11 **Abstract:** A weak El Niño during 2014-15 boreal winter was developed as a strong boreal summer
12 event in 2015 which continued and even enhanced during the following winter. In this work, the
13 detailed changes in the structure, dynamics and trace gases within the Asian summer monsoon
14 anticyclone (ASMA) during extreme El Niño of 2015-16 is delineated by using Aura Microwave
15 Limb Sounder (MLS) measurements, COSMIC Radio Occultation (RO) temperature, and NCEP
16 reanalysis products. Our analysis concentrates only on the summer months of July and August
17 2015 when Nino 3.4 index started to exceed 1.5 values. The results show that the ASMA structure
18 was quite different in summer 2015 as compared to the long-term (2005-2014) mean. In July, the
19 spatial extension of the ASMA shows larger than the long-term mean in all the regions except over
20 northeastern Asia, where, it exhibits a strong southward shift in its position. The ASMA splits into
21 two and western Pacific mode is evident in August. Interestingly, the subtropical westerly jet (STJ)
22 shifted southward from its normal position over northeastern Asia as resulted mid-latitude air
23 moved southward in 2015. Intense Rossby wave breaking events along with STJ are also found in
24 July 2015. Due to these dynamical changes in the ASMA, pronounced changes in the ASMA
25 tracers are noticed in 2015 compared to the long-term mean. A 30% (20%) decrease in carbon

26 monoxide (water vapor) at 100 hPa is observed in July over most of the ASMA region, whereas
27 in August the drop is strongly concentrated in the edges of the ASMA. Prominent increase of O₃
28 (>40%) at 100 hPa is clearly evident within the ASMA in July, whereas in August the increase is
29 strongly located (even at 121 hPa) over the western edges of the ASMA. Further, the temperature
30 around the tropopause shows significant positive anomalies (~5K) within the ASMA in 2015. The
31 present results clearly reveal the El Niño induced dynamical changes caused significant changes
32 in the trace gases within the ASMA in summer 2015.

33 **Keywords:** Trace gases, El Niño, Asian summer monsoon anticyclone, tropopause

34 **1. Introduction**

35 The Asian summer monsoon anticyclone (ASMA) is a distinct circulation system in the upper
36 troposphere and lower stratosphere (UTLS) during northern hemisphere boreal summer, centered
37 at ~25°N and extending roughly between 15°N to 40°N (Park et al., 2004; Randel et al., 2010). It
38 is encircled by the subtropical westerly jet stream to the north and by the equatorial easterly jet to
39 the south (Randel and Park, 2006). It is well recognized that the ASMA circulation is a prominent
40 transport pathway for troposphere pollutants to enter the stratosphere (Randel et al., 2010).
41 Previous studies have concluded that deep convection during summer monsoon can effectively
42 transport the pollutants, aerosols and tropospheric tracers from the boundary layer into the UTLS
43 region (Vogel et al., 2016; Santee et al., 2017). These transported pollutants, tracers and aerosols
44 become confined in the ASMA and, consequently, affect the trace gas composition in the UTLS
45 region (Randel et al., 2010; Solomon et al., 2010; Riese et al., 2012; Hossaini et al., 2015). It is
46 clearly evident from the previous studies that the ASMA has a higher concentrations of
47 tropospheric tracers such as carbon monoxide (CO), hydrogen cyanide (HCN) and Methane (CH₄)
48 and lower concentrations of stratospheric tracers including Ozone (O₃) and nitric acid (HNO₃)

49 (Park et al., 2004; Li et al., 2005; Park et al., 2008; Randel et al., 2010; Vernier et al., 2015; Yan
50 and Bian, 2015; Yu et al., 2017; Santee et al., 2017; Vernier et al., 2018). The comprehensive study
51 on the climatological composition within the ASMA can be found in Santee et al. (2017). The ASM
52 convection and orographic lifting are the primary mechanisms for the higher concentrations of the
53 tropospheric tracers in the ASMA (Li et al., 2005; Park et al., 2009; Santee et al., 2017). Apart
54 from these trace gases a strong persistent tropopause-level aerosol layer called as ‘Asian
55 Tropopause Aerosol Layer’ (ATAL) also existed between 12 to 18 km within the ASMA and it was
56 first detected from the CALIPSO measurements (Vernier et al., 2011).

57 Similarly, higher concentrations of water vapor (WV) within the ASMA during the summer
58 monsoon is well documented in the literature (Gettelman et al., 2004; Park et al., 2007; Randel et
59 al., 2010; Bian et al., 2012; Xu et al., 2014; Jiang et al., 2015; Das and Suneeth, 2020). It is well
60 known that most of the WV enters the stratosphere through the tropical tropopause (Fueglistaler
61 et al., 2009) and the temperature presented at the tropical tropopause strongly controls the WV
62 entering the lower stratosphere (LS). It is also well documented that several processes such as
63 convection, strength of the Brewer-Dobson circulation, El Niño–Southern Oscillation (ENSO) and
64 Quasi-Biennial Oscillation (QBO) are responsible for the WV transport to the UTLS region
65 (Holton et al., 1995; Dessler et al., 2014; Jiang et al., 2015). Other factors such as gravity waves
66 and horizontal advection can also influence the WV transport in the UTLS region. For example,
67 Khan and Jin (2016), studied the effect of gravity waves on the tropopause and WV over Tibetan
68 Plateau and reported that the gravity wave is the source for the WV transport from the lower to
69 higher altitudes. Recently, Das and Suneeth (2020) reported about the distributions of WV in the
70 UTLS over the ASMA during summer using 13 years of Aura Microwave Limb Sounder
71 observations. They concluded that WV in the UTLS region inside the central part of ASMA is

72 mostly controlled by horizontal advection and very less from the local process and tropopause
73 temperature in both summer and winter.

74 Convection during the summer monsoon is one of the major sources to transport the boundary
75 layer pollutants into the UTLS region (Randel et al., 2010). It is well established fact that the ENSO
76 has a strong influence on convection and circulation changes over the Asian monsoon region
77 (Kumar et al., 1999; Wang et al., 2015; Gadgil and Francis, 2016). Enhanced (suppressed)
78 convection over the Asian monsoon region generally observed in the cold phase of ENSO (warm
79 phase of ENSO) known as La Niña (El Niño). Few studies have existed to date on the impact of
80 ENSO on the ASMA trace gas composition changes and its dynamical changes. For example, Yan
81 et al. (2018) reported the influence of ENSO on the ASMA with a major focus on how the ENSO
82 winter signal propagates into the following seasons. They showed the weaker O₃ transport into the
83 tropics during the onset of the ASMA after boreal winter El Niño events, but the difference between
84 El Niño and La Niña composites becomes insignificant in the summer. In another study, Tweedy
85 et al. (2018) demonstrated the impact of boreal summer ENSO events on O₃ composition within
86 the ASMA in different phases of ENSO events. They reported that the ASMA forms earlier and
87 stronger in the La Niña period that leads to greater equatorward transport of O₃-rich air from the
88 extra-tropics into the northern tropics than during El Niño periods. Recently, Fadnavis et al. (2019)
89 reported higher concentrations of aerosol layers observed in the ATAL region during the El Niño
90 period over the northern part of South Asia. However, the above- mentioned studies are mainly
91 focused on changes in the ASMA with respect to ENSO on seasonal scales or mature stage of
92 monsoon (combined mean of July and August).

