Title

Decoupling of urban CO_2 and air pollutant emission reductions during the European SARS-CoV2 lockdown

Abstract

Lockdown and the associated massive reduction in people's mobility imposed by SARS-CoV-2 mitigation measures across the globe provide a unique sensitivity experiment to investigate impacts on carbon and air pollution emissions. We present an integrated observational analysis based on long-term in-situ multispecies eddy flux measurements, allowing to quantify near real time changes of urban surface emissions for key air quality and climate tracers. During the first European SARS-CoV-2 wave we find that the emission reduction of classic air pollutants decoupled from CO_2 and was significantly larger. These differences can only be rationalized by the different nature of urban combustion sources, and point towards a systematic bias of extrapolated urban NO_x emissions in state-of the art emission models. The analysis suggests that European policies, shifting residential, public and commercial energy demand towards cleaner combustion, have helped to improve air quality more than expected, and that the urban NO_x flux remains to be dominated (e.g. >90%) by traffic.

Introduction

      Managing air pollution and climate change are among the most important environmental challenges of modern society. As urban population continues to grow, emissions from metropolitan areas play an increasingly important role. For example, European cities already host about 74% of the population (UN, 2019) and are a major contributor to air pollutant and greenhouse gas emissions. Urban growth, along with socioeconomic development, and without mitigation can lead to substantial increases in anthropogenic emissions. Many cities are committing to sustainable development goals, and improvement of air pollution and mitigation of climate change are emerging as key sustainability priorities across the globe. Quantifying the diversity of urban emissions is often one of the most uncertain components of complex atmospheric models, and development of a robust predictive capability requires accurate data and careful evaluation of bottom-up emissions (Blain et al., 2019; NAS, 2016).

      During the last two decades Europe's policy to reduce mid-term carbon emissions has fostered the proliferation of Diesel driven vehicles (EU-EUR-Lex, 2008). While soot emissions can be successfully removed with a Diesel particulate filter, the reduction of NO_x from Diesel exhaust has been more challenging, and was at the center of "Dieselgate" (Franco, V., Posada Sanches, F., German, J., Mock, 2014). As a consequence, European NO_x concentrations have declined less rapidly than elsewhere (Carslaw and Rhys-Tyler, 2013; Im et al., 2015; Karl et al., 2017), and put the EU-28 emission target for NO_x reductions (2005-2030: -63%) in jeopardy (EU-EUR-Lex, 2008). Nitrogen oxides have therefore emerged as a primary public health concern (Anenberg et al., 2017). European suppression measures due to the SARS-CoV2 outbreak provide a unique opportunity to track drastic changes in urban mobility during the lockdown phase, and combined with eddy flux methods allow investigating the sensitivity towards emission changes directly.

      After the initial SARS—CoV2 emergence in China in late 2019, the World Health Organization declared the outbreak a global pandemic on March 11 2020. Worldwide measures to mitigate or suppress exponential growth of SARS-CoV2 have resulted in an unprecedented global intervention on mobility and industrial activity (WHO, 2020), allowing to study a number of environmental aspects (e.g. Liu et al., 2020b; Schiermeier, 2020; Quéré et al., 2020). A growing number of studies document regional and global air composition (e.g. Menut et al., 2020; Bao and Zhang, 2020) changes with respect to lockdown measures, including remote sensing observations and aspects of adequate data processing strategies (e.g. Liu et al., 2020a; Sussmann and Rettinger, 2020).

71 In Europe, most countries have implemented suppression strategies involving a more or

72 less extensive lockdown of public life. At the beginning of the pandemic, the level of suppression

73 varied among different countries, with some imposing very early ('China' like) lockdown

74 measures (e.g. Austria), others shifting from gradual social distancing measures to a lockdown

75 after re-consideration of alternative strategies (e.g. the UK). Depending on the magnitude of the

76 outbreak, European countries put increasingly stringent measures in place. The extent of different

77 lockdown measures has been assessed early on via cell phone activity tracking. For example,

78 Google mobility reports published in March 2020, suggested an 80% reduction of retail and

79 recreational activities across Europe. Traffic count data show a 60% reduction of urban mobility

80 due to a state-wide quarantine in the state of Tirol early during the pandemic. Such a drastic

81 mobility reduction during the suppression period allows performing a granular assessment of

82 processes impacting emissions and the distribution of air pollutant and climate gases.

83 A direct and quantitative way to assess air pollutant and climate gas emission changes can

84 be based on the eddy covariance method (Aubinet et al., 2012; Dabberdt et al., 1993). Briefly, in

85 its simplest form for stationary conditions and neglecting horizontal advection, the turbulent

86 surface - atmosphere flux (measured at height h) can represent the diffusive flux at the surface:

87 $$\left(\overline{w'c'}\right)_h = -D\left(\frac{\partial \bar{c}}{\partial z}\right)_0, \tag{1}$$

88
89 where w' represents the vertical fluctuation of wind speed, D the molecular diffusion coefficient,

90 and c' the concentration fluctuation. The turbulent flux at the measurement height h (left side)

91 equals the diffusive surface flux (right side), which we are usually interested in. Brackets denote

92 the averaging interval. The ensemble average is typically 30 minutes. Eddy covariance

93 measurements have been extensively used in atmospheric sciences (Foken and Wichura, 1996;

94 Oncley et al., 2007; Patton et al., 2011) and biogeochemistry (Aubinet et al., 2012; Baldocchi et

95 al., 1988; Fowler et al., 2009; Rannik et al., 2012) (e.g. Ameriflux: https://ameriflux.lbl.gov/;

96 Euroflux: http://www.europe-fluxdata.eu/icos). The method has also become more tractable for

97 reactive trace gases such as NMVOC (Karl et al., 2001; Rinne et al., 2001; Spirig et al., 2005) or

98 NO_x (Lee et al., 2015), and has been used at urban sites (Christen, 2014; Langford et al., 2009;

99 Velasco et al., 2005; Squires et al., 2020). Urban eddy covariance methods can monitor

100 aggregated emission changes in real time. Here we build on a set of long-term multispecies flux

101 and concentration datasets for NO_x, O_3, aromatic NMVOC, and CO_2 (Karl et al., 2020). Being

102 inspired by early empirical persistence models used in atmospheric chemistry and ecology, we

103 propose a new quantitative way for the analysis of urban fluxes during an intervention experiment

104 by combining eddy covariance data with a boosted regression tree model (Duffy and Helmbold,

105 2002). This method allows to directly assess changes of surface fluxes for different trace gases in

106 response to the SARS-CoV2 lockdown and rebounding effects.

