Abstract. Ammonia (NH_3) is an important agent involved in atmospheric chemistry and nitrogen cycling. Current estimates of NH_3 emissions from biomass burning (BB) differ by more than a factor of two, impeding a reliable assessment of their environmental consequences. Combining high-resolution satellite observations of NH_3 columns with network measurements of the concentration and stable nitrogen isotope composition ($\delta^{15}N$) of NH_3, we present

coherent estimates on the amount of NH_3 derived from BB in the heartland of Southeast Asia, a tropical monsoon environment. Our results reveal a strong variability of atmospheric NH_3 levels in time and space across different landscapes. All evidence in hand suggests that anthropogenic activities are the most important modulating control with regards to the observed patterns of NH_3 distribution in the study area. N-isotope balance considerations revealed that during the intensive fire period, the atmospheric input from BB accounts for not more than $21\pm5\%$ (1σ) of the ambient NH_3, even at the rural sites and in the proximity of burning areas. Our N-isotope based assessment of the variation of the relative contribution of BB-derived NH_3 is further validated independently through the measurements of particulate K^+, a chemical tracer of BB. Our findings underscore that BB-induced NH_3 emissions in the tropical monsoon environments can be much lower than previously anticipated, with important implications for future modeling studies to better constrain the climate and air quality effects of wildfires.

1 Introduction

Biomass burning (BB) in tropical vegetation regions due to wildfires has been recognized as a globally important source of trace gases (including CO_2, CO, and ozone precursors) and aerosols (mostly black and organic carbon) (Crutzen and Andreae, 1990; Andreae and Merlet, 2001; Shi et al., 2015; Andreae, 2019; Crutzen et al., 1979). Most BB hotspots occur in West Africa and South America (Crutzen and Andreae, 1990; van der Werf et al., 2006; Shi et al., 2015), but recent studies have highlighted the importance also of Southeast (SE) Asia in this regard, mainly because of the much higher population densities near intensive fire burning areas (Huang et al., 2013; Marlier et al., 2013; Lee et al., 2017; Betha et al., 2014). The climate over large parts of SE Asia is governed by a wet (typically May, June, July) and dry (typically February, March, April) season caused by seasonal shifts in the monsoon winds. During the dry season, dry plant materials (e.g., forest, peatland, banana leaf) readily ignite, resulting in large wildfires that can markedly modify the atmospheric composition in the tropics, while the tropical

rain belt causes plentiful rainfall during summer, preventing such fires during the rainy season (Lee et al., 2017; Chu et al., 2018).

Besides carbon soot, BB also emits large amounts of reactive nitrogen compounds (Lobert et al., 1990; Bauters et al., 2018), in particular ammonia (NH_3), which is believed to represent the major source of NH_3 during intensive fires period (Akagi et al., 2011; Whitburn et al., 2015). However, these emissions are subject to large uncertainties (differences by a factor of two or greater).(Bray et al., 2018; Whitburn et al., 2015; Whitburn et al., 2016b; Van Damme et al., 2015b) For example, BB is probably the second most important NH_3 source after agriculture, contributing 11-23% of the global burden (Paulot et al., 2017; Bouwman et al., 1997). Minor NH_3 sources include fossil fuel burning and biogenic activity (Chang et al., 2012; Chang et al., 2016b; Chang et al., 2019b; Chang et al., 2020). A recent paper also highlighted the underestimated importance of industrial emissions (Van Damme et al., 2018). Once emitted in the atmosphere, NH_3 is rapidly removed by dry or wet deposition (Asman et al., 1998). Excess NH_3 is known to be responsible for several environmental issues: eutrophication of terrestrial and aquatic ecosystem, soil acidification, and loss of plant diversity (Sutton et al., 2008; Aneja et al., 2008; Sutton et al., 2011). In the atmosphere, NH_3 can neutralize acid gases (mostly sulfuric acid, nitric acid or hydrochloric acid), resulting in the formation of secondary aerosols that in turn negatively affect climate and human health (Wang et al., 2011; Wang et al., 2013; Paulot and Jacob, 2014; Souri et al., 2017).

To assess the environmental impacts of BB (e.g., air quality and climate change), atmospheric chemistry models incorporating BB-related emissions have widely been used over the past decades (Huang et al., 2013; Aouizerats et al., 2015; Wang et al., 2013; Wang et al., 2011; Souri et al., 2017) but are afflicted with a relatively large uncertainty regarding the input parameters used in the models (Hantson et al., 2016; Whitburn et al., 2015; Paulot et al., 2017). The uncertainties, for example, for carbon emissions and for other trace gases (including NH_3), can be over 200% (Whitburn et al., 2015; Paulot et al., 2017; Zhu et al., 2013; Pan et al., 2019). In recent years,

hyperspectral sounders on board satellites have demonstrated their capabilities to directly measure tropospheric column concentrations of NH_3 gas (Van Damme et al., 2018; Van Damme et al., 2014; Van Damme et al., 2015b; Clarisse et al., 2009). Satellite observations therefore offer a "top-down" alternative to the bottom-up estimates. Still, the biggest challenge of satellite-based NH_3 assessments is the requirement for the atmosphere to be cloud-free during observations, and the need for a sizeable temperature difference between land or sea surface and the atmosphere (Van Damme et al., 2015a; Whitburn et al., 2015; Martin, 2008; Streets et al., 2013; Clarisse et al., 2010).