93 Based on the above-mentioned studies, it can be concluded that the ENSO also has a strong
94 influence on the ASMA structure and its composition. The recent 2015-16 El Niño event was

95 recorded as an extreme and long-lasting event in the 21st century (Huang et al., 2016; Avery et al.,
96 2017). It was started as a weak El Niño during 2014-15 boreal winter and it developed as a strong
97 boreal summer El Niño event in 2015 (Tweedy et al., 2018). Further, this strong boreal summer
98 event was continued and significantly enhanced until the boreal winter of 2015-16. In this event,
99 several unusual changes occurred in the tropical UTLS region including, the strong enhancement
100 in the lower stratosphere WV (higher positive tropopause temperature anomalies) over Southeast
101 Asia and western Pacific regions (Avery et al., 2017) and anomalous distribution of trace gases in
102 the UTLS region (Diallo et al., 2018; Ravindra Babu et al., 2019a). Similar way, the response of
103 different trace gases (O₃, HCl, WV) to the disrupted 2015–2016 quasi-biennial oscillation (QBO)
104 associated with 2015-16 El Niño event is also reported by Tweedy et al. (2017). Dunkerton (2016),
105 discussed the possible role of unusual warm ENSO event in 2015-2016 to the QBO disruption by
106 triggering the extratropical planetary waves. Therefore, in the present study, we investigated the
107 detailed changes observed in the ASMA 2015 particularly by focusing on the structure, dynamics
108 and trace gases variability within the ASMA in July and August 2015 by using satellite
109 observations and reanalysis products. The present research article is organized as follows.
110 Database and methodology adopted in this study are discussed in Section 2. The results and
111 discussions are illustrated in Section 3. Finally, the summary and conclusions obtained from the
112 present study are summarized in Section 4.

113 **2. Database and Methodology**

114 **2.1. Microwave Limb Sounder (MLS) measurements**

115 In the present study, version 4.2 Aura MLS measurements of CO, O₃ and WV are utilized.
116 The MLS data of July and August months in each year from 2005 to 2015 period are considered.
117 The vertical resolution for CO is in the range 3.5–5 km from the upper troposphere to the lower

118 mesosphere and the useful range is 215–0.0046 hPa. The horizontal resolution for CO is about 460
119 km at 100 hPa and 690 km at 215 hPa. For WV, the vertical resolution is in the range of 2.0 to 3.7
120 km from 316 to 0.22 hPa and the along-track horizontal resolution varies from 210 to 360 km for
121 pressure greater than 4.6 hPa. For O₃, the vertical resolution is ~2.5 km and the along-track
122 horizontal resolution varies between 300 and 450 km. The precision (systematic uncertainty) for
123 WV is ~ 10-40% (~10-25%), for O₃ is ~0.02–0.04 (~0.02–0.05) ppmv and for CO, it is ~ 19 ppbv
124 (30%), respectively. More details about the MLS version 4 level 2 data can be found in Livesey et
125 al. (2018).

126 **2.2. COSMIC Radio Occultation measurements**

127 To see the changes in the tropopause temperature and height within the ASMA, we used high-
128 resolution, post-processed products of level 2 dry temperature profiles obtained from Constellation
129 Observing System for Meteorology, Ionosphere, and Climate (COSMIC) Radio Occultation (RO).
130 Each month of July and August from 2006 to 2015 are considered. The data is downloaded from
131 the COSMIC Data Analysis and Archival Center (CDAAC) website. We used 200 m vertical
132 resolution temperature profiles in the study. Details of the temperature retrieval from the bending
133 angle and refractivity profiles obtained from the RO sounding are presented well in the literature
134 (Kursinski et al. 1997; Anthes et al. 2008). The COSMIC temperature have a precision of 0.1%
135 between 8 and 25 km (Kishore et al. 2009; Kim and Son, 2012). The temperature accuracy in the
136 UTLS is better than 0.5 K for individual profiles and ~0.1 K for averaged profiles (Hajj et al.
137 2004). It is noted that for individual RO temperature profiles, the observational uncertainty
138 estimate is 0.7 K in the tropopause region, slightly decreasing into the troposphere and gradually
139 increasing into the stratosphere (Scherllin-Pirscher et al., 2011a). For monthly zonal-averaged
140 temperature fields, the total uncertainty estimate is smaller than 0.15 K in the UTLS (Scherllin-

141 Pirscher et al., 2011b). Overall, the uncertainties of RO climatological fields are small compared
142 to any other UTLS observing system for thermodynamic atmospheric variables. Note that these
143 data are compared with a variety of techniques including GPS radiosonde data and observed good
144 correlation particularly in the UTLS region (Rao et al. 2009; Kishore et al. 2009). The COSMIC
145 RO profiles have been widely used for studying the tropopause changes and its variabilities (Kim
146 and Son, 2012; RavindraBabu et al. 2015; RavindraBabu and Liou, 2021).

147 **2.3. National Centers for Environmental Prediction (NCEP) Reanalysis data**

148 We also utilized monthly mean Geopotential height (GPH) and wind vectors (zonal and
149 meridional wind speed) from the NCEP-DOE Reanalysis 2 (Kanamitsu et al.,2002), covering the
150 same time period as the MLS observations (2005-2015). NCEP-DOE Reanalysis 2 is an improved
151 version of the NCEP Reanalysis I model that fixed errors and updated parametrizations of physical
152 processes. The horizontal resolution of NCEP-DOE Reanalysis 2 is $2.5^\circ \times 2.5^\circ$, respectively.

153 Apart from the above-mentioned data sets, we also used European Centre for Medium-Range
154 Weather Forecasts (ECMWF) interim reanalysis potential vorticity (PV) data particularly at 350K
155 isentropic surface in July and August 2015 (ERA-Interim; Uppala et al., 2005; Dee et al., 2011).

156 **2.5. Methodology**

157 Daily available MLS profiles of O₃, CO, and WV in each month are constructed and gridded
158 by averaging the profiles inside bins with a resolution of 5° latitude \times 5° longitudes. The following
159 equation is used to estimate the relative change in percentage.

$$160 \quad \text{Relative change in percentage} = \left(\frac{x_i - \bar{x}}{\bar{x}} \right) \times 100 \quad (1)$$

161 where x_i represents the monthly mean of July/August in 2015, and \bar{x} is the corresponding monthly
162 long-term mean which is calculated by using the data from 2005 to 2014.