107

108 **Methods**

109

110 **Eddy covariance**

111

112   Here we analyze air quality data based on the eddy covariance method (e.g. Aubinet et al.,

113 2012; Dabberdt et al., 1993), which represents the most direct meteorological method to

114 determine surface emissions (Baldocchi et al., 1988; Fowler et al., 2009). The method is widely

115 established in biogeosciences (e.g. Euroflux, http://www.europe-fluxdata.eu/icos (last access: 18

116 December 2020), Ameriflux, https://ameriflux.lbl.gov/ (last access: 18 December 2020). A

117 number of studies investigated eddy fluxes of chemical species and aerosols in urban settings

118 (Nemitz et al., 2008; Velasco et al., 2009; Rantala et al., 2016; Lee et al., 2015; Karl et al., 2017;

119 Vaughan et al., 2017; Striednig et al., 2019). Briefly, the method relies on the conservation

120 equation of a scalar, which under homogenous conditions can be simplified to

121

122 $$\frac{\partial C}{\partial t} + \frac{\partial F}{\partial z} = S, \tag{2}$$

123

124 where dC/dt represents the storage term, dF/dz the measured vertical turbulent flux as in eq. 1 and

125 S sources and sinks between the surface and height z.

126

127 Integration of eq. 2 yields

128

129 $$\int_0^h \frac{\partial C}{\partial t}\,dz + \overline{(w'c')}_h = \overline{(w'c')}_0 := F_s, \tag{3}$$

130

131 where h is the measurement height (39 m above street level), and F_s represents the surface flux. In

132 this context the turbulent flux term usually dominates the left hand side. The storage term

133 typically accounted for 5-7% of the fluxes on average, and we consider it a minor component in

134 our analysis. Similarly we neglect advection fluxes. We take advantage of the fact that our

135 analysis is based on relative changes of different air pollutant fluxes normalized by a boosted

136 regression tree model. Any systematic bias therefore cancels out under the assumption of

137 comparable source distribution verified by the emission inventory. The datasets are analyzed with

138 the innFLUX code (Striednig et al., 2019), which outputs standard parameters used for filtering

139 flux data as described by Foken and Wichura (1996). In addition to raw data filters (spike

140 removals, weather flags), we applied standard criteria using u* and the stationarity criterion for all

141 species (Foken and Wichura, 1996). We specifically do not apply tests on integral turbulence as

142 parameterizations for urban areas are not available/accurate. After applying the above mentioned

143 filters 73% of the flux data were used for the training dataset, and 82% of the flux data were used

144 for the intervention period. Systematic errors due to attenuation caused by slow sensor response

145 was assessed previously (Karl et al., 2017). It is considered minor due to the large eddy size

146 above the urban roughness layer and for the trace gases considered here is on the order of 2-5 %.

147 A detailed description of errors and data treatment for this site was published by (Striednig et al.,

148 2019).

149
150

151 **Flux footprint and IAO observations**

152

153 A site description of the Innsbruck Atmospheric Observatory (IAO), instrumentation and

154 site validation were previously described extensively (Karl et al., 2020). The flux footprint (Fig 1)

155 was calculated according to Kljun et al. (2015). For the measurement - inventory comparison we

156 mapped the two-dimensional climatological footprint (March-May) onto the spatially

157 disaggregated Austrian EMIKAT emission inventory (www.emikat.at). The relative seasonal

158 variability was accounted for by scaling total yearly traffic emissions to measured seasonal traffic

159 activity (Land Tirol, AT), and total yearly RCP emissions to measured seasonal NG consumption

160 (TIGAS, AT, https://www.tigas.at/). The land surface distribution within the flux footprint (Fig.

161 S1) is dominated by roads and building surfaces with a fraction between 70-88% depending on

162 the wind sector. For comparisons the district level emission distribution from the inventory was

163 mapped onto the land surface distribution and then weighted according to the footprint function.

164 Traffic counts used in the data comparisons were based on a conductive loop measuring

165 directional traffic flows along Innrain provided by the Land Tirol, a main street dissecting the flux

166 tower footprint and considered representative of traffic activity surrounding the flux tower. The

167 inductive loop provides rudimentary information on light vs heavy duty vehicles and suggests that

168 95% of traffic is caused by vehicles <3.5t. We assume that all fuel types used for heating

169 appliances and warm water consumption track relative changes of NG consumption, which is

170 largely a function of base load and degree heating days (Fig. S2). Since many commercial

171 buildings (e.g. shops, restaurants, retail) are not clearly separable from residential buildings in

172 European cities (e.g. upper floors are used for housing and ground floor houses shops or

173 restaurants using shared heating), it is hard to clearly separate the RCP into individual

174 components in the urban core. Overall, heating energy supply in the RCP sector is comprised of

175 district heating (8.7%), oil (34.5%), natural gas (34%), biomass (16%), electricity (6.1%), and

176 alternative sources (0.7%).

177   NO_x measurements were based on a dual channel chemiluminescence instrument (CLD

178 899 Y; Ecophysics). The instrument was operated in flux mode acquiring data at about 5Hz. A

179 NO standard was periodically introduced for calibration. Zeroing was performed once a day close

180 to midnight. The chemiluminescent instrument is equipped with a metal oxide (ie. molybdenum)

181 converter. It has been shown (Steinbacher et al., 2007) that this can result in an overestimation of

182 NO_2 due to decomposition of NO_y species. For Innsbruck we have evaluated the accuracy using

183 side by side measurements with a cavity ring down spectrometer in 2015 (Karl et al., 2017). Both

184 independent techniques agreed to within 6%, confirming that this problem plays a minor role for

185 polluted sites. CO_2, and H_2O were measured with a closed path eddy covariance system (CPEC

186 200; short inlet, enclosed IRGA design; Campbell Scientific) along with three dimensional

187 winds. Calibration for CO_2 was performed once a day. Aromatic NMVOC (ie. benzene, toluene,

188 xylenes+ethylbenzene, and C_9 benzenes) were measured with a PTR-TOFMSx6000 mass

189 spectrometer (IONICON, AT), operated in hydronium mode at standard conditions in the drift

190 tube of about 112 Townsend. The instrument was set up to sample ambient air from a turbulently

191 purged 3/8" Teflon line. Zero calibrations were performed by providing NMVOC free air from a

192 continuously purged catalytical converter though a setup of software controlled solenoid valves.

