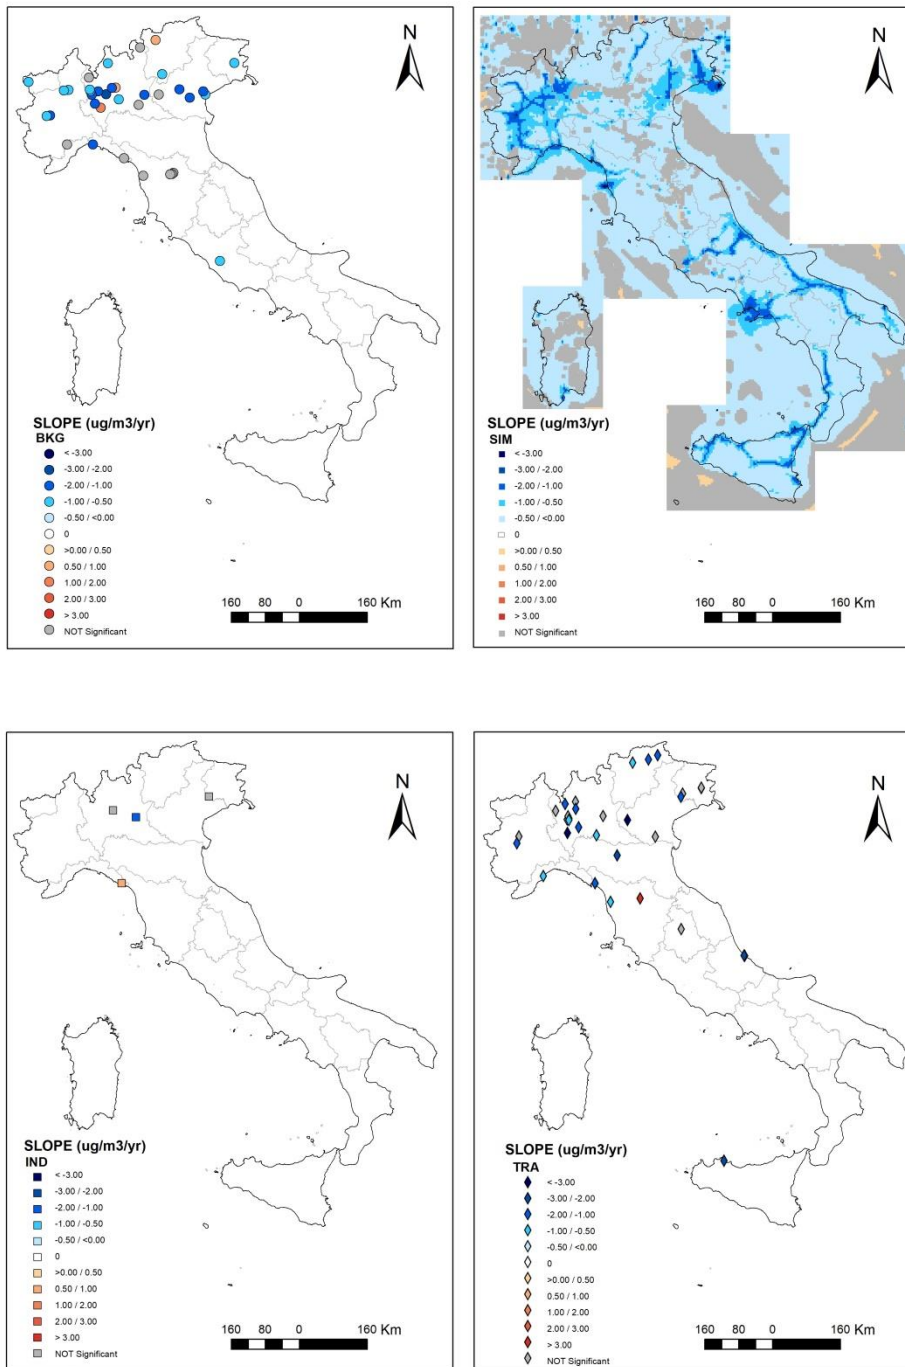

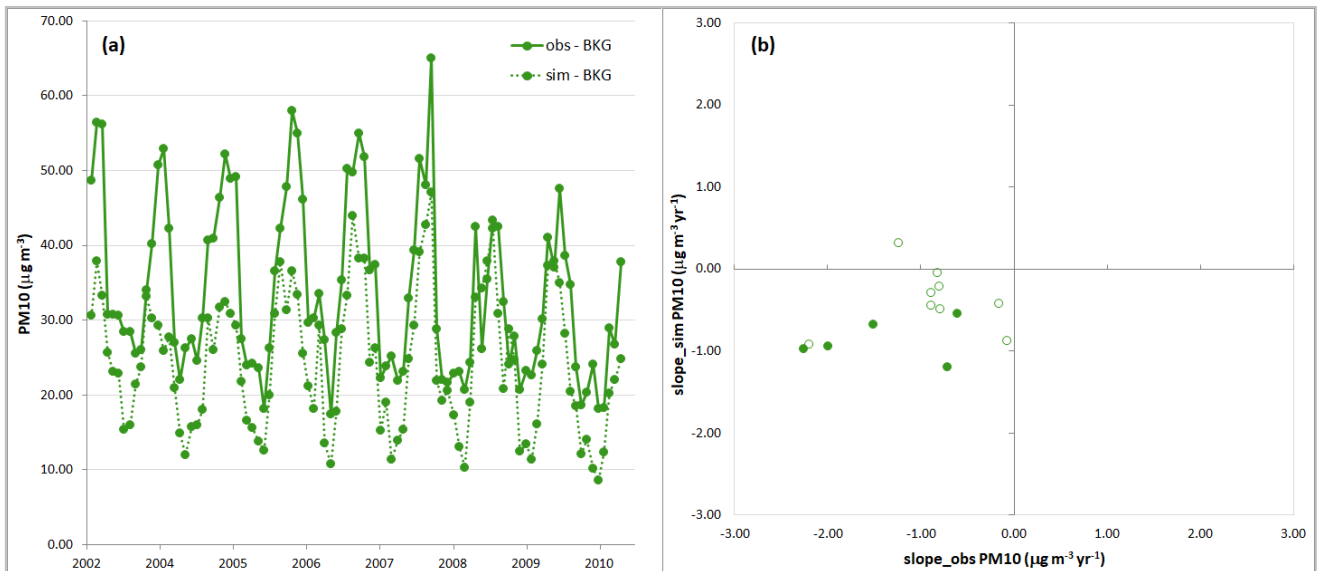

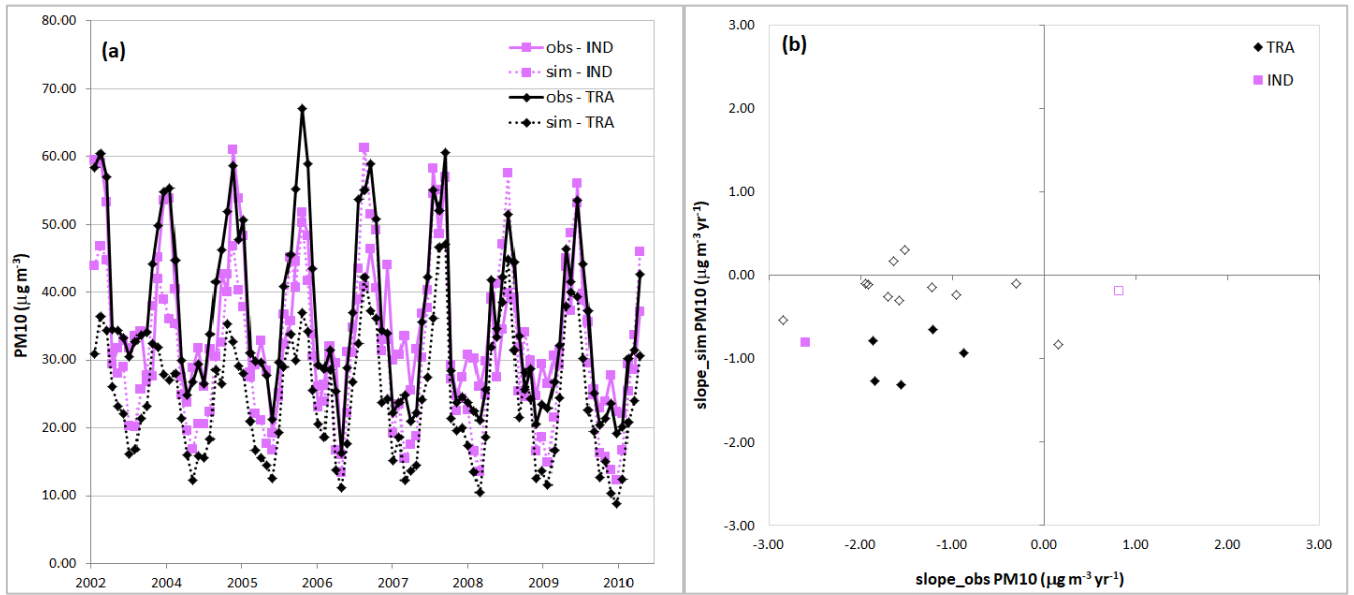

Figure 6: Slopes of NO₂ ($\mu\text{g m}^{-3}\text{yr}^{-1}$) observed at background (BKG – upper left panel), industrial (IND – lower left panel) and traffic (TRA – lower right panel) stations and simulated (upper right panel) slopes at each grid point. The grey symbols refer to not significant trends for both the observations and the simulated data.

925 **Figure 7:** Percentage of sites where statistically significant upward trends (dark red), not significant upward trends (dashed/dark red), significant downward trends (dark blue) and not significant downward trends (dashed/dark blue) were obtained for PM10 observations and simulated data.

930 **Figure 8:** (a) Observed (solid line) and simulated (dashed line) monthly means of PM10 concentrations (in $\mu\text{g m}^{-3}$) for all the background monitoring stations. (b) Scatter plot of observed and simulated slopes (in $\mu\text{g m}^{-3} \text{yr}^{-1}$) at each individual stations. Sites where significant slopes are estimated for both observations and simulated data are indicated with a filled symbol.

935 | **Figure 9: (a) Observed (solid line) and simulated (dashed line) monthly means of PM10 concentrations (in $\mu\text{g m}^{-3}$) for all the traffic (black diamond) and industrial (blue-pink square) monitoring stations. (b) Scatter plot of observed and simulated slopes (in $\mu\text{g m}^{-3} \text{ yr}^{-1}$) at each individual stations. Sites where significant slopes are estimated for both observations and simulated data are indicated with a filled symbol.**