163 **3. Results and Discussion**

164 It is well reported that the ASMA is highly dynamic in nature with respect to its position and shape.
 165 Also it varies at different time scales i.e day-to-day, weekly and monthly scales caused by internal
 166 dynamical variability (Randel and Park, 2006; Garny and Randel, 2013; Pan et al., 2016; Nützel
 167 et al., 2016; Santee et al., 2017). The intensity and spatial extension of the ASMA are prominent
 168 in July and August where the monsoon was in the mature phase (Santee et al., 2017; Basha et al.,
 169 2019). It can be noticed that the 2015-16 El Niño event was one of the strongest boreal summer
 170 events that occurred in the entire MLS data record (Tweedy et al., 2018). In this event, the Nino
 171 3.4 data was exceeded +1.5 in July and +1.8 in August (**Fig. 1**). Therefore, in the present study,
 172 we mainly focused on ASMA behavior and trace gases changes within the ASMA on monthly
 173 scales particularly in July and August 2015 which represents strong El Niño.

174
 175 **Figure 1.** Temporal evolution of observed Niño3.4 Index data from January 2005 to December
 176 2016.

177 **3.1. Structure and dynamical changes in ASMA during 2015**

178 In general, the studies looking at monthly or seasonal timescales related to the thermo-
 179 dynamical features in the ASMA, the anticyclone region is mostly defined from the simple
 180 constant GPH contours at different pressure levels (Randel and Park, 2006; Yan et al., 2011;

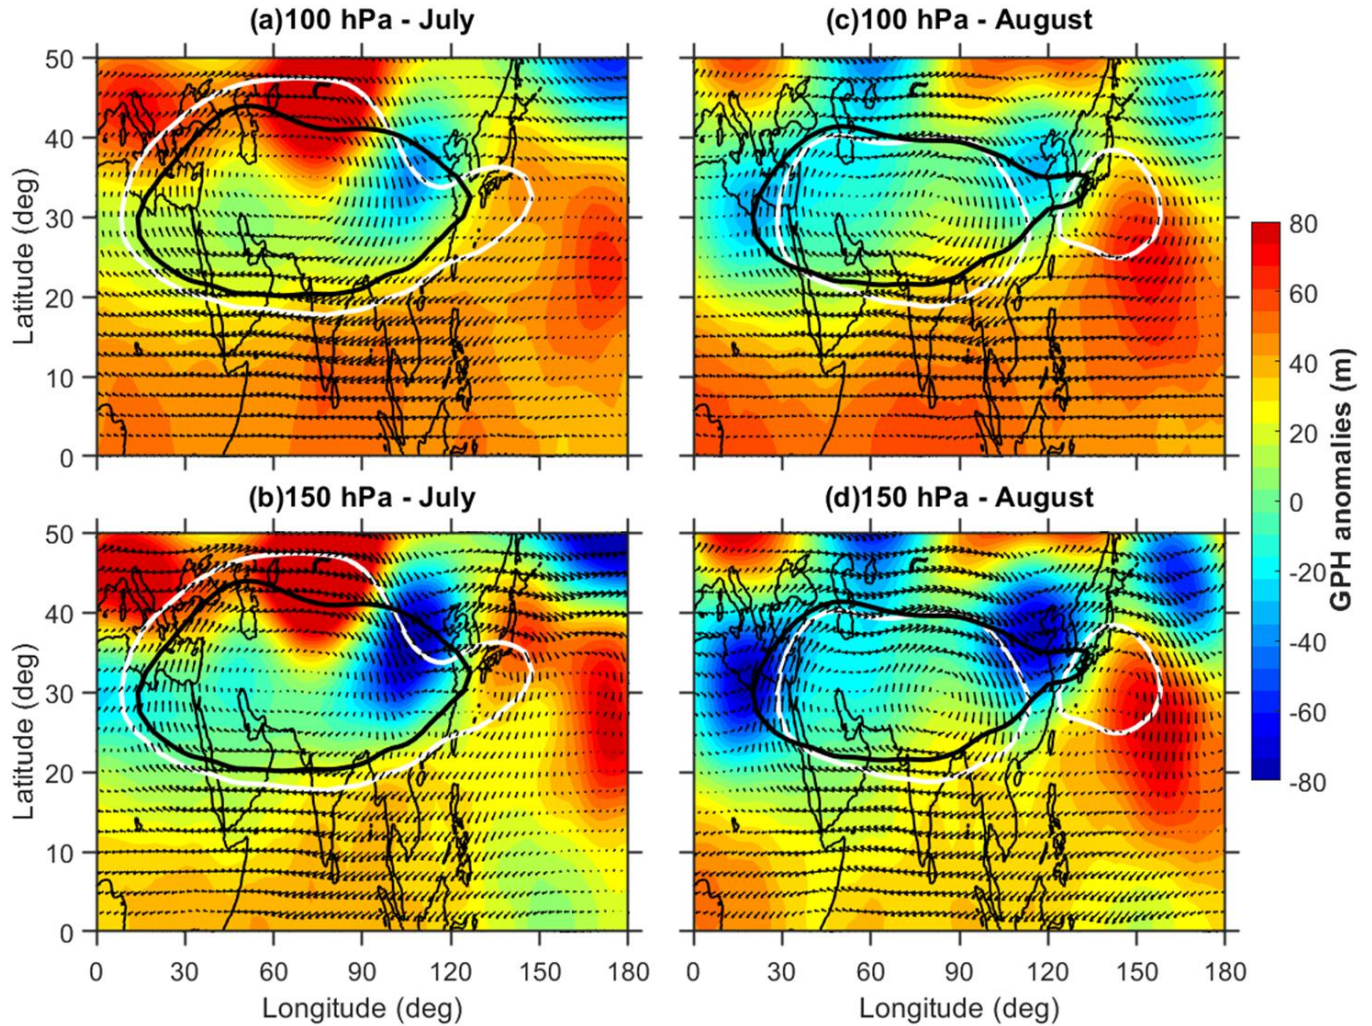

181 Bergman et al., 2013; Basha et al., 2019). Previous researchers used different GPH contours at 100
182 hPa to define the anticyclone region. For example, Yan et al. (2011) used 16.7 km, Bergman et al.
183 (2013) used 16.77 km and recently Basha et al. (2019) used 16.75 km GPH contour as the
184 anticyclone region. In a similar manner, we also defined the ASMA region based on NCEP-DOE
185 Reanalysis 2 obtained GPH at 100 hPa and considered the 16.75 km GPH contour as the
186 anticyclone region.