Large uncertainties remain regarding global or regional atmospheric budgets of NH_3, and the attribution of emissions to specific sources, emphasizing the need for independent verification methods. An impressive body of previous work has studied the BB influence on the concentration and composition of aerosols in SE Asia (Betha et al., 2014; Aouizerats et al., 2015; Lee et al., 2017; Bikkina et al., 2019). However, to our knowledge, there are no reports on the detailed spatiotemporal patterns of atmospheric NH_3 concentration and nitrogen isotopic composition ($\delta^{15}N$-NH_3) associated with BB in this region. Due to isotopic fractionation associated with NH_3 production, pyrogenic NH_3 displays a distinctly higher $\delta^{15}N$-NH_3 ($\delta^{15}N$ defined as ($R_{sample}/R_{standard}$ -1)x1000, where R refers to the $^{15}N/^{14}N$ ratio in a sample or a standard) than temperature-dependent volatilized sources (Felix et al., 2013; Chang et al., 2016a). The N isotopic analysis of ambient NH_3 has been proven a useful tool to constrain sources of NH_3 emissions in the atmosphere, where both natural and anthropogenic activities are relevant (Chang et al., 2019b; Chang et al., 2019a; Elliott et al., 2019). Here, we integrate high-resolution satellite observations with discrete NH_3 concentration measurements and $\delta^{15}N$-NH_3 data obtained from a regional passive monitoring network during and after the dry season of large-scale forest fires in the mountain areas of northern Thailand, SE Asia.

2 Methods

2.1 Site description

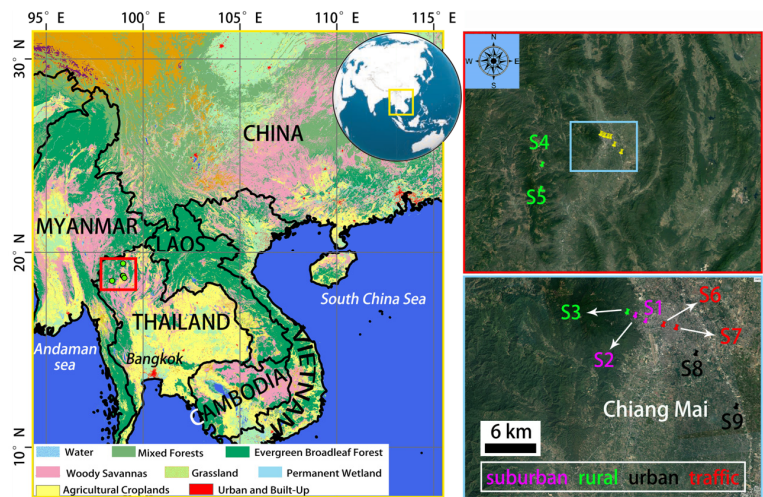
Surrounded by the mountain ranges of the northern Thailand highlands, the Chiang Mai Province covers an area of approximately 20107 km^2, with a total population of over 1.7 million. Chiang Mai is characterized by a tropical
85 monsoon climate, tempered by the low latitude and moderate elevation, with warm to hot weather year-round. Some 70% of the area is covered by forests, and 13.4% of the area is under agriculture. A continuing environmental issue in Chiang Mai is the smoke pollution from wildfires that primarily occurs every year towards the end of the dry season between February and April (Tsai et al., 2013) before the relatively cool and rainy season from May on. During the period from March to July 2018, ambient NH$_3$ concentrations and δ^{15}N-NH$_3$ values were determined at
90 9 monitoring stations across the Chiang Mai Province. Figure 1 illustrates the location of sampling sites (with the different land use regimes indicated), while Fig. S1 reports meteorological data for Chiang Mai and Table S1 details the information of each station.


Figure 1. Location of sampling sites. Land-cover map (left; revised from Chang et al., 2016b) with zoom-in in
95   lower panels (right). The chosen sampling sites are representative for gradient in land use from urban to rural.