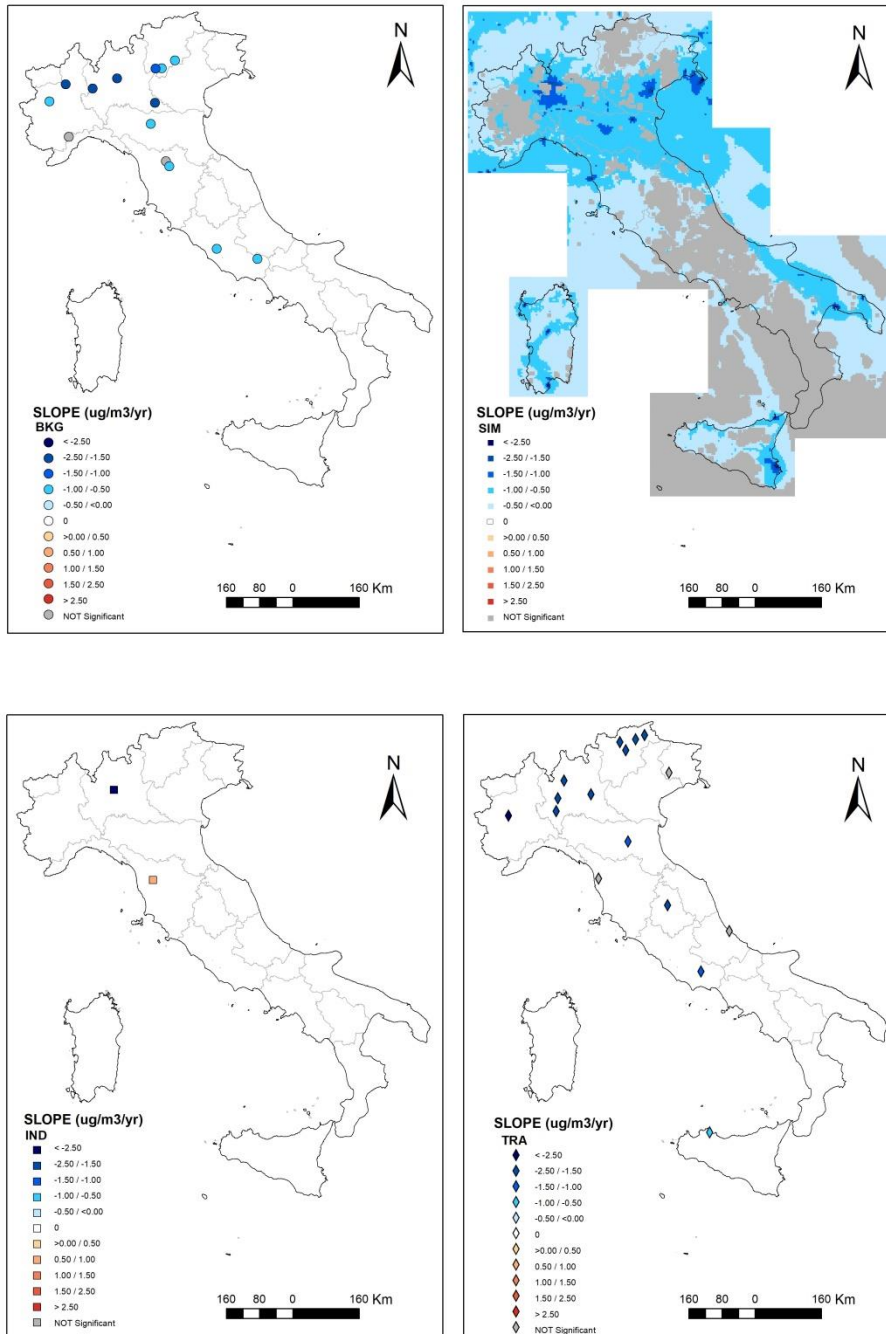

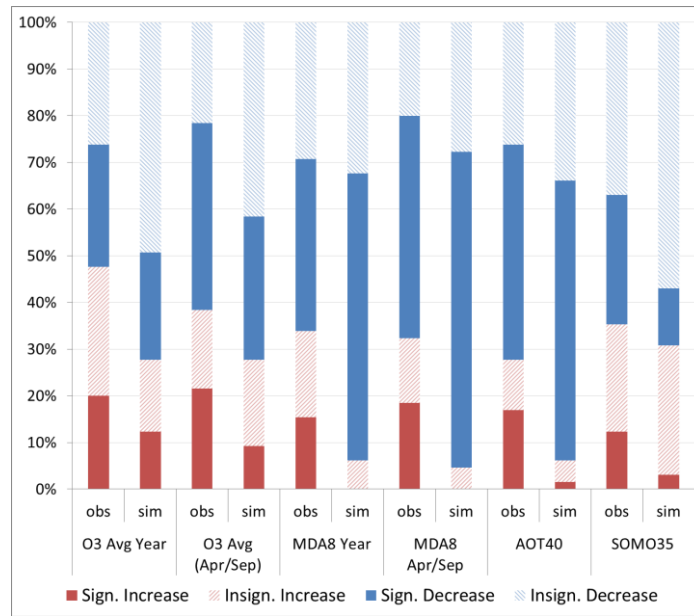

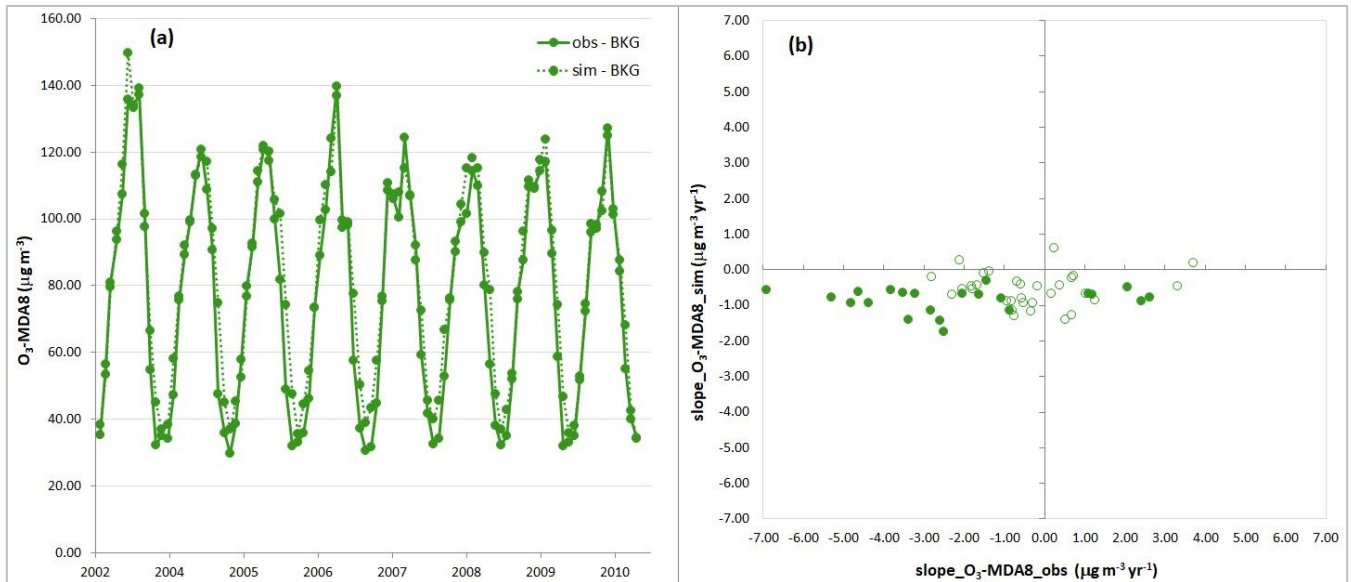

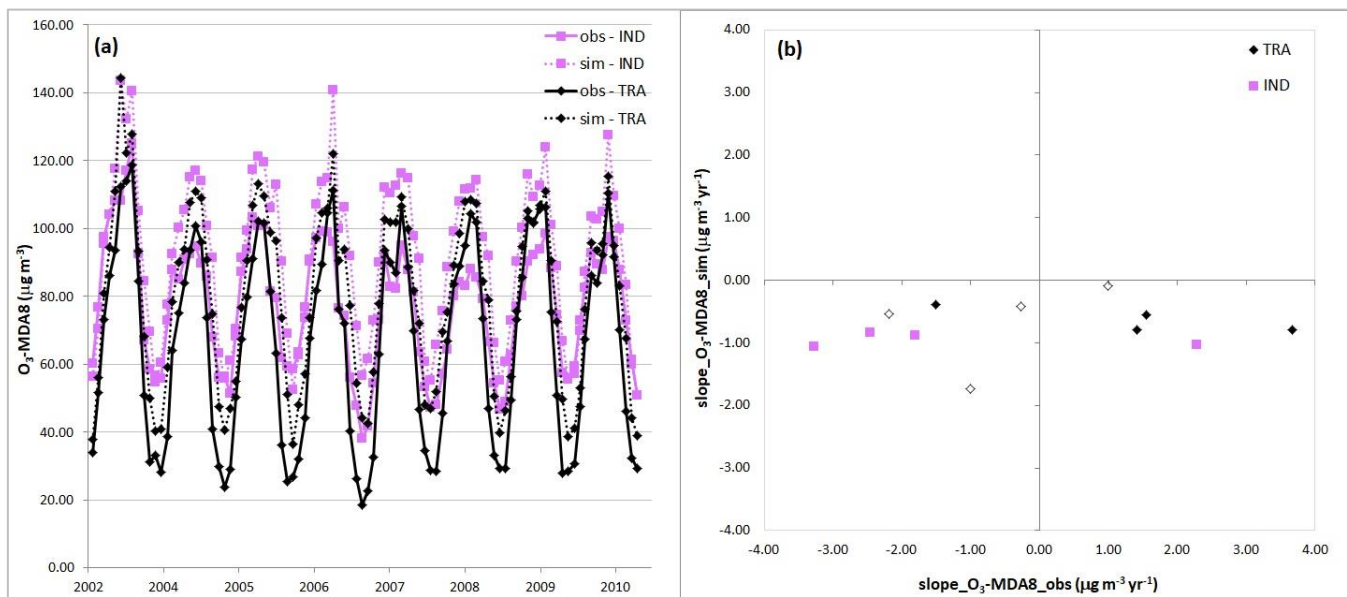

Figure 10: Slopes of PM10 ($\mu\text{g m}^{-3} \text{yr}^{-1}$) observed at background (BKG – upper left panel), industrial (IND – lower left panel) and traffic (TRA – lower right panel) stations and simulated (upper right panel) slopes at each grid point. The grey symbols refer to not significant trends for both the observations and the simulated data.

945 | Figure 11: Percentage of sites where statistically significant upward trends (dark red), not significant upward trends (dashed/dotted dark red), significant downward trends (dark blue) and not significant downward trends (dashed/dotted dark blue) were obtained for different observed and simulated metrics for O₃ for different O₃ observed and simulated metrics.

950 | Figure 12: (a) Observed (solid line) and simulated (dashed line) monthly means of O₃-MDA8 concentrations (in µg m⁻³) for all the background monitoring stations. (b) Scatter plot of observed and simulated slopes (in µg m⁻³ yr⁻¹) for O₃-MDA8 in the period April/September at each individual stations. Sites where significant slopes are estimated for both observations and simulated data are indicated with a filled symbol.

955 | Figure 13: (a) Observed (solid line) and simulated (dashed line) monthly means of O_3 -MDA8 concentrations (in $\mu\text{g m}^{-3}$) for all the traffic (black diamond) and industrial (pink square) monitoring stations. (b) Scatter plot of observed and simulated slopes (in $\mu\text{g m}^{-3} \text{ yr}^{-1}$) for MDA8 in the period April/September at each individual stations. Sites where significant slopes are estimated for both observations and simulated data are indicated with a filled symbol.