187
188 **Figure 2.** Spatial distribution of geopotential height obtained from NCEP-DOE Reanalysis 2 data
189 during July 2015 (a) at 100 hPa and (b) 150 hPa superimposed with wind vectors at the respective
190 corresponding levels. Subplots of (c) and (d) are the same as (a) and (b) but for the month of
191 August. The black color solid contour lines represent the ASMA region at 100 hPa (16.75 km GPH
192 contour).

193 The spatial distribution of GPH at 100 hPa and 150 hPa for the month of July (August) is
194 shown in **Fig. 2a and 2b (Fig. 2c and 2d)**. The corresponding monthly mean winds at respective
195 pressure levels are also shown in **Fig.2**, respectively. The black solid line represents the ASMA
196 region at 100 hPa based on 16.75 km GPH contour. The GPH distribution in **Fig. 2** shows clear
197 distinct variability in the ASMA spatial structure between July and August at both pressure levels.
198 For example, at 100 hPa, the maximum GPH center was located over western side in July whereas
199 it was located over near to the Tibetan region in August. Interestingly the ASMA itself separated
200 into two anticyclones (16.75 km GPH contour black solid line in the figure) in August compare to
201 July. The center of the small anticyclone was located over the Northwestern Pacific near 140°E
202 with the closed circulation indicated by the wind arrows.

203

204

205 **Figure 3.** Spatial distribution of geopotential height anomalies obtained from NCEP-DOE
 206 Reanalysis 2 data during July 2015 (a) at 100 hPa and (b) 150 hPa superimposed with wind vectors
 207 at the respective corresponding levels. Subplots of (c) and (d) same as (a) and (b) but for the month
 208 of August. The white color solid contour lines represent the ASMA region at 100 hPa (16.75 km
 209 GPH contour) observed in 2015 whereas the black color line represents the mean of 2005-2014.

210 Further, we compared the ASMA structure in 2015 with referenced long-term mean. For
 211 this, we obtained the GPH anomalies by subtracting the background long-term mean (2005-2014)
 212 from 2015. **Figure 3** shows the latitude-longitudinal distribution of GPH anomalies (color shaded)
 213 along with wind vectors depicting circulation pattern at 100 hPa as well as at 150 hPa during July
 214 and August. The white (black) color contour represents 16.75 km GPH at 100 hPa for the

215 corresponding month in 2015 (long-term mean). The GPH anomalies at both pressure levels show
216 quite different features in July and August. A clear wave-like structures can be observed from the
217 GPH anomalies. In July, the GPH anomalies exhibit strong negative maxima over 25-40°N, 90-
218 120°E and positive maxima over 40-50°N, 60-80°E regions. The 16.75 km GPH contour lines in
219 the ASMA region exhibits higher extension in all the directions except over the northeastern edges
220 of the ASMA in July compared to the long-term mean. At the same location (northeastern edges),
221 the ASMA exhibits a pronounced southward extension in July. Distinct features of GPH anomalies
222 are noticed in August as compared to July. In August, the strong negative GPH anomalies are
223 situated over the west and north-eastern edges of the ASMA.

224 It is well known that the subtropical westerly jet is an important characteristic feature of
225 the ASMA (Ramaswamy 1958), and thus its changes during 2015 are also investigated. As the
226 peak intensity of the westerly jet was located at 200 hPa (Chiang et al., 2015), we focused mainly
227 on 200 hPa zonal wind changes in July and August. **Figure 4a and 4c (Fig. 4b and 4d)** show the
228 spatial distribution of long-term (2015) monthly mean zonal wind at 200 hPa during July and
229 August. In general, the subtropical westerlies are located near to ~40°N latitude during the mature
230 phase of the monsoon period (Chiang et al., 2015). Compared to long-term mean, a significant
231 weakening of the subtropical westerlies is noticed in 2015. Further, a strong southward shift in the
232 westerlies is observed over the northeastern Asia region. This southward shift is moved even up
233 to 30°N in both months. From zonal wind at 200 hPa (**Fig. 4**) and wind vectors at 100/150 hPa
234 (**Fig. 2**), it is clear that anomalous changes have occurred in the subtropical westerlies over the
235 northeastern parts of the AMSA around 30-40°N, 90-120°E during July and August 2015. The
236 southward shift in the westerlies is strongly associated with the southward extension of the ASMA
237 over the northeastern side of the ASMA (**Fig. 2**). This is strongly supported by the previous

238 findings by Lin and Lu (2005) where they showed the southward extension of the South Asian
 239 High could lead to the southward shift of the westerlies.

240

241

242 **Figure 4.** Spatial distribution of monthly mean zonal winds obtained from NCEP-DOE Reanalysis
 243 2 data at 200 hPa during July during (a) 2005-2014 (b) 2015 year. Subplots of (c) and (d) same as
 244 (a) and (b) but for the month of August. The white color solid contour lines represent the ASMA
 245 region at 100 hPa (16.75 km GPH contour).

246

From the GPH and winds observations, it is clear that pronounced changes are evident in
 247 the dynamical structure of the ASMA in 2015 and also relatively different features are noticed
 248 between July and August months. Interestingly the ASMA itself separated into two anticyclones
 249 during August 2015 and the separation exactly coincided with the strong negative GPH anomalies

250 and southward meandering of subtropical westerlies over the northeastern side of the ASMA. The
251 Western Pacific (WP) mode of the anticyclone is visible in August. The split of the anticyclone
252 and the formation of the WP mode are in agreement with previous studies reported by few
253 researchers earlier (e.g. Honomichl and Pan, 2020). The presence of the WP mode may be due to
254 the eastward eddy shedding of the ASMA system in the process of its sub-seasonal zonal
255 oscillation (Honomichl and Pan, 2020) or Rossby wave breaking (RWB) in the subtropical
256 westerly jet (Fadnavis and Chattopadhyay, 2017). Fadnavis and Chattopadhyay (2017) also
257 identified the split of ASMA into two anticyclones: one over Iran and another over the Tibetan
258 region due to the RWB in June 2014 monsoon period. To see any signatures of these RWB in 2015,
259 we further analyzed the RWB through the ERA interim reanalysis potential vorticity (PV) data.
260 Based on previous studies, it is reported that RWBs can be identified from PV distribution at 350
261 K isentropic surface (Samanta et al. 2016; Fadnavis and Chattopadhyay, 2017). We used 350 K
262 isentropic surface PV data in July and August 2015 in the present analysis.

263 **Figure 5a–b** shows the distribution of ERA interim monthly mean PV at the 350 K
264 isentropic surface during July and August 2015. It can be seen that, during July and August 2015,
265 clear RWB signatures evident near 100°E. It is noted that the equatorial advection of high PV
266 values with a steep gradient and the southward movement of PV from the westerly jet are the basic
267 features of the RBW (Vellore et al., 2016; Samanta et al. 2016). These features are clearly exhibited
268 in **Figure 5** with higher PV values extends up to ~ 30°N in both months over 100°E region. The
269 location of this RWB is significantly correlated with a southward meandering of westerlies and
270 strong negative GPH anomalies. However, the observed RWB signatures in both months are from
271 monthly mean PV data. Further, to see the clear signatures of these RWB, we made weekly based
272 analysis for July month. For this we considered 1-7 July as week-1 and 8-14 July as week-2 so on.