2.2 Sampling and laboratory analysis

In order to obtain information regarding the spatial and temporal variability of NH_3 concentrations over Chiang
Mai, ambient gas-phase NH_3 concentrations at each site were collected weekly using passive sampling devices
100   (PSD) (ALPHA - Adapted Low-cost, Passive High Absorption; Centre for Ecology and Hydrology, Edinburg, UK)
(Chang et al., 2016a). The ALPHA PSD is a circular polyethylene vial (26 mm height, 27 mm diameter) with one
open end. The vial holds a 25 mm phosphorous acid-impregnated filter and a PTFE membrane for gaseous NH_3
diffusion. These PSDs have been widely used in Europe, China, and the US, and are capable of detecting NH_3
concentrations as low as 0.03 μg m^{-3} (Chang et al., 2016a; Puchalski et al., 2011; Liu et al., 2013; Tang et al., 2018).
105   In the laboratory, the ALPHA filter samples were soaked in 10 mL deionized water (18 MΩ·cm) in a 15 mL vial
for 30 min with occasional shaking. Concentrations of NH_3-derived NH_4^+ in extracts were determined using a
Dionex^{TM} ICS-5000$^+$ system (Thermo Fisher Scientific, Sunnyvale, USA). The IC system was equipped with an
automated sampler (AS-DV), an IonPac CG12A guard column, and a CS12A separation column. Aqueous
methanesulfonic acid (MSA, 30 mM L^{-1}) served as eluent at a flow rate of 1 mL min^{-1}. The isotopic analysis of the
110   extracted NH_4^+ was based on the isotopic analysis of nitrous oxides (N_2O) after chemical conversion (Liu et al.,
2014). More precisely, dissolved NH_4^+ in DI extracts was oxidized to NO_2^- by alkaline hypobromite (BrO^-), and
then reduced to N_2O by hydroxylamine hydrochloride ($NH_2OH.HCl$). The produced N_2O was analyzed using a
purge and cryogenic trap system (Gilson GX-271, IsoPrime Ltd., Cheadle Hulme, UK), coupled to an isotope ratio
mass spectrometer (PT-IRMS) (IsoPrime 100, IsoPrime Ltd., Cheadle Hulme, UK) (Liu et al., 2014). In order to
115   correct for any machine drift and procedural blank contribution, international NH_4^+ (IAEA N1, USGS 25, and

USGS 26) standards were processed in the same way as samples (Liu et al., 2014). The analytical precision for N isotope analyses was better than 0.5‰ ($n = 5$).

2.3 Isotope-based source apportionment

Isotopic mixing models represent valuable tools to estimate the fractional contributions of multiple sources (emission sources of NH_3 in this study) within a mixture (the ambient NH_3 in this study) (Layman et al., 2012). By explicitly taking into account the uncertainties associated with the isotopic signatures of single sources and the N isotope fractionation during transformations, the application of Bayesian methods to stable isotope mixing models yields robust probability estimates on source apportionments, and its application to natural systems is more appropriate than the application of simple linear mixing models (Parnell et al., 2010). Here, a novel Bayesian approach using a mixing model, implemented in the software package SIAR (Stable Isotope Analysis in R), was used to resolve multiple NH_3 source categories by generating potential solutions of source apportionment as true probability distributions of the single source contribution to the total NH_3 pool. The generation of such source contribution probability distributions allows estimating likelihood ranges of source contributions even at under-constrained conditions (i.e., the number of potential sources exceeds the number of different isotope system parameters + 1). The SIAR package is available to download from the packages section of the Comprehensive R Archive Network site (CRAN; http://cran.r-project.org/), which has been widely applied in a number of fields (Chang et al., 2019a; Chang et al., 2019b). Model frame and computing methods are detailed in Text S1.

2.4 Satellite observations of ammonia and fires

NH_3 total columns (molec cm^{-2}) are retrieved from the Infrared Atmospheric Sounding Interferometer (IASI) observations. IASI instruments are onboard the Metop satellite series; in this work, we use IASI/Metop-A (launched in 2006) and IASI/Metop-B (launched in 2012) data. Both instruments have an overpass time around 9:30 am and

pm (local solar time when crossing the equator) and therefore provide in total a global coverage four times a day. The retrieval strategy, based on artificial neural networks, is fully detailed in previous work (Whitburn et al., 2016a; Van Damme et al., 2017). Here we only consider morning observations, as they are more sensitive to the lower layer of the atmosphere. Fire Radiative Power (FRP) from the Moderate Resolution Imaging Spectroradiometer (MODIS) and fire counts derived from the 375-m Visible Infrared Imaging Radiometer Suite (VIIRS) are also used (Li et al., 2020).

3 Results and discussion

3.1 Satellite-observed NH$_3$ distributions

Figure 2a illustrates the monthly spatial distribution of NH$_3$ columns obtained from IASI in 2018 at a spatial resolution of $0.25° \times 0.5°$ cells. Our study area is set within a large domain of $5.00° \times 3.25°$ (red and black rectangles in Fig. 2a and Fig. 2b, respectively), in which totally 260 gridded pixels ($0.25° \times 0.25°$ per cell) are used for dividing active fire points (Fig. 2b). Intriguingly, from this plot, one is tempted to conclude that fires do play a very important role in NH$_3$ emissions, as the NH$_3$ columns are much higher in March and April (dry season), which is coincident with high number of monthly fire activities (indicated by the number of fire points). Further, using 11 years (2008-2018) of IASI satellite data, Figure S2 presents a climatology of monthly NH$_3$ columns over Chiang Mai at a much finer spatial resolution, which also support the pervasive contribution of BB during dry season (March and April). Based on the average observed temporal distribution of satellite-constrained wildfires, the sampling period in this study can be divided into two contrasting fire-regime periods, i.e., BB season (March and April) and non-BB season (May and June). Interestingly, however, although the number of fire points in March (43613 points) is significantly ($p < 0.01$) higher than that in April (27905 points) (Fig. 2b), the average NH$_3$ column in March is nearly the same as that in April (Fig. 2a). This implies that there is not a one-to-one relationship between BB and NH$_3$ emissions,