193 In addition, daily calibrations were performed using known quantities of a suite of NMVOC from

194 a 1ppm calibration gas standard (Apel & Riemer, USA) that were added to the NMVOC free air

195 and dynamically diluted into low ppbv mixing ratios. Errors arising from analytical uncertainty

196 mainly stem from calibration proceedures. For NMVOC these are estimated as 10% for aromatic

197 NMVOC compounds based on a calibration standard, similarly the uncertainty of NO_x is 2%, and

198 for CO_2 5%, respectively.

199   This study builds on long-term NO_x and CO_2 flux measurements that run operationally

200 since June 1st 2018. NMVOC fluxes were measured during a field campaign from March 11th

201 2019 to April 9th 2019, and during the SARS-CoV2 lockdown, when measurements started on

202 March 16th 2020. The NMVOC analysis presented in this paper spans from March 16th 2020 to

203 May 1st 2020.

205

206

Boosted regression tree model

Statistical persistence and regression models have a long history in atmospheric chemistry (Robeson and Steyn, 1990) to predict empirical trends of pollutants (e.g. ozone), that factor in meteorological and chemical processes. These approaches have been used to forecast local surface ozone (Cobourn, 2007; Prybutok et al. 2000) and more recently trends of other atmospheric pollutants (Grange and Carslaw, 2019). Here we developed a boosted regression tree model using machine learning that is widely used in ecological modeling (Elith et al., 2008): for each variable we based the model on the following key astronomical and environmental driving variables: day of year (DOY), time of day (TOD), weekday/holiday (WDY), cartesian wind vectors (NS- and WE-direction), temperature (T), relative humidity (RH), global radiation (GR) and pressure (P). The model is setup using the machine learning toolbox in Matlab (Mathworks Inc, USA) and trained for individual datasets until February 29th 2020 or during key reference periods (SI Table S1). The model performance was assessed by comparing predicted and observed quantities using reference datasets (SI Table S2). To obtain a quantitative measure of emission changes, the differences between observed and predicted fluxes are integrated from the beginning of the lockdown period. As the predicted and observed quantities diverge, the integrated relative difference serves as a quantitative measure of emission (or activity) alteration (e.g. reduction).

Multispecies Pollutant Model

Based on two major and distinct urban pollution sources (ie. road traffic and energy production in the residential, public and commercial sectors) proportional contributions to the observed flux changes can be attributed based on a two end member mixing model: Traffic emissions are primarily related to exhaust from internal combustion engines. The Austrian passenger car fleet is comprised of 43% gasoline and 55% Diesel driven cars (Statistik, Austria, 2020, www.statistik.at), with the latter being a key player for urban NO_x emissions. The second significant emission source stems from fossil energy production in the residential, public and commercial sectors with a significant contribution of natural gas combustion. In its simplest form we can therefore aggregate the observed flux changes into two main emission source categories using a two end member mixing model:

$$\frac{\delta F(s)}{F(s)} = a_s * \frac{\delta T}{T} + b_s * \frac{\delta R}{R} + \varepsilon, \tag{4}$$

240 where $\frac{\delta F(s)}{F(s)}$ is the measured relative flux difference between the boosted regression tree model

241 output and the actual flux observations of species s (e.g. NO_x, CO_2, aromatic NMVOC), $\frac{\delta T}{T}$ is the

242 traffic load difference determined from traffic count data, $\frac{\delta R}{R}$ is the residential energy consumption

243 change, a_s and b_s are proportionality terms, and ε is an error term. The proportionality terms (a_s

244 and b_s) represent the area weighted emission factors of the fleet average traffic (a_s) and RCP

245 sector (b_s). By definition $a_s + b_s := 1$, if only two sources are considered.

246
Results
248
249   *The urban NO-NO2-O3 triad:* Due to the short atmospheric lifetime (e.g. up to 7 h

250 (Laughner and Cohen, 2019)) nitrogen oxides can serve as a gage to assess air pollution changes

251 as their atmospheric concentrations rapidly respond to shifting surface fluxes. The quantitative

252 assessment of NO_x emissions based on ambient air concentrations however remains challenging

253 due to non-linearities within the NO-NO_2-O_3 triad in polluted regions (Lenschow et al., 2016).

254 Under sun-light conditions and high NO_x pollution the cycling between the NO-NO_2-O_3 triad is

255 described by the following reaction sequence:

256

257 $NO_2 + h\nu \rightarrow NO + O$ (5)

258 $O + O_2 \rightarrow O_3$ (6)

259 $NO + O_3 \rightarrow NO_2 + O_2$ (7)

260

261 The chemical timescale of the NO_x triad (eq 5 to 7) can be derived (Lenschow and Delany, 1987)

262 as

263 $$\tau = \frac{2}{\sqrt{[j^2 + k_3^2([O_3] - [NO])^2 + 2j \cdot k_3([O_3] + [NO] + 2 \cdot [NO_2])]}}$$ (8)

264

265   For typical conditions encountered during this study, this equates to timescales of about

266 100 s, comparable to the vertical turbulent exchange time in cities. Due to the rapid

267 interconversion, the partitioning between NO and NO_2 is typically dominated by fast chemistry,

268 and the bulk of NO_2 in the urban atmosphere is produced secondarily via the reaction of NO and

269 O_3. In the urban atmosphere this leads to a non-linear relationship between NO_2 and NO_x

270 concentrations as depicted in Fig. 2. A repartitioning can be observed during the suppression

271 phase for example, when the NO_2 to NO_x trajectory moves from an urban NO_x saturated regime to

272 a more NO_x limited regime. During the SARS-CoV2 lockdown this shift was more pronounced

273 than for typical weekend-weekday variations (Fig 2 B,C). As a consequence the relationship

274 between changes of NO_x fluxes and NO_2 concentrations becomes a non-linear function of NO_x

275 concentrations when moving from NO_x saturated to NO_x limited conditions. Data from a nearby

276 air quality station support these conclusions showing significantly different NO_x concentrations

277 during the 2020 lockdown compared to the previous 5 years (ie. a 50% reduction of NO_x), but no

278 significant change for O_x (:= NO_2+O_3) based on the z hypothesis test. This chemical repartitioning

279 and vertical redistribution in the surface layer needs to be accounted for when quantifying

280 changing NO_x emissions from concentrations. A more quantitative picture of changing NO_x

281 emissions can be obtained from direct flux measurements that are intrinsically linked to surface

282 emissions (Vaughan et al., 2016).