273 The weekly mean distribution of 350K isentropic surface PV during July is shown in **Fig. 6**.

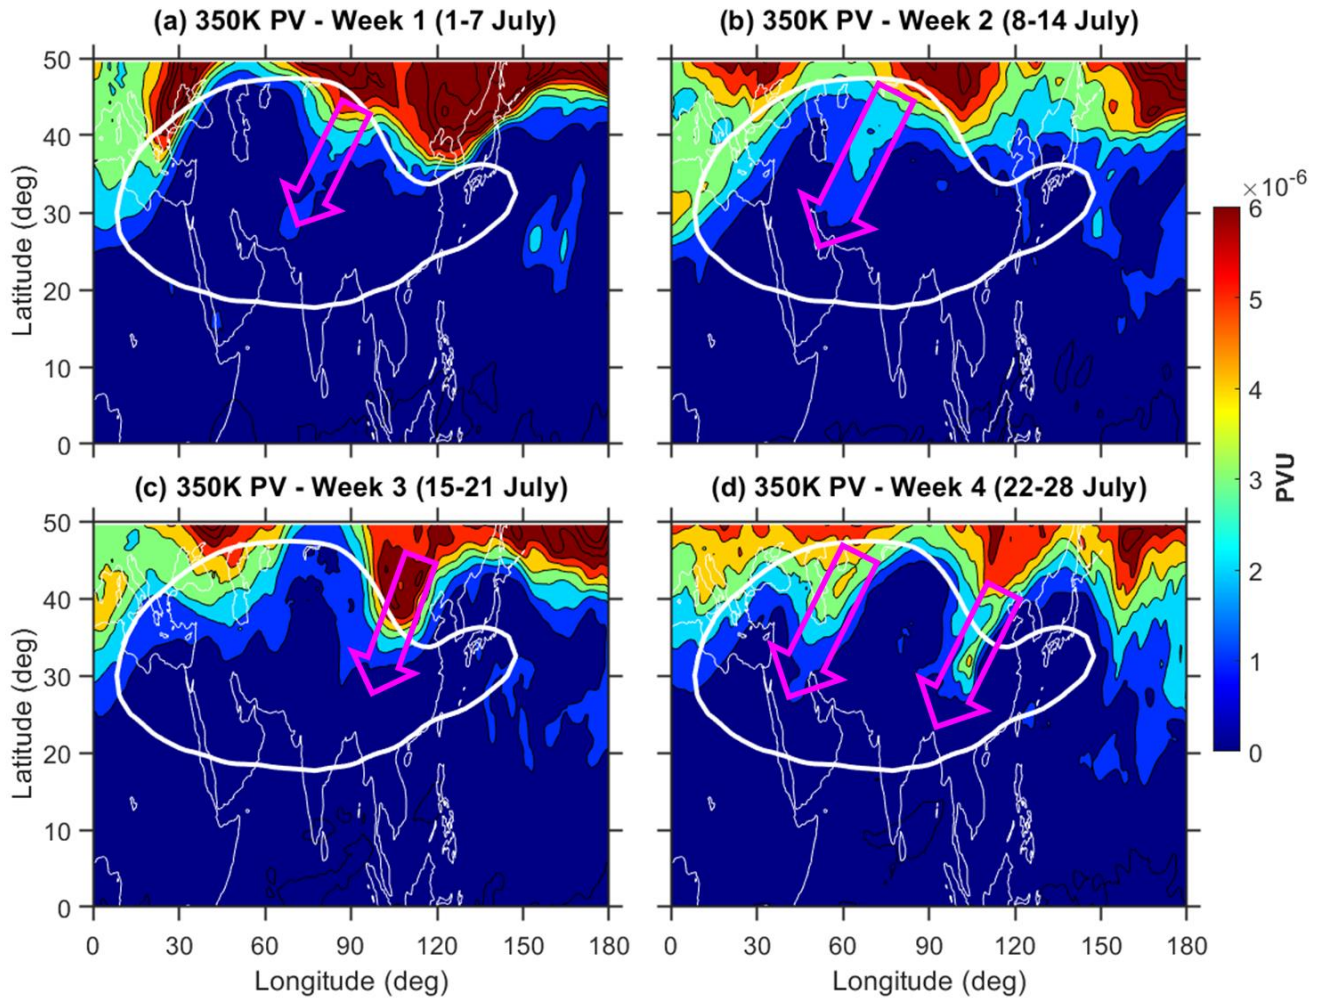

274

275 **Figure 5.** ERA Interim observed spatial distribution of potential vorticity (PV) on a 350 K
276 isentropic surface in PVU ($1 \text{ PVU} = 10^{-6} \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$): (a) monthly mean of July and (b) monthly
277 mean of August 2015. The white color solid contour lines represent the ASMA region at 100 hPa
278 (16.75 km GPH contour).

279 The magenta colored arrows which are shown in the Fig. 6 represents the RBW events during July
280 2015. A clear signature of air with high values of PV traverses from extra-tropics to ASMA is
281 evident from Fig.6. At weekly scales, clear RWB signatures are observed over the anticyclone
282 region. For example, in week-1 and week-2, the RWB signatures are evident over the northern

283 region of the ASMA. However, in week-3 and week-4, these RWB signatures are very clear over
 284 northeastern Asia even in week-5 (29July-04August), we noticed RWB signatures in PV data
 285 (Figure not shown). This clearly shows that The RWB splits the ASMA into two anticyclones: one
 286 over the Tibetan region and another over the WP region. It is clear that the equatorward penetration
 287 of extra tropical forcing through the subtropical westerly jet has started in July and further
 288 amplified by the splitting of the ASMA into two during August.

289
 290 **Figure 6.** Same as **Figure 5**, but for the weekly distribution of PV in July 2015. Magenta colored
 291 arrows indicate the regions of RWB.

292 It is well known that the RWB is an important mechanism for horizontal transport between
 293 the extratropical lower stratosphere to the tropical UTLS region. These RWBs can act as an agent

294 for the transport of extratropical stratospheric cold, dry, and O₃-rich air into the ASMA during the
295 summer monsoon. Overall, it is concluded that the combination of the RWBs and strong southward
296 meandering of the subtropical westerly jet in 2015 causes significant dynamical and structural
297 changes in the ASMA. These changes in the ASMA dynamical structure in 2015 can influence the
298 concentrations of the different trace gases within the ASMA. Further, we quantified the changes
299 in O₃, CO and WV concentrations within the ASMA during 2015 caused by the dynamical effects.
300 The changes that occurred in the O₃ and CO, WV, are discussed in the following sections.