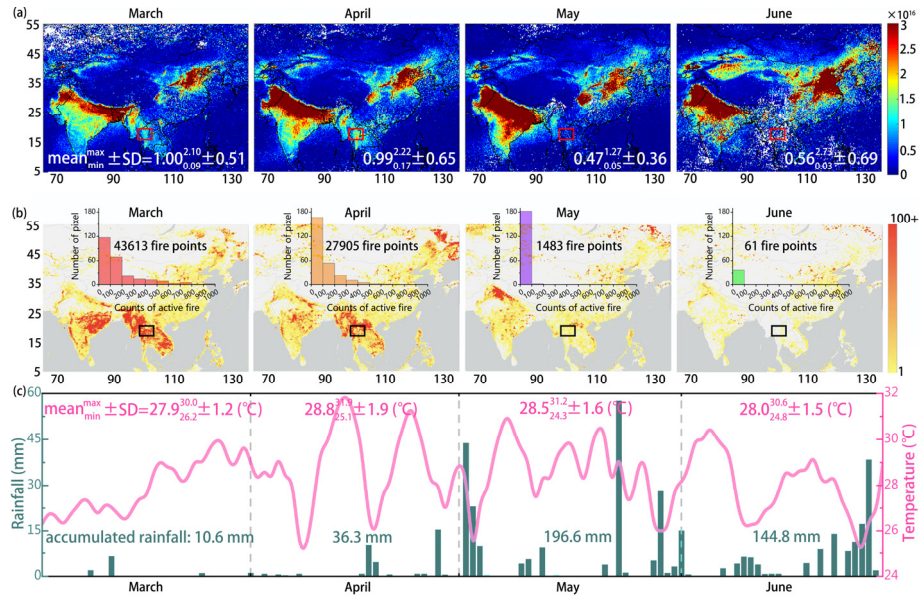
and in turn that other sources or factors (e.g., soil dryness, agricultural emissions, precipitation, temperature dependence, etc.) must also play a significant role.


Figure 2. (a) Monthly (March, April, May, June) spatial distributions of the NH_3 total columns (molecules cm^{-2}) in 2018 obtained from the satellite measurements by the Infrared Atmospheric Sounding Interferometer (IASI)/MetOp-A instrument in $0.25° \times 0.5°$ cells. (b) Monthly distributions of gridded counts of active fire pixels ($0.25° \times 0.25°$ per cell) derived from the 375-m Visible Infrared Imaging Radiometer Suite (VIIRS). The red and black squares indicate our study area in Chiang Mai. (c) Daily variations of (°C) and rainfall (mm) in Chiang Mai City.

Given that the average monthly temperature varies only little, in contrast to the drastic change of rainfall during our study period (Fig. 2c), it is reasonable to assume that temperature-dependent NH_3 volatilization is not the main driver of changes in the NH_3 columns. The amount of rainfall, on the other hand, can have multi-faceted impact on NH_3 emissions. First of all, there is an obvious link between precipitation rates and the number of wildfires, and, if

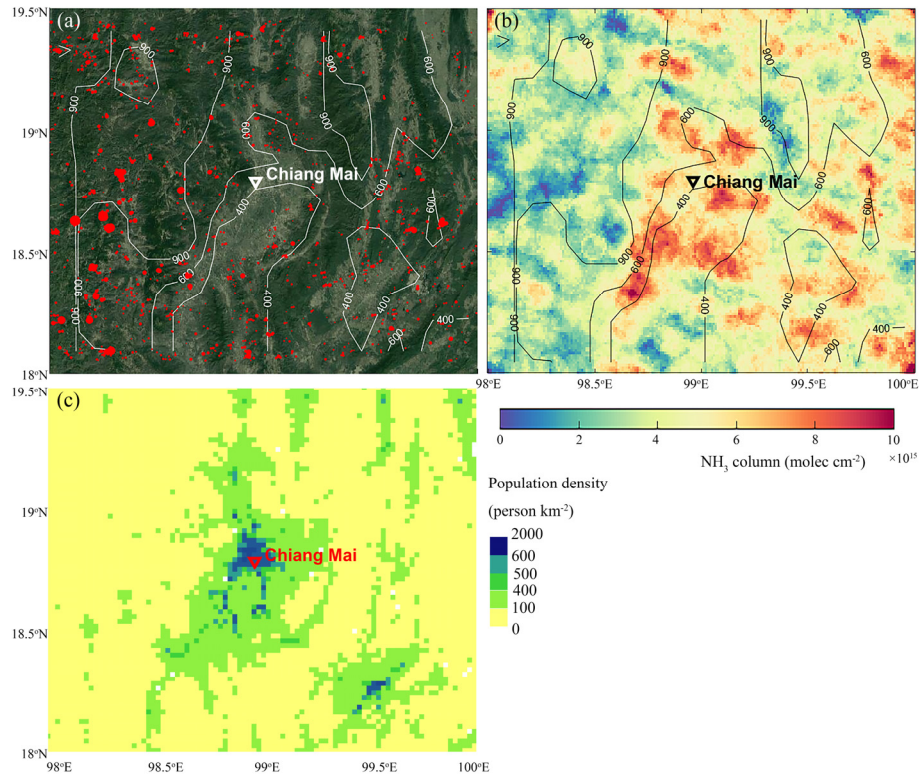
BB is a major NH_3 emission source, we can also expect a relationship between the NH_3 columns and monthly rainfall rates. Secondly, and maybe more importantly, rain will dissolve atmospheric particulate NH_4^+, and will act to clean the air from NH_3, which may partly explain the low NH_3 levels during May and June. On the other hand, comparison between March and April reveals higher NH_3 levels in April despite higher rain rates, suggesting that other processes than BB and rain-scavenging of BB-derived NH_3 must be relevant factors. In Fig. 3a and 3b, we superimposed the orography at the scale of the study area (Chiang Mai and surrounding mountains) onto the images of year-long averaged MODIS FRP (Fire Radiative Power) and IASI-NH_3 for 2018, respectively. Just by visual evaluation it seems obvious that there is no strong correlation between fire intensity/number of fires and the observed IASI-NH_3, suggesting only limited influence of BB on NH_3. Yet more strikingly, the IASI-NH_3 distribution matches that of the population density quite well (Fig. 3c). More precisely, hot spots of atmospheric NH_3 (Fig. 3b) appear to be concentrated in urban areas with dense population. Hence, our satellite remote sensing observations suggest a significant influence of non-BB emissions on NH_3 concentrations, seemingly related to urban anthropogenic activities.