283   Fig. 3 gives an overview of NO_x and CO_2 fluxes which have been continuously measured

284 at the study site in Central Europe since 2018. In addition, we have performed regular field

285 campaigns augmenting these long-term datasets with NMVOC flux measurements (Karl et al.,

286 2020). While atmospheric concentrations of primary air pollutants often exhibit strong surface

287 maxima due to inversion layers during winter and spring, the corresponding emission fluxes

288 typically track urban emission source activity and reflect changes in emission strengths and flux

289 footprint. Turbulent fluxes typically exhibit midday maxima, reflecting increases in urban

290 emission sources, which in the case of nitrogen oxides closely follow traffic load patterns (Karl et

291 al., 2017). Urban CO_2 fluxes follow these general trends, but are to some extent less pronounced

292 (e.g. weekend-weekday effect). During the vegetation period, CO_2 emission fluxes can be

293 suppressed (Ward et al., 2015) due to photosynthetic uptake by urban plants. For Innsbruck, we

294 have assessed this effect previously and find that within the flux footprint the contribution of

295 vegetation is relatively small (ie. only about 10% of the urban surface within the flux footprint is

296 covered by plants). Urban CO_2 fluxes are therefore primarily controlled by combustion processes.

297 The flux site is situated in a valley with two dominant wind sectors, which cover a typical inner

298 city residential and business district (Fig. 1) with no significant industrial activities. In order to

299 quantitatively investigate emission flux changes in response to SARS-CoV2 intervention

300 measures, we implemented a boosted regression tree model to define a business as usual scenario

301 of the observed fluxes (Duffy and Helmbold, 2002). The model allows factoring in differences in

302 weather patterns (e.g. meteorological variations such as temperature, wind direction and flux

303 footprint etc.), and describes changes that can be primarily attributed to the intervention itself.

304 Accounting for seasonal differences is key to an accurate analysis of emission alterations due to

305 lockdown measures. The essential time period of pre and post-lockdown measures in Europe

306 spans from March to about May 2020. Weather patterns in Europe can be particularly variable

during this period as the continent transitions from winter to summer. The climate of Tyrol is fairly representative of central Europe, where the transitional period between March to May can exhibit significant synoptic variability. For example, average monthly temperatures in March 2020 were about 0.9 K colder than in 2019. April and May 2020 tended to be 1.8 and 3.2 K warmer than 2019. Warmer temperatures in spring 2020 resulted in 24% fewer degree heating days (DHT) than in the year 2019 (SI). Consistent with these observations, natural gas consumption in Tirol (SI) was reported to be 25% lower during this period than in 2019. We can quantify changes of the observed fluxes due to the lockdown intervention in spring 2020 by referencing actual flux measurements to results from a trained boosted regression tree model (Fig. 4).

Shortly after the European SARS-CoV2 outbreak first sparked in Italy, which was among the first European countries, the greater part of the Alps was under lockdown by Mid-March to inhibit cross-border transmission. Tyrol implemented extensive measures of shelter in place and a state wide quarantine (QA) on top of the Austrian lockdown (LO) on March 16th, one week after all Universities closed. At the same time, European wide measures of border control impacted all major north-south transport corridors to Italy. These measures resulted in massively reduced local mobility in combination with significant disruptions of one of the major transport routes across the Alps. As a consequence, average traffic loads in Innsbruck decreased by ~64%. The traffic data allow partitioning traffic into 'all vehicles', 'truck-similar vehicles', 'HDV' and 'semi trailer trucks'. The reductions were 64% (all vehicles), 40% (truck-similar vehicles), 35% (HDV) and 21% (semi trailer trucks). Since it is an inner-city location the fraction of passenger cars dominate. In absolute numbers, the distribution is dominated by passenger cars (<3.5t) amounting to 95% of all traffic, with the remainder attributed to the truck categories. The Austrian rate of infections reached a peak of 900 newly confirmed cases per day in Mid-March and started to decline at the end of March. Along with efforts to reduce SARS-CoV2 transmission, the shelter in place legislation resulted in a rapid decline of NO_x, CO_2 and aromatic NMVOC (benzene, toluene, xylenes+ethylbenzene, and C_9 benzenes) fluxes (Fig. 4 A) reaching significantly lower emission fluxes relative to the "business as usual" scenario. The cumulative reduction of surface emissions of air pollutants (NO_x and aromatic NMVOC) closely follows traffic (Fig. 4 B and C), declining by about 64% during the lock-down period. At the end of the Austrian Lockdown, traffic counts and integrated emissions of NO_x, and aromatic NMVOC were -64 %, -59%, and -56% lower compared to the business as usual scenario. This is significantly lower than the observed reduction of CO_2 fluxes leveling out at about -38%. Notably benzene emissions also declined less pronounced than toluene and higher aromatic NMVOC, which track NO_x and traffic

341 loads more closely. These different sensitivities indicate a non-linear relationship between the

342 reduction of carbon dioxide and air pollution gases due to different urban combustion sources.

343 Particularly reductions of NO_x and CO_2 exhibit quite different emission trajectories during the

344 lockdown phase (Fig. 5). The observed reduction of air pollution gases, such as NO_x, is

345 significantly larger than estimated by early bottom-up model predictions for expected NO_x to CO_2

346 emission changes (Quéré et al., 2020). Can these observations be reconciled with bottom-up

347 emission projections?