960

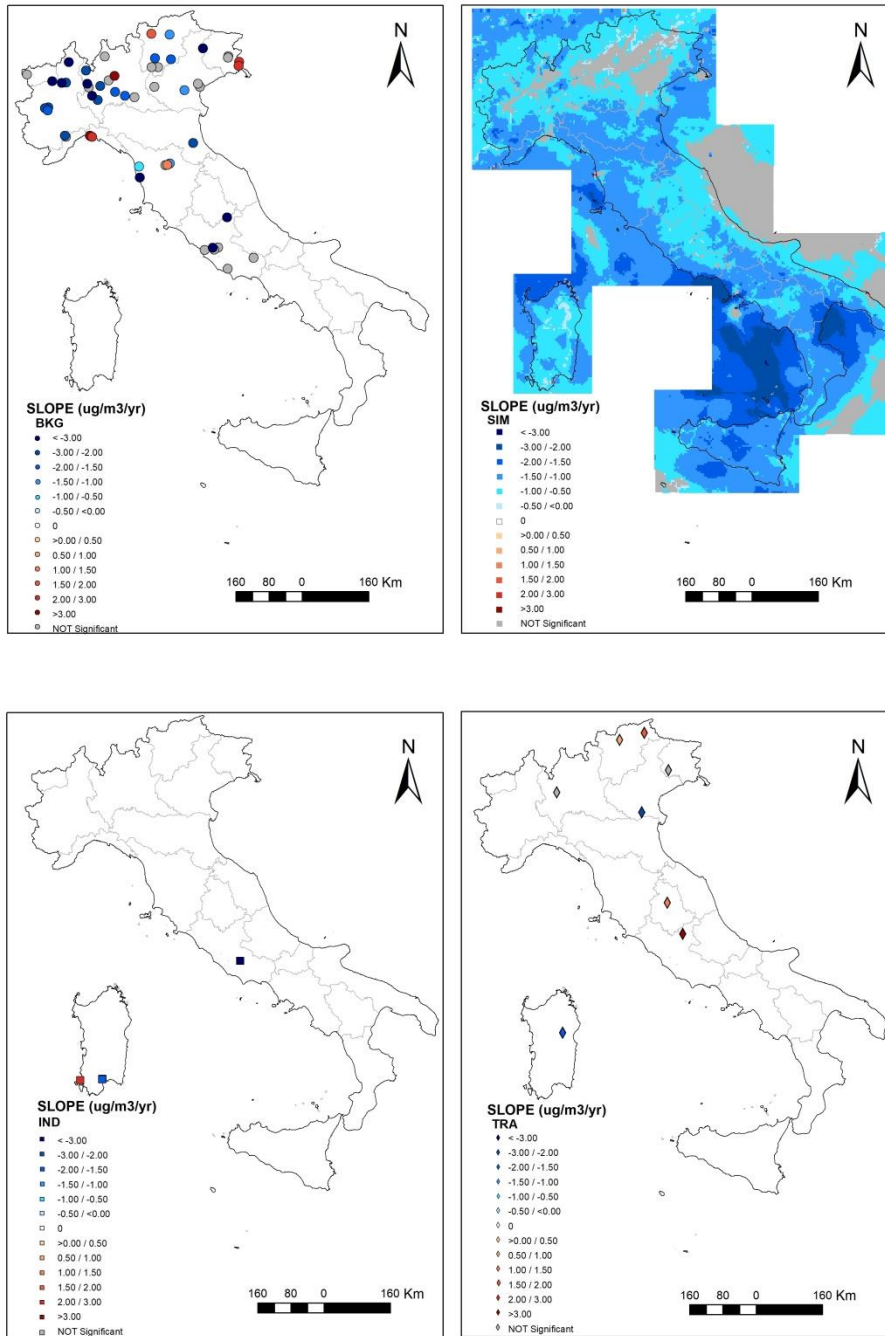

Figure 14: Slopes of O_3 -MDA8 ($\mu g m^{-3} yr^{-1}$) observed at background (BKG – upper left panel), industrial (IND – lower left panel) and traffic (TRA – lower right panel) stations and simulated (upper right panel) slopes at each grid point. The grey symbols refer to not significant trends for both the observations and the simulated data.