Figure 3. (a) The MODIS FRP (fire radiative power) (the size of red dots is proportional to arbitrary FRP values) and (b) the IASI Metop-A and Metop-B averaged NH$_3$ distribution (molec cm^{-2}) for 2018. (c) Number of people per grid-cell in the Chiang Mai area in 2018 at a resolution of 3 arc minute.

3.2 Discrete concentration measurements confirm urban areas as hot spots of NH$_3$ emissions

A total of more than 150 samples were collected in this study for analyzing NH$_3$ concentrations (Fig. 4). The atmospheric NH$_3$ concentrations over Chiang Mai ranged from 2.5 to 46.4 μg m^{-3}, with mean ($\pm$ 1σ) and median values of 14.5 ($\pm$ 9.2) and 11.4 μg m^{-3}, respectively. Consistent with the IASI satellite-based NH$_3$ assessment, the weighted average NH$_3$ concentration ($\text{mean}_{\text{min}}^{\text{max}} \pm 1\sigma$) during the dry season (i.e., when wildfires were markedly more abundant) was significantly (p < 0.01) higher ($20.6_{6.8}^{46.4} \pm 9.8$ μg m^{-3}) than during the rainy season ($10.2_{2.5}^{31.9} \pm 5.7$ μg m^{-3}). Again, it is tempting to conclude that there is a direct link between higher atmospheric

NH$_3$ levels and the higher number of BB events. However, there are several aspects that appear to speak against

BB as the main, or only, driver of ambient NH$_3$ concentrations. Firstly, from a global perspective, the ambient NH$_3$

concentrations we measured in northern Thailand are generally lower than in tropical regions with dense population

or intensive agricultural production (also see Fig. 2a) (Carmichael et al., 2003; Chang et al., 2016b). Secondly,

within the study area, large spatial differences in NH$_3$ concentrations were found (Fig. 4). Yet, despite their

200 proximity to wildfires at the time, the three rural sites always displayed the lowest NH$_3$ concentrations

($8.3_{2.5}^{26.8}$ ± 4.6 μg m^{-3}; Fig. 4; see detailed discussion in the next section).
Figure 4. Temporal variations of measured NH$_3$ concentrations (μg m^{-3}) between sites of different land-use regimes.

The error bar indicates one standard deviation.

205 Despite relatively large uncertainties, it is well accepted that globally atmospheric NH$_3$ is primarily emitted by

agricultural activities and biomass burning (Asman et al., 1998; Bouwman et al., 1997). As a consequence, one

would expect the NH$_3$ concentrations in the atmosphere over rural environments with lush vegetation and

agricultural land-use to be higher than those in (sub)urban areas, where agricultural activities are mostly absent. In

our study, the average NH$_3$ concentrations at the nine sites, respectively, are: $19.5_{6.5}^{39.4}$ ± 9.5 (S1; suburban),

210 $11.9_{4.5}^{19.7} \pm 4.6$ (S2; suburban), $8.8_{4.4}^{16.6} \pm 3.9$ (S3; rural), $9.0_{2.8}^{26.8} \pm 5.8$ (S4; rural), $7.0_{2.5}^{13.7} \pm 3.8$ (S5; rural),

$20.2_{9.1}^{40.5} \pm 8.6$ (S6; urban traffic), $18.1_{7.2}^{46.1} \pm 12.1$ (S7; urban traffic), $19.6_{4.2}^{46.4} \pm 10.1$ (S8; urban), and

$16.6_{6.7}^{30.6} \pm 8.0$ (S9; urban) $\mu g\ m^{-3}$ (see also compilation in Fig. 4). Thus, against current paradigms, the observed

NH$_3$ concentrations clearly reflect an urban ($18.6_{4.2}^{46.4} \pm 9.7$, n = 68) to suburban ($15.6_{4.5}^{39.4} \pm 8.3$, n = 34) to rural

($8.3_{2.5}^{26.8} \pm 4.6$, n = 51) gradient. Such a concentration gradient can be taken as evidence that non-agricultural

215 activities (including on-road traffic), at least in some regions, can outweigh agriculture and/or BB as the dominant

NH$_3$ source in urban areas.