348

349

350 **Discussion**

351 Our analysis indicates that the reduction of classic air pollutant emissions during the

352 SARS-CoV2 lockdown was more significant than that of CO_2 which comes as surprise.

353 Comparable to most European countries, Austrian specific bottom up emission models typically

354 attribute 40% of CO_2 emissions to traffic and 19% to the residential, commercial and public

355 (RCP) sector (UBA, 2019). For NO_x, Austrian and European bottom-up emission projections

356 predict similar contributions (ie. 58% from traffic and 12% from the RCP sector). In its simplest

357 form, by using a two member pollutant model, we can test these assumptions in more detail, and

358 compare our observations with an Austrian state of the art emission model (www.emikat.at) used

359 for national emission reporting. For the analysis we take advantage of the fact that the seasonal

360 influence on pollutant fluxes is factored in by referencing the flux analysis to the trained boosted

361 regression tree model. Further, measured relative reductions of vehicle counts are assumed to

362 represent the decrease of traffic activity reasonably well. We are then left with constraining the

363 intervention specific changes in the RCP sector. We argue that these must not have changed

364 much, because (a) heating appliances are primarily driven by temperature (Liu et al., 2020b)

365 (accounted for by our analysis) (b) changes in electricity needs do not enter the local pollutant

366 budget, and (c) less time spent in commercial/public buildings was compensated by more time in

367 residential buildings. Google mobility reports (Alphabet Inc., 2020) based on cellphone tracking

368 suggest a 20% increase in time spent in the residential sector and a 30% decrease in the

369 commercial/public sector for Tyrol during the lockdown period. The energy mix in Innsbruck for

370 heating demand is partitioned in residential and 'other' (Land Tirol). The relative contributions to

371 the energy mix for heating in these two broad categories are comparable. In the residential sector

372 it is comprised of 9% district heating, 34% oil, 34% natural gas, 16 % biomass, 6 % electricity

373 and the remainder (1%) attributed to alternative energy. The category 'other' (i.e. everything else)

374 is comprised of 4% district heating, 37% oil, 42% gas, 11% biomass, 4% electricity, and the

375   remainder (2%) attributed to alternative energy. Liu et al. (2020) estimated a decline of

376   commercial and residential emissions by 3.6%, Le Quéré et al. (2020) assumed an increase of

377   residential emissions by 4% and a decrease in the public sector by 33% for Europe. As a

378   conservative estimate we bracket changes in the RCP sector activity between 0 and -20%, with a

379   best estimate based on the local Google mobility index (-10%). The observed flux changes can

380   then be partitioned into NO_x emissions from vehicular traffic (94^{+2}_{-11}%) and the RCP sector

381   (6^{+11}_{-2}%) accordingly. For CO_2, benzene, toluene and the sum of aromatic NMVOC we calculate

382   59^{+7}_{-10}%, 70^{+5}_{-7}%, 94^{+2}_{-11}%, and 87^{+2}_{-11}% arising from vehicular traffic emissions, and 41^{+7}_{-11}%,

383   30^{+5}_{-8}%, 6^{+11}_{-1}%, and 13^{+2}_{-3}% respectively, coming from the RCP sector. These results suggest that

384   NO_x is dominated by vehicular traffic emissions and that CO_2 is partitioned more equally between

385   the traffic and RCP sectors. In contrast, urban NMVOC emissions are generally more diverse

386   (Karl et al., 2018). Here we investigate aromatic NMVOC, that are closely linked to combustion

387   processes and fossil fuel use (EPA, 1998). We observe that toluene and higher aromatic

388   NMVOCs closely track reductions of NO_x emissions and vehicular traffic activity. Benzene

389   declined less readily, suggesting that benzene emissions could be more prevalent from the RCP

390   sector. Speciated NMVOC emission factors from residential gas and oil combustion are still quite

391   uncertain, but recent reports from shale gas operations in the US for example indicate a higher

392   contribution of benzene than toluene emissions from natural gas combustion when compared to

393   traffic sources (Gilman et al., 2013; Halliday et al., 2016; Helmig et al., 2014).

394   After mapping NO_x and CO_2 emissions from a spatially disaggregated emission model on

395   the seasonal flux footprint (SI), the observationally inferred results from above can be compared

396   to the relative attribution of inventory based emission projections. As for NO_x and CO_2, the

397   official local bottom up emission inventory apportions 78% of NO_x fluxes coming from vehicular

398   traffic, and 21% from the RCP sector. For CO_2 these relative contributions are 54% (traffic

399   sector) and 46% (RCP sector), respectively. These inventory based results are roughly in line with

400   a recently published bottom-up assessment for CO_2 emissions (Quéré et al., 2020). We also find

401   that CO_2 fluxes are consistent with the relative emission attribution in the inventory, but that NO_x

402   emissions are significantly overestimated from the RCP sector (e.g. 21% vs 6%) in favor of traffic

403   (Fig. 4). This suggests cleaner NO_x combustion sources in the RCP sector and higher NO_x

404   emissions from the traffic sector.

405   The European gas demand has increased significantly over the past decades (European

406   Commission, 2020). As an example, consumption of natural gas increased by about a factor of 4

407   in Austria (Statistik Austria, 2019) since 1965, and has expanded to 9 billion m^3. Across Europe

408   growing demand has increased dependence on gas imports, triggering fierce competition between

409   major gas producing nations (European Commission, 2020). Apart from the power sector,

410   residential demand has contributed significantly to the overall consumption growth across Europe

411   (European Commission, 2020). While residential gas consumption per inhabitant varies quite

412   drastically across European countries, many countries have invested in developing the residential

413   sector towards a higher fraction of natural gas by fuel subsidy policies. Particularly urban areas,

414   where gas infrastructure is in place, have seen significant growth. As an example, the residential

415   energy sector has seen a doubling of the natural gas share for space heating appliances in Western

416   Austria over the last 9 years (Statistik Austria, 2019). In parallel, oil and solid fuel consumption

417   have decreased by about 40% in the residential sector over the same period. On average, gas

418   represents about a third of the final energy consumption in the residential sector in Austria and

419   across Europe (European Commission, 2020). One of the reasons for promoting natural gas

420   through subsidies in the past was that gas combustion releases about 25% less CO_2 than oil and

421   40% less than solid fuels (IEA, 2020). In addition to more efficient energy production, natural gas