301 **3.2. Trace gases anomalies observed within the ASMA in 2015**

302 It is well-documented that the ASMA contains low (high) concentrations of stratospheric
303 tracers such as O₃ (tropospheric tracers such as CO, WV and etc.) and higher tropopause height
304 compared to the region outside the ASMA during boreal summer (Park et al., 2007; Randel et al.,
305 2010; Santee et al., 2017; Basha et al., 2019). Differences of the trace gases within and outside of
306 the ASMA are attributed to the strong winds and closed streamlines associated with the ASMA,
307 which act to isolate the air (Randel and Park 2006; Park et al. 2007). To see the changes in the
308 trace gases during 2015, we generated the background long-term mean of CO, O₃, and WV by
309 using 10 years of MLS trace gas data from 2005 to 2014. Here the results are discussed mainly
310 based on the percentage changes relative to the respective long-term monthly mean trace gases
311 using **Equ. 1**.

312

313

314 **Figure 7.** Ozone relative percentage change in July 2015 with respect to background

315 climatological monthly mean observed at (a) 82 hPa, (b) 100 hPa and (c) 121 hPa. Subplots of (d),

316 (e) and (f) same as (a), (b) and (c) but for the month of August. The white (black) color contour

317 represents 16.75 km geopotential height at 100 hPa for the corresponding month in 2015 (mean of

318 2005-2014). The star symbols (black) shown in figure represent the anomalies greater than the $\pm 2\sigma$

319 standard deviation of long-term mean. The results are obtained from MLS measurements.

320 **Figure 7a-c (Fig. 7d-f)** shows the distribution of relative percentage change in the O₃
321 concentrations within the ASMA at 82 hPa, 100 hPa and 121 hPa during July (August) 2015. The
322 anomalies larger than $\pm 2\sigma$ standard deviation of long-term mean are highlighted with star symbols
323 in the respective figures. The spatial distribution of changes in the O₃ (Fig. 7) shows a clear
324 increase in the O₃ mixing ratios (>40%) within the ASMA in 2015. The observed increase within
325 the ASMA is quite distinct between July and August. In July, the O₃ shows a pronounced increase
326 within the ASMA at all the pressure levels. Note that the observed increase was statistically
327 significant with larger than 2σ standard deviation of long-term mean (see the star symbols). This
328 increase is quite significant over the northeastern edges of the ASMA and quite high at 100 hPa
329 compared to 82 hPa and 121 hPa. In August, the O₃ shows quite different features compared to
330 July (Fig. 7d-f). A strong increase in the O₃ is observed over the western and eastern edges of the
331 ASMA at all the pressure levels. The increase is quite significant at 100 hPa and even at 121 hPa.
332 The increase of O₃ is still appearing over the northeastern edges of the ASMA in August as
333 observed in July. Overall, a significant enhancement of O₃ within the ASMA is clear evidence in
334 July and August 2015.

335 The significant increase of O₃ within the ASMA in 2015 might be due to the transport from
336 the mid-latitudes through the STJ and also due to the stratosphere to the troposphere transport. For
337 example, the strong enhancement of O₃ within the ASMA at 100 hPa in July was strongly matched
338 with the observed high values of PV at 350 K isentropic surface (Fig. 6). This is further supported
339 by the strong southward meandering of STJ in July (Fig. 3), respectively. Thus, a clear transport
340 of mid-latitude air with high PV and high O₃ is evident during 2015. At the same time, the
341 enhancement of O₃ was clearly observed at all the pressure levels from 82 hPa to 121 hPa which
342 is further supported for the stratosphere to the troposphere transport. Note that 82 hPa can represent

343 the lower stratosphere and 121 hPa for the upper troposphere (Das et al., 2020). It can be noticed
344 that the ASMA is strongly associated with troposphere-stratosphere transport as well as
345 stratosphere-troposphere transport (Garny and Randel, 2016; Fan et al., 2017). Also, it is well
346 reported that the northern part of the ASMA is an active region for stratosphere-troposphere
347 transport processes (Sprenger et al., 2003; Škerlak et al., 2014).

348 Similarly, significant lowering of O₃, particularly at 100 hPa and 82 hPa is clearly noticed
349 over the tropics (Fig. 7). This is quite expected due to the enhanced tropical upwelling (bringing
350 poor O₃ air from troposphere) caused by the strong El Niño conditions in July and August 2015.
351 As mentioned in the previous sections, strong El Niño conditions are clearly evident in July and
352 August 2015 (Fig. 1). The observed strong negative O₃ anomalies over the tropics from the present
353 study are well matched with the previous studies (Randel et al., 2009; Diallo et al., 2018). From
354 the present results, it is very clear that there is a significant decrease over the tropics and the
355 increase over the mid-latitudes in 2015. These changes observed in the O₃ (decrease and increase)
356 are attributed due to the strengthening of the tropical upwelling and enhanced downwelling from the
357 shallow branch of the Brewer-Dobson circulation in the mid-latitudes due to the strong El Niño
358 conditions in 2015. Overall, it is concluded that initially, during July, the O₃ is transported into the
359 anticyclone from the northeastern edges of the ASMA region through the sub-tropical westerlies
360 and then it is isolated within the ASMA region. This is further supported by the southward
361 meandering of the westerly jet and southward shift of the ASMA (negative GPH anomalies) over
362 the same region in July (**Fig. 3**). Also, significant transport of mid-latitude dry air is clear from the
363 Fig. 6. Thus, it is clear from the results that the stratosphere to troposphere transport and horizontal
364 advection along with the subtropical jet caused the strong enhancement of the O₃ within the ASMA
365 in 2015.

366 **Figure 8a-b (Fig. 8c-d)** shows the spatial distribution of CO relative percentage change at
367 100 hPa and 146 hPa observed during July (August) 2015. The white (black) color contour
368 represents 16.75 km GPH at 100 hPa for the corresponding month in 2015 (climatological mean).
369 The observed changes in the CO clearly exhibit quite distinct features between July and August as
370 observed in the O₃. A significant decrease (~30%) is noticed in the CO concentrations over most
371 of the AMSA in July. The maximum decrease of CO is noticed over the northeastern edges of the
372 ASMA, located ~ 30-45°N, 90-120°E region. Whereas in August, the decrease of CO is more
373 concentrated over the east and western edges of the ASMA at both the pressure levels. Overall, the
374 MLS observed CO was ~30% below average (percentage decrease) compared to the climatological
375 monthly mean within the ASMA in July and edges of the ASMA in August 2015. It is noted that
376 there is a considerable year-to-year variability of the CO sources over the ASM region (Santee et
377 al., 2017). The major sources of the CO over the ASM region are from the biomass burning and
378 industrial emission. The observed decreased CO within the ASMA in 2015 might be due to the
379 year-to-year variability in the CO sources and the weaker vertical transport due to the El Niño
380 conditions in 2015.