Indeed, a growing body of studies confirm that the urban atmosphere can be a hot spot of NH$_3$ release. Non-agricultural activities, such as wastewater treatment, coal combustion, solid garbage handling, as well as vehicular exhaust, and urban green space contribute strongly to urban to NH$_3$ emissions (Chang et al., 2016a; Chang et al.,

220 2019b; Teng et al., 2017; Chang et al., 2015; Li et al., 2016; Sun et al., 2017). For example, high vehicular NH$_3$ emissions from three-way catalysts (TWCs) have been demonstrated in chassis dynamometer vehicle experiments, road tunnel tests, and through ambient air measurements (Huang et al., 2018; Chang et al., 2016b; Chang et al., 2019b).

3.3 N isotopic constraints on the sources of natural and anthropogenic NH$_3$

225 The correlative analysis of spatiotemporal concentration patterns with variations in land use effects provides first qualitative constraints with regards to the relative importance of natural/BB and anthropogenic NH$_3$ emissions, but it is insufficient when a more quantitative assessment is required. The N-isotopic composition of NH$_3$ (i.e., δ^{15}N-NH$_3$) can provide help in this regard, as it is sensitive to changes of NH$_3$ sources with distinct isotopic composition (Elliott et al., 2019; Felix et al., 2013). δ^{15}N-NH$_3$ values determined in this study ($-27.04_{-46.28}^{-12.35} \pm 7.22‰$, n = 145)

230 show a relatively large variability in time and space (Fig. 5). NH$_3$ emitted from the five major NH$_3$ sources displays

distinct isotopic signatures (N-fertilizer application, -50.0 ± 1.8‰; urban waste volatilized sources, -37.8 ± 3.6‰; livestock breeding, -29.1 ± 1.7‰; on-road traffic, -12.0 ± 1.8‰; biomass burning, 12‰) (see coloured bars in Fig. 4) (Chang et al., 2016a; Kawashima and Kurahashi, 2011; Chang and Ma, 2016). Thus, the measurement of δ^{15}N-NH$_3$ can be used to distinguish between specific sources, and to quantify their contribution to the measured total

235 NH$_3$ pool (note that the isotopic signature determined by Kawashima and Kurahashi (2011) is for particulate NH$_4^+$, not NH$_3$). As a first step, we examine the spatiotemporal characteristics of the measured δ^{15}N-NH$_3$ relative to the N isotopic source signatures to infer seasonal changes of NH$_3$ sources.
Figure 5. (left) Weekly-based variations of the δ^{15}N values (‰) of ambient NH$_3$ measured in urban, suburban, and

240 rural environments (setting 0 as the breaking point). The error bars indicate two standard deviations. (right) Box plots of the distribution of δ^{15}N-NH$_3$ during BB season and non-BB season for each type of sampling sites.

The lowest δ^{15}N-NH$_3$ values were observed at the rural sites (S3-S5) during the dry season ($-32.72^{-20.38}_{-46.28} \pm 6.46‰$, n = 21). These δ^{15}N values are much lower than the δ^{15}N of BB-related NH$_3$ and indicate the pervasive influence of agricultural NH$_3$ emissions in rural environments, rather than BB. During the rainy

245 season, a drastic increase of δ^{15}N-NH$_3$ ($-23.97^{-12.35}_{-37.99} \pm 7.50‰$, n = 22) at the rural sites was observed. Again, if BB was the dominating modulator of NH$_3$ levels, an increased contribution from of BB-derived NH$_3$ during the

dry versus the wet season in rural areas should have resulted in higher, and not lower δ^{15}N-NH$_3$ values. The increased δ^{15}N-NH$_3$ during the non-BB (i.e., rainy) period can probably be explained by the fact that agricultural NH$_3$ emissions with low δ^{15}N-NH$_3$ can be dramatically lowered by continuous and heavy rainfall (Zheng et al., 2018; Chang et al., 2019a) so that at low levels, local sources can become more important (e.g., residential kitchens, nearby burning of biofuels for cooking).