422   combustion releases less air toxics, such as NO_x, CO, NMVOC and SO_2, when compared to

423   biomass and other solid fuels (EEA, 2019). However, emissions from the RCP sector are quite

424   uncertain and often rely on TIER I upscaling methodology (Blain et al., 2019; EEA, 2019). As the

425   European community is committed to transitioning to a carbon-neutral economy (OECD, 2015),

426   the air quality benefit from natural gas in the residential sector needs to be considered,

427   particularly when introducing renewable alternatives such as wood and pellet combustion on a

428   large scale. Our data suggest that the air quality benefit for the release of reactive nitrogen in the

429   RCP sector might have been underestimated in bottom-up emission inventories used for policy

430   making. Official inventory data show that the increase of natural gas combustion in the RCP

431   played a significant role in Europe's energy policy. Wood combustion on the other hand would

432   release significant amounts of reactive nitrogen in the gas and aerosol phase depending on fuel N

433   content (Roberts et al., 2020). While pellet combustion is considered cleaner than wood

434   combustion, TIER I emission factors for NO_x are still about twice as high compared to natural gas

435   combustion, and the release of aerosols is of particular concern (EEA, 2019). When transitioning

436   to a climate neutral economy, the air quality penalty arising from some renewables needs to be

437   sustainable. From the present analysis we find that the biggest gain for the reduction of urban NO_x

438   in Europe remains in the mobility sector, and that NO_x emissions from the RCP sector are

439   significantly lower than expected. Europe's push towards a Diesel driven car fleet has helped to

440   curb CO_2 emissions in the mobility sector, but created excess emissions of nitrogen oxides. While

441   the extent of cheating devices used in cars to simulate lower than actual NO_x emissions is still

442   unravelling, aggressive reductions of nitrogen oxides are needed to meet Europe's air quality

443   goals (EU-EUR-Lex, 2008). A significant NO_x emission reduction in the mobility sector could

444   help counteract potential increases of air pollutants from promoted renewables such as biomass

445   combustion in the future. Urban eddy flux methods present a top down methodology allowing to

446   quantify and test urban sustainability goals of air pollution and climate gas emissions. In

447   combination with an intervention experiment as shown here they can provide a unique and

448   independent verification method of anticipated air quality and climate policy targets.

672

673 **Acknowledgments**
674 We thank Christoph Haun, Land Tirol, Johann Haun, TIGAS, and Florian Haidacher, Land Tirol,
675 for providing official emissions, gas consumption and traffic data referenced in this study.
676 Funding: This work was supported by the Austrian National Science fund (FWF) through grant
677 P30600.

678 **Code availability:** codes used to analyse eddy covariance data are open source and can also be
679 requested from the corresponding author.
680 **Author contributions:** T.K. conceived the overall analysis. T.K., C.L., M.G. designed and
681 performed the field experiments, and interpreted the data. M.S. (1) conducted the NMVOC flux
682 analysis. M.S. (2) assisted with the field experiments. All authors contributed to writing the
683 manuscript.