381
 382 **Figure 8.** Carbon monoxide relative percentage change during July 2015 with respect to
 383 climatological monthly mean observed at (a) 100 hPa and (b) 146 hPa. Subplots of (c) and (d)
 384 same as (a) and (b) but for the month of August. The white (black) color contour represents 16.75
 385 km geopotential height at 100 hPa for the corresponding month in 2015 (mean of 2005-2014). The
 386 star symbols (black) shown in figure represent the anomalies greater than the $\pm 2\sigma$ standard
 387 deviation of long-term mean. The results are obtained from MLS measurements.

388 Similarly, the WV relative percentage change at 82 hPa, 100 hPa and 146 hPa in July (August)
 389 2015 are shown in **Fig. 9a-c (Fig. 9d-f)**. The WV shows quite different changes at all the pressure
 390 levels in July and August. At 146 hPa, the WV exhibits a strong decrease ($> 20\%$) within the ASMA
 391 in July as well as in August also. However, at 100 hPa and 82 hPa, the WV shows a relatively
 392 significant decrease within the ASMA in July compared to August. From the WV observations, it
 393 is concluded that the WV is strongly decreased at 146 hPa in both months. Whereas at 100 hPa

394 and 82 hPa, the decrease in WV is quite high in July compared to August. It is also observed from
395 the Fig. 9 that there is a significant enhancement of WV over the tropics at 146 hPa in both months.
396 But the WV enhancement is quite significant at 100 hPa, particularly during August compared to
397 July. This enhancement in the WV around the tropical tropopause region in August is quite
398 expected due to the El Niño conditions (Randel et al., 2009; Konopka et al., 2016). Overall, the
399 tropospheric tracers (CO and WV) significantly decreased (~30% and 20%) within the ASMA
400 during July and August 2015. These changes in the tropospheric tracers are might be due to the
401 weaker vertical motions during the 2015 monsoon. A weaker vertical transport from the boundary
402 layer to the UTLS is generally observed over the ASM region during El Niño period (Fadnavis et
403 al., 2019). The El Niño conditions will suppress the monsoon convection and cause weaker vertical
404 transport during monsoon. Also it is reported that the summer monsoon in 2015 was weaker
405 monsoon due to the strongest El Niño conditions existed in 2015 (Tweedy et al., 2018; Yuan et al.,
406 2019; Fadnavis et al., 2019).

407
 408 **Figure 9.** Water vapour relative percentage change in July 2015 with respect to background
 409 climatological monthly mean observed at (a) 82 hPa, (b) 100 hPa and (c) 146 hPa. Subplots of (d),
 410 (e) and (f) same as (a), (b) and (c) but for the month of August. The white (black) color contour
 411 represents 16.75 km geopotential height at 100 hPa for the corresponding month in 2015 (mean of
 412 2005-2014). The star symbols (black) shown in figure represent the anomalies greater than the $\pm 2\sigma$
 413 standard deviation of long-term mean. The results are obtained from MLS measurements.

414 From these results, it is clear that the enhancement of O_3 and lowering of CO/WV is evident
 415 in July and August 2015 compared to the long-term monthly mean. The observed high O_3 and low

416 WV within the ASMA from the present study are consistent and well-matched with the previous
417 study reported by Li et al. (2018). They demonstrated the importance of the large-scale
418 atmospheric dynamics and the stratospheric intrusions for high O₃ and low WV over Lhasa within
419 the ASMA by using in-situ balloon-borne measurements. The O₃/WV changes strongly influence
420 the background temperature structure within the UTLS region (Venkat Ratnam et al., 2016;
421 RavindraBabu et al., 2019b). Further, we investigated the tropopause temperature changes within
422 the ASMA by using COSMIC RO data. The results are presented in the next following section.

423 **3.3. Tropopause temperature anomalies in 2015**

424 It is well known that the tropopause plays a crucial role in the exchange of WV, O₃ and other
425 chemical species between the troposphere and the stratosphere. Most of these exchanges (WV to
426 the lower stratosphere and O₃ to the upper troposphere) known as stratosphere troposphere
427 exchange (STE) take place around the tropopause region (Fueglistaler et al., 2009; Venkat Ratnam
428 et al., 2016; RavindraBabu et al., 2019b). It is well reported that the tropopause within the ASMA
429 is higher than the outside regions at the same latitude (Randel et al., 2010; Santee et al., 2017). In
430 the present study, we mainly focused on changes in the cold point tropopause temperature (CPT)
431 and lapse rate tropopause temperature (LRT) within the ASMA in July and August 2015. The July
432 and August 2015 monthly mean tropopause parameters are removed from the respective
433 climatological monthly mean which is calculated by using COSMIC RO data from 2006 to 2014.
434 One can note that we have strictly restricted our analysis within 40°N region for the cold point
435 tropopause. **Figure 10a-b (Fig. 10c-d)** shows the CPT and LRT anomalies observed in July
436 (August) 2015. The tropopause temperature anomalies (CPT/LRT) also exhibit a distinct pattern
437 in July and August as observed in O₃ (**Fig. 7**). In July, the CPT/LRT show strong positive anomalies
438 (~5 K) in most of the ASMA region. High positive CPT/LRT anomalies are also noticed over the

439 NWP region particularly below 20°N. These CPT/LRT anomalies observed over the NWP region
440 might be due to the El Niño induced changes in the Walker circulation and convective activity.
441 Previous studies also observed significant warm tropopause temperature anomalies over WP and
442 maritime continent during the El Niño period (Gettleman et al., 2001). In August, the strong
443 positive CPT/LRT anomalies (~5K) are concentrated over the northeastern edges of the
444 anticyclone where the WP mode of the anticyclone was separated from the ASMA. The
445 temperature anomalies at 1 km above and below the CPH also show similar behavior as seen in
446 the CPT/LRT during August 2015 (figures not shown). Overall, the tropopause temperature
447 anomalies in July and August 2015 within the ASMA are well correlated with the strong
448 enhancement in the O₃ as shown in **Fig. 7**. However, the enhanced O₃ anomalies (heating due to
449 the O₃) itself cannot explain the observed positive tropopause temperature anomalies within the
450 ASMA in 2015. This might be due to the El Niño induced changes in the convective activity and
451 the circulation. It is well known that the reversal of walker circulation and the shifting of the
452 convective activity (suppressed convective activity over ASM region) are generally observed
453 during the warm phase of ENSO. One can be noticed that apart from the convection, other factors
454 such as stratospheric QBO, atmospheric waves (gravity waves and Kelvin waves) also strongly
455 influenced the tropopause temperatures.