As for the urban sites, the mean δ^{15}N-NH$_3$ values at S6, S7, S8, and S9 were $-23.95_{-34.00}^{-16.35} \pm 4.61‰$, $-25.53_{-35.01}^{-14.10} \pm 6.11‰$, $-24.47_{-33.08}^{-16.86} \pm 4.20‰$, and $-25.32_{-39.44}^{-17.13} \pm 7.75‰$, respectively. The overall average δ^{15}N-NH$_3$ value at the four urban sites ($-24.82_{-39.44}^{-14.10} \pm 5.74‰$, n = 68) was significantly (p < 0.01; one-way analysis of variance and paired-sample t test; similarly hereinafter) higher than that at the rural ($-28.24_{-46.28}^{-12.35} \pm 8.22‰$, n = 43) and suburban ($-29.94_{-45.62}^{-18.78} \pm 7.35‰$, n = 34) sites, respectively, indicating a greater contribution of NH$_3$ emissions from pyrogenic (e.g., on road traffic) sources. The average value of urban δ^{15}N-NH$_3$ during the dry season ($-24.21_{-34.47}^{-14.10} \pm 4.82‰$, n = 28) was very similar to the average value observed during the rainy season ($-25.25_{-39.44}^{-15.31} \pm 6.33‰$, n = 40), after the pronounced decrease of NH$_3$ concentrations due to wet removal. This rather minor difference can hardly be ascribed to the influence of BB emissions, given the large seasonal fluctuation of wildfire intensity mentioned above. Based on the absolute δ^{15}N-NH$_3$ values in the urban settings, and their rather invariant temporal trends, we argue that vehicle/transport-related is a more important and apparently steady source of pyrogenic NH$_3$ in the studied urban areas.

The two suburban sites (S1 and S2) are located geographically within the transition zone between the urban and rural environments, and this transitional character seems also indicated by their intermediate δ^{15}N-NH$_3$ values ($-29.94_{-45.62}^{-18.78} \pm 7.35‰$, n = 34). However, interestingly, in comparison to the urban and rural sites, the overall

δ^{15}N-NH$_3$ value for the two suburban sites was significantly (p < 0.01) higher during the BB season ($-24.84^{-21.49}_{-28.56} \pm 2.29$‰, n = 14) than that during non-BB season ($-33.52^{-18.78}_{-45.62} \pm 7.59$‰, n = 20) (Fig. 5). In fact, among the three different land-use regimes, during the BB season, the average δ^{15}N-NH$_3$ was highest for the suburban sites, and closer the NH$_3$ isotopic signatures of pyrogenic sources, raising questions as to how important the contribution of BB versus road traffic in the suburban areas during BB season really is.

3.4 Isotope-based quantification of BB contribution to ambient NH$_3$

There are several challenges that need to be overcome when trying to more accurately quantify the contribution of BB emissions to ambient NH$_3$ based on N isotope data. Firstly, given the use of only one isotope parameter (δ^{15}N; in contrast to NO$_x$ where also the δ^{18}O can be analyzed), more than three potential NH$_3$ sources (e.g., urban and suburban sites) will introduce large uncertainties in isotopic endmember mixing models in terms of quantifying their relative contributions to the ambient NH$_3$ (Chang et al., 2015). Secondly, atmospheric wet scavenging could further compromise/alter the primary NH$_3$ N isotopic signatures (Elliott et al., 2019; Zheng et al., 2018; Chang et al., 2019a). For these reasons, we focus here on the samples collected at the three rural sites during the dry BB season (lasting seven weeks) to isotopically examine the contribution of BB emissions to ambient NH$_3$. We separated these samples into seven groups based on the week of their sampling, and we integrated the measured δ^{15}N-NH$_3$ values as well as the N isotopic signatures of potential NH$_3$ sources (i.e., biomass burning, livestock breeding, fertilizer application) into the Bayesian isotopic mixing model (see Text S1 for details). The results of NH$_3$ source apportionment are reported in Fig. 6. With a certain degree of variability, the contribution of BB to the ambient NH$_3$ in the rural areas during the seven weeks of sampling in the dry season was only 21.0% ($\pm$ 4.7%). Hence, NH$_3$ emission from BB significantly less important than from livestock breeding (37.1 $\pm$ 7.1%) and fertilizer application (41.8 $\pm$ 5.9%). This comes at a surprise, given the fact that the study area belongs to one of the most

important BB regions in SE Asia, or even in the world, and the samples used for isotopic source apportionment were collected during the season of intensive BB.
Figure 6. Source apportionment results of ambient NH$_3$ in rural areas during the dry season based on Bayesian isotopic mixing modelling and the isotopic source signatures. The error bars indicate two standard deviations.

During the dry season, we also analyzed particulate potassium (K$^+$), a chemical tracer of biomass combustion, at two rural sites (S4, S5; in 39 daily fine-particle (PM$_{2.5}$) samples). The particulate K$^+$ data offer a valuable opportunity to validate our isotope-based source apportionment results. Again, we divided the dry-season data set into seven groups based on the week of NH$_3$ passive sampling. The correlation between the particulate K$^+$ concentration and the total NH$_3$ concentration at the rural sites was rather poor ($r^2 = 0.43$; blue symbols in Fig. 7a). Such a weak correlation supports our conclusion regarding the isotope-based source apportionment results (see above), providing additional independent evidence that BB can hardly be the dominant source of NH$_3$ during the sampling period at the studied rural areas. In contrast, the correlation between the particulate K$^+$ concentration and the estimated BB-derived NH$_3$ concentration (instead of total NH$_3$) is much better ($r^2 = 0.76$; Fig. 7a), and thus further validates our modelling approach. While the independent particulate K$^+$ data further increase our confidence in the N-isotope based assessment, still some uncertainty remains with regards to the robustness of the endmember

source $\delta^{15}N$ values, potential source-altering effects, and in turn our estimates on the BB-associated NH_3