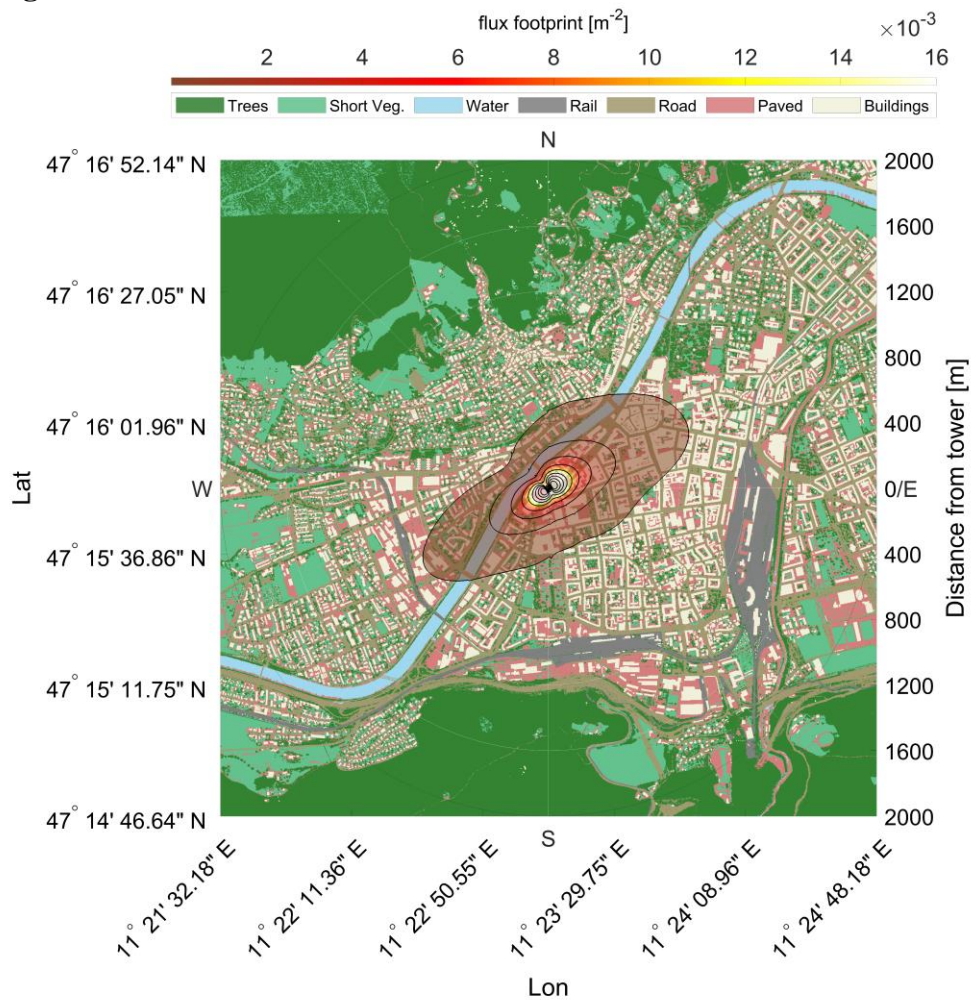
688 **Figures**


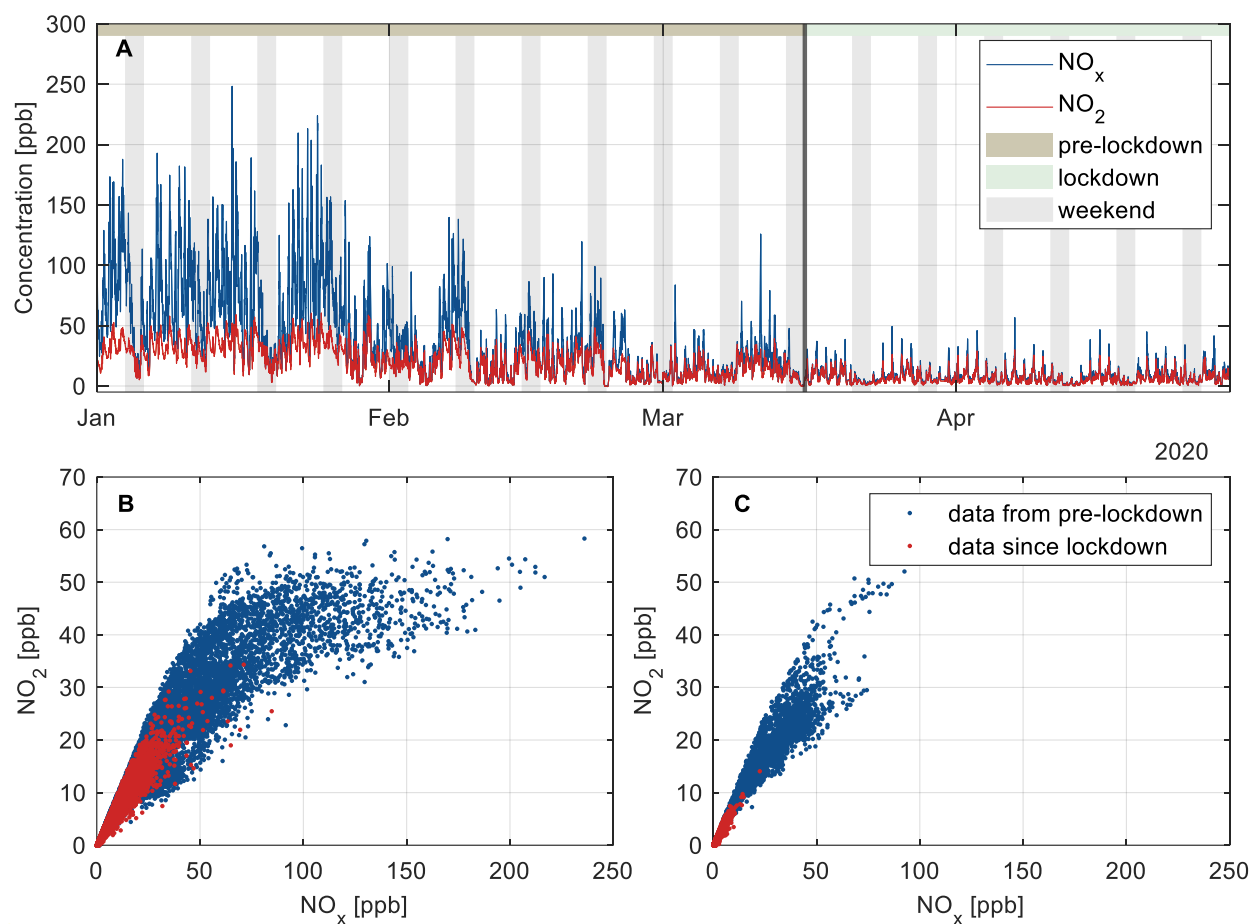
689
690
691 **Fig. 1:** Flux footprint surrounding the IAO tower plotted on top of a gridded landuse map derived
692 from OpenStreetMap (© OpenStreetMap contributors 2020. Distributed under a Creative
693 Commons BY-SA License).
694