456
 457 **Figure 10.** Spatial distribution of (a) lapse rate tropopause temperature (LRT), (b) cold point
 458 tropopause temperature (CPT) anomalies during July 2015. Subplots of (c) and (d) same as (a) and
 459 (b) but for the month of August 2015. The white (black) color contour represents 16.75 km
 460 geopotential height at 100 hPa for the corresponding month in 2015 (mean of 2005-2014). The star
 461 symbols (black) shown in figure represent the anomalies greater than the $\pm 2\sigma$ standard deviation
 462 of long-term mean.

463 4. Summary and Conclusions

464 In this study, we investigated the detailed changes observed in the structure, dynamics and
 465 trace gases (Ozone, Water Vapor, Carbon Monoxide) variability within the ASMA in 2015 by using
 466 reanalysis products and satellite observations. The tropopause temperature (CPT and LRT) on

467 monthly scales particularly during July and August 2015 also discussed. To quantify the changes
468 that happened within the ASMA region, 11 years (2005-2015) of O₃, WV and CO observations
469 from the Aura-MLS data and 10 years (2006-2015) of tropopause temperature data from the
470 COSMIC RO temperature profiles are used. The NCEP-DOE Reanalysis 2 observed winds and
471 GPH data from 2005 to 2015 are also utilized. The results are obtained by comparing the trace gas
472 quantities in July and August 2015 with corresponding long-term monthly mean quantities.

473 The trace gases within the ASMA exhibit substantial anomalous behavior in July and August
474 2015. During July and August 2015, we observed an enhancement of O₃ and the lowering of CO
475 and WV over most of the ASMA region. The decrease of the tropospheric tracers (CO and WV) is
476 quite expected due to the weaker upward motions from the weak monsoon in 2015. This is
477 supported by a recent study reported by Fadnavis et al. (2019). They showed weaker upward
478 motions and deficient rainfall in the 2015 monsoon due to the strong El Niño conditions. However,
479 the strong enhancement in the stratospheric tracer (O₃) within the ASMA particularly over the
480 northeastern edges of the ASMA during July is quite interesting. This is might be due to the
481 stratospheric intrusions as well as transport from the mid-latitudes. Based on Fishman and Seiler
482 (1983), it was stated that the positive correlation between CO and O₃ indicates, the O₃ is produced
483 by in-situ in the troposphere whereas the correlation is negative means the O₃ originates from the
484 stratosphere. We noticed a strong negative correlation between CO and O₃ in the present study
485 with increased O₃ and decreased CO from the MLS measurements. This clearly reveals that the
486 observed increased O₃ within the ASMA during 2015 is the stratospheric origin. This is further
487 supported by higher negative GPH anomalies associated with a southward meandering of the
488 subtropical westerly jet over northeastern Asia in July (**Figs. 3 and 4**). Further, the increased O₃ at
489 100 hPa and 121 hPa over western edges of the ASMA during August clearly indicates the transport

490 of the O₃ towards outer regions through the outflow of the ASMA (Fig. 7e-f). Interestingly, the
491 tropopause temperature obtained from the COSMIC RO data in July 2015 shows strong positive
492 temperature anomalies (~5 K) over the entire ASMA region. These warm tropopause temperatures
493 again supported the increased O₃ within the ASMA during 2015. The major findings obtained from
494 the present study are summarized in the following.

495 ❖ The spatial extension of the ASMA region shows higher than long-term mean except over
496 northeastern Asia where it exhibits a strong southward shift in July. Whereas in August, the
497 AMSA further separated into two anticyclones and the western Pacific mode anticyclone is
498 clearly evident in August.

499 ❖ The combination of Rossby wave breaking and pronounced southward meandering of
500 subtropical westerlies play a crucial role on the dynamical and structural changes in the
501 ASMA in 2015.

502 ❖ Strong enhancement in O₃ at 100 hPa (>40%) is clearly evident within the ASMA and
503 particularly higher over the northeastern edges of the ASMA in July. The enhanced O₃ is
504 strongly associated with a dominant southward meandering of the subtropical westerlies. In
505 August, the increased O₃ is significantly located over the western edges of the ASMA. This
506 clearly indicates the transport from the ASMA to the edges through its outflow.

507 ❖ A significant lowering of CO and WV within the ASMA is noticed during summer 2015. The
508 lowering of WV is higher at 146 hPa than 100 hPa.

509 ❖ Significant positive tropopause temperature anomalies (~5 K) is observed in the entire ASMA
510 region in July whereas, in August, the strong positive anomalies are concentrated over the
511 northeastern side of the ASMA.

512 The changes in the O₃ concentrations (increase/decrease) within the ASMA are one of the possible

513 mechanisms to strengthening/weakening of the ASMA (Braesicke et al., 2011). By using idealized
514 climate model experiments, Braesicke et al. (2011) clearly demonstrated that the strengthening
515 (weakening) of the ASMA occurred when the O₃ is decreased (increased) within the ASMA. The
516 increased O₃ within the ASMA warms the entire anticyclone region and weakens the ASMA
517 (Braesicke et al., 2011). Our results from the present study also in agreement with the results of
518 Braesicke et al. (2011). We also observed a pronounced increase of O₃ within the ASMA associated
519 with significant warming of tropopause as well as above and below the tropopause region in 2015.
520 By using precipitation index, wind data and stream functions, previous studies reported that the
521 ASMA circulation in 2015 was weaker than the normal (Tweedy et al., 2018; Yuan et al., 2019).
522 Based on our present results, the strongly enhanced O₃ within the ASMA also might be one of the
523 plausible reasons for weakening of the ASMA in 2015.

524 **Author contributions:** SRB designed the study, conducted research, performed initial data
525 analysis and wrote the first manuscript draft. MVR, GB, SKP and NHL edited the first manuscript.
526 All authors edited the paper.

527 **Data Availability:** All the data used in the present study is available freely from the respective
528 websites. The MLS trace gases data obtained from Earth Science Data website. The
529 NCEP_Reanalysis 2 data provided by the NOAA/OAR/ESRL PSL, Boulder, Colorado, USA, from
530 their web site (<http://www.cpc.ncep.noaa.gov/products/wesley/reanalysis2/kana/reanl2-1.htm>)
531 The COSMIC data is available from COSMIC CDAAC website (<http://cdaac->
532 www.cosmic.ucar.edu/cdaac/products.html).

533 **Competing interests:** The authors declare that they have no conflict of interest.

534 **Acknowledgments:** Aura MLS observations obtained from the GES DISC through their FTP site
535 (<https://mls.jpl.nasa.gov/index-eos-mls.php>) is highly acknowledged. We thank the COSMIC Data

536 Analysis and Archive Centre (CDAAC) for providing RO data used in the present study through
537 their FTP site (<http://cdaac-www.cosmic.ucar.edu/cdaac/products.html>). We also thank to
538 NCEP/NCAR reanalysis for providing geopotential and wind data. We thank ECMWF for
539 providing ERA interim reanalysis data.