305 contribution. In other words, the latter is probably sensitive to the considered range in the $\delta^{15}N$ of potential NH_3

emission sources, and this range may be quite large/uncertain at least for some of the sources. The $\delta^{15}N$-NH_3 from

BB, in particular, is only poorly constrained, with hardly any reports from the literature (e.g., Kawashima and

Kurahashi (2011)). In recent chamber experiments, we found that the $\delta^{15}N$-NH_3 produced by combustion of a

variety of biomass types (subtropical trees and agricultural residues) ranged between -11.8‰ and -4.6‰ (Chang et

310 al., 2016, 2019a), which is distinctly lower than the N isotopic signature of BB-emitted NH_4^+ (12‰) determined

previously (Kawashima and Kurahashi, 2011), and adopted in this study. Assuming that the true N isotopic

signatures of BB-emitted NH_3 in the study area falls somewhere within the range of -12‰ and 12‰ (based on our

published data (Chang et al., 2016,2019a) and the value reported in (Kawashima and Kurahashi, 2011)), we re-

calculated the source apportionment estimates as function of the different $\delta^{15}N$ values for BB-emitted NH_3 (Fig.

315 7b). The estimates are not sensitive to the choice of the N isotopic composition of the BB-associated NH_3 source.

Specifically, independent of the chosen $\delta^{15}N$-NH_3 value, BB is always the least important of the three main NH_3

sources in rural areas, contributing not more than 29.6%. This is because that although the isotopic signatures of

BB-emitted NH_3 have a wide range of $\delta^{15}N$ values, their $\delta^{15}N$-NH_3 values are still significantly (p < 0.01) higher

(i.e., without overlap as shown in Fig. 4) than the measured $\delta^{15}N$ values of ambient NH_3 at the rural sites.

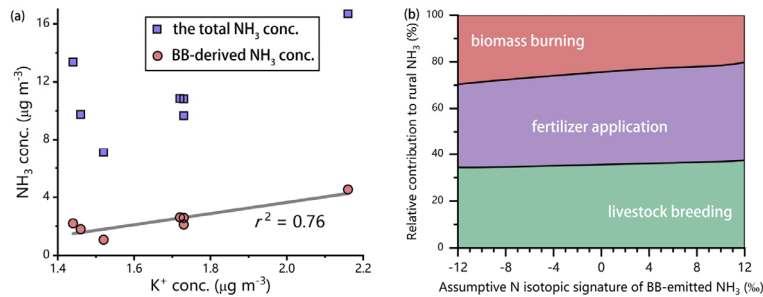
320


Figure 7. (a) Scatter plots of the aerosol K^+ concentrations versus total NH_3 concentrations, as well as the NH_3 concentrations from BB emissions, at the rural sites during the dry season. (b) Bayesian isotope modelling-based source apportionment results of ambient NH_3 at the rural sites during dry season, as function of the assumed N isotopic signatures of BB-emitted NH_3.

325 As illustrated by the pie chart in Fig. 6, the average contribution of BB to ambient NH_3 at the rural sites during the season of intensive fire events is 2.4 $\mu g\ m^{-3}$, which can be regarded as the maximum possible concentration of BB-emitted NH_3 for the urban and rural sites, which are much further away from the fire areas. Based on the total NH_3 concentrations measured at the other sites, we calculate, in turn, that the contribution of BB to the ambient NH_3 in the urban and suburban areas are on the order of 9.6% (ranging from 5.2% to 14.8%) and 12.3% (ranging from 6.1% 330 to 19.9%), respectively.

4 Conclusion

In this study, we integrated satellite constraints on atmospheric NH_3 levels and fire intensity, discrete NH_3 concentration measurement, and N isotopic analysis of NH_3 in order to assess the regional-scale contribution of BB to ambient NH_3 in the heartland of Southeast Asia. The combined approach provides a cross-validation 335 framework for source apportioning of NH_3 in the lower atmosphere and will thus help to ameliorate predictions of BB emissions beyond the tropics, particularly in areas of high vegetation fire risk. Our results suggest that during the dry wildfire season, BB emissions represent a ubiquitous but comparatively small NH_3 source, which accounts for 9.6%, 12.3%, and 21.0% of ambient NH_3 in urban, suburban, and rural environments, respectively. While we do not claim that our results necessarily apply also at the global scale, and we do not question that globally BB is 340 one of the most important NH_3 sources, we find that at least in the heartland of SE Asia, BB related NH_3 emissions to the atmosphere are rather moderate, and vary significantly in time and space. Both satellite observations and field/ground-based measurements capture these variations. Our findings underscore that BB-induced NH_3

emissions in tropical monsoon environments can be much lower than previously anticipated. Existing atmospheric transport models may overestimate current, and likely future, NH$_3$ emissions under changing climate conditions. While the full implications of our results remain to be explored, they promise to provide important guidance for revising NH$_3$ emissions from BB in atmospheric transport models to assess on air quality, human health and climate change.