Fig. 2 (A): Time series of ambient NO_2 and NO_x mixing ratios before and during the lockdown. Shaded gray vertical bars indicate weekends. The gray vertical solid line depicts the start of lockdown measures on March 16th 2020; **(B):** NO_2 vs NO_x during weekdays (Tuesday to Thursday); **(C):** NO_2 vs NO_x on Sundays
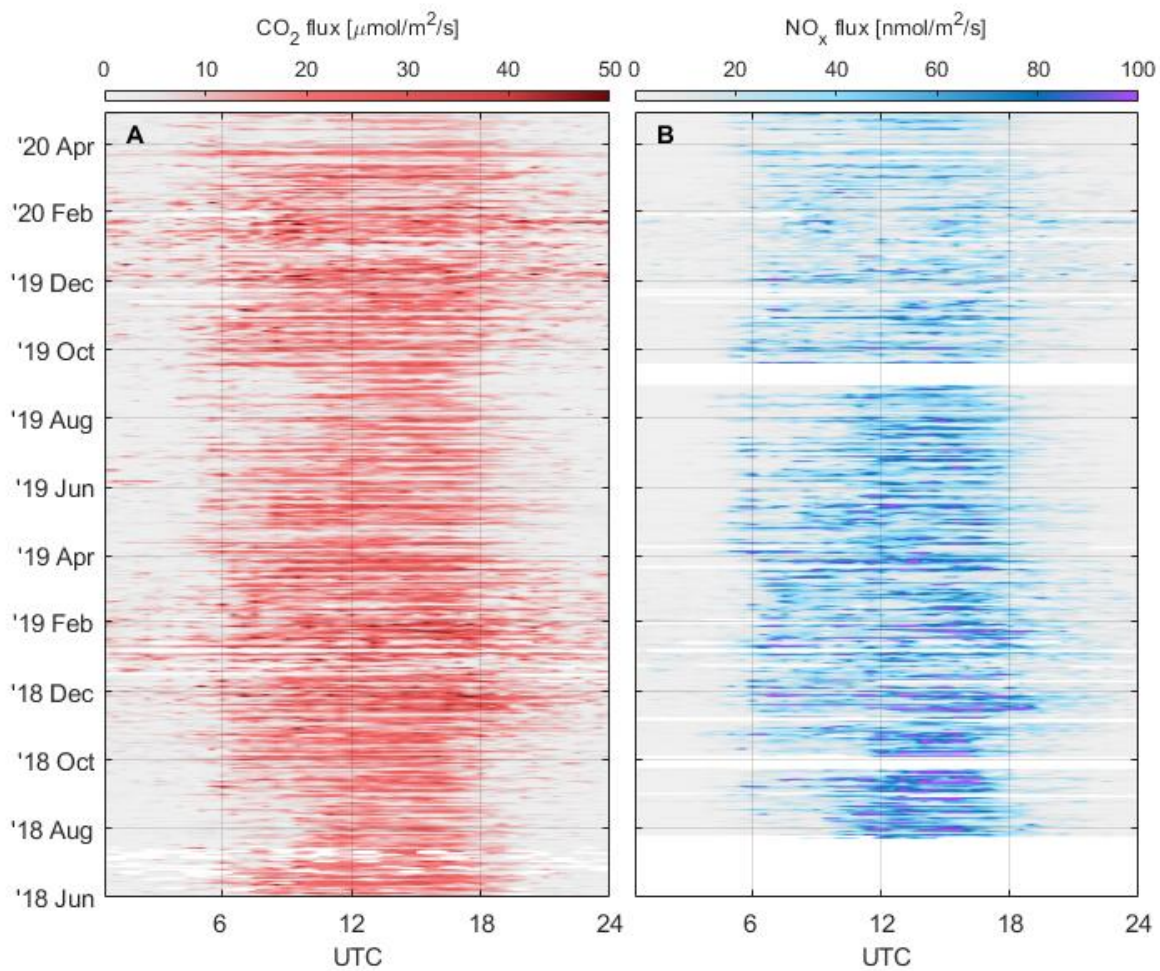
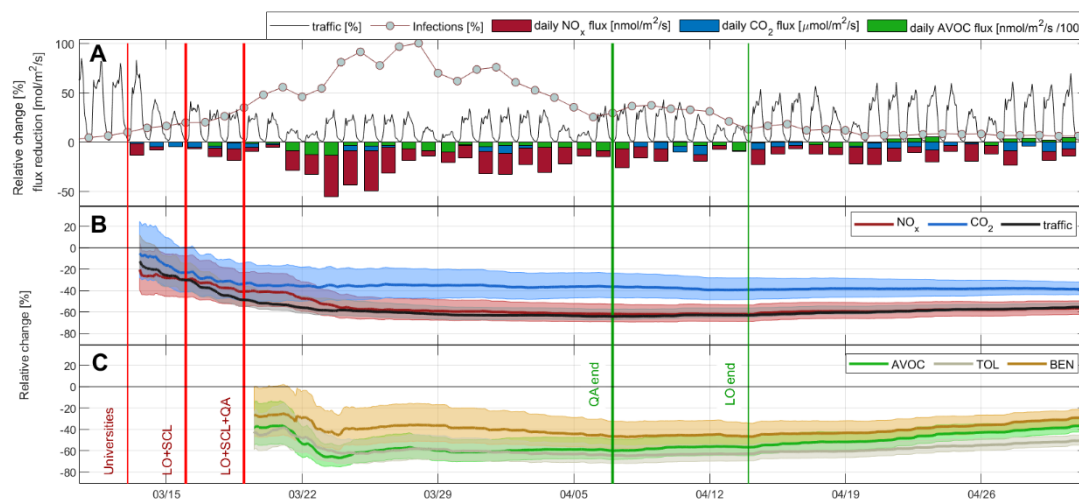
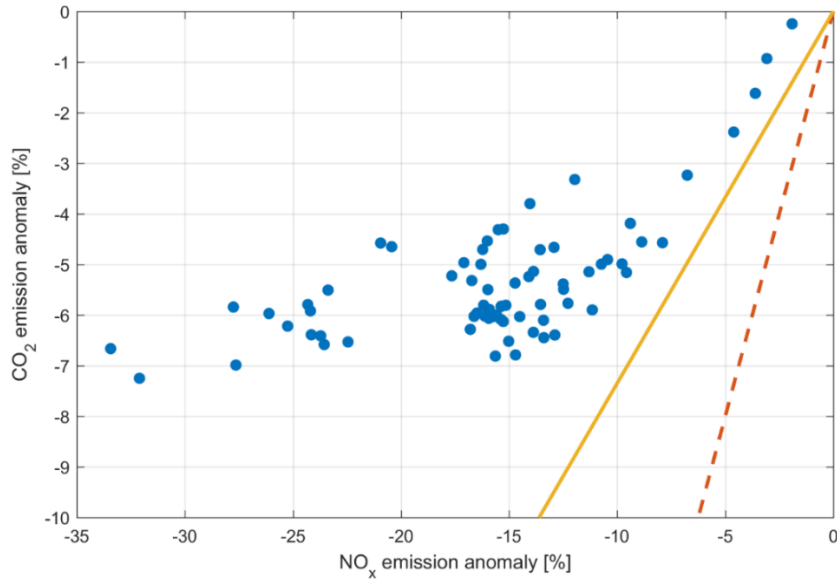


701
702 **Fig. 3** Diurnal variations of CO_2 **(A)** and NO_x **(B)** fluxes since 2018.
703

704


705
706 **Fig. 4.** Observed changes of air pollutant fluxes, CO_2 flux and traffic during the course of the first
707 SARS-CoV2 wave: **(A)** Normalized traffic counts, daily infection rate and daily average
708 flux reduction. **(B)** Cumulative reduction of NO_x, and CO_2 fluxes and traffic activity. **(C)**
709 Cumulative reduction of aromatic VOCs (AVOC), toluene (TOL) and benzene (BEN)
710 fluxes. Red vertical lines indicate the start of University closure, Austrian Lockdown
711 (LO), school closure (SCL) and quarantine (QA) in the state of Tyrol. Green vertical lines
712 show the lifting of mobility restrictions. Light shaded areas represent the uncertainty of
713 the boosted regression tree model analysis (SI).
714

715


716
717 **Fig. 5.** Daily change of CO_2 and NO_x fluxes during the lockdown period. Flux observations are
718 depicted by the blue dots. Emission model projections are represented by the solid orange
719 line (Austrian emission inventory) and the dashed red line (Quéré et al., 2020).
