Abstract. The variation of NO₂ concentrations in mainland China is analyzed on different time scales, from decadal to weekly, using both satellite data and data from ground-based monitoring networks. TROPOMI (TROPOspheric Monitoring Instrument) data were used to study the spatial variations of tropospheric NO₂ vertical column densities (TVCDs) over the study area during 16-20 weeks after the Chinese Spring Festival (25 January 2020). These data were used to select 11 regions for more detailed analysis of the variation of NO₂ TVCDs on a decadal time scale. In this analysis, monthly and annual averaged NO₂ TVCDs derived from OMI (Ozone Monitoring Instrument) observations were used for the years 2011 to 2019. The results show the NO₂ TVCD trends for different regions, all decreasing in response to emission reduction policies, but with a different onset and a possible halt of the decrease in recent years; trends and period in the south of the study area are different from those in the north. Variations of NO₂ TVCDs on shorter time scales, monthly and weekly, were analyzed using TROPOMI data. In addition, the variations of weekly averaged ground-based NO₂ concentrations in 11 major cities were analyzed together with those for O₃ and PM_{2.5}. In particular these data were used to determine their effect on the air quality as expressed by the air quality index (AQI). For quantitative estimates, the use of weekly concentrations is more accurate than the use of monthly values, and the effects of long term trends and their reversal needs to be taken into account for the separation of effects of the lockdown and the Spring Festival. Neglecting the possible reversal of the trends leads to overestimation of the lockdown effect in the south and underestimation in the north. The ground-based data confirm earlier reports, based on satellite observations, that the expected improvement of air quality due to the reduction of NO₂ concentrations was offset by the increase of the concentrations of O₃ and the different effects of the lockdown measures on PM_{2.5}, as well as effects of meteorological influences and heterogeneous chemistry. The AQI seems to be mostly influenced by PM_{2.5} rather than NO₂. A qualitative comparison between time series of satellite and ground-based NO₂ observations shows both similarities and differences. The study further shows the different behavior in city clusters in the north and south of China, and inland in the Sichuan and Guanzhong basins. Effects of other holidays and events are small, except in Beijing where the air quality in 2020 was notably better than in previous

years. This study was undertaken for China, but the methodology and results have consequences for air quality studies in other areas and part of the conclusions are generally applicable.

1. Introduction

45 Concentrations of aerosols and trace gases in the atmosphere over China have been increasing in response to industrial development and urbanization and are among the highest worldwide. However, during the last decade, air pollution control strategies were implemented as part of a series of government plans to reduce the concentrations of pollutants (Jin et al., 2016; van der A et al., 2017; Zheng, 2018) and thus improve air quality. Indeed, the concentrations of SO₂, NO₂ and aerosols decreased and the trends, from the on-set of the reduction
50 until recent years, have been quantified using satellite observations (Krotkov et al., 2016; Koukouli et al., 2016; van der A et al., 2017; de Leeuw et al., 2018; Sogacheva et al., 2018; Zhao et al. 2017; Zhang et al., 2018). In addition, an unprecedented reduction of the concentrations of NO₂ was observed at the end of January, 2020, by the TROPospheric Monitoring Instrument (TROPOMI), on board the Copernicus Sentinel-5 Precursor satellite, following the nationwide lockdown in response to the COVID-19 outbreak (e.g., Fan et al., 2020a; Liu et al.,
55 2020; Bauwens et al., 2020). The decrease of anthropogenic NO₂ emissions in early 2020 was quantified by, e.g., Ding et al. (2020) and Zhang et al. (2020a). In response to the reduction of the NO₂ emissions, observations at ground-based monitoring stations showed the increase of O₃ concentrations (e.g., Fan et al., 2020a; Shi and Brasseur, 2020; Le et al., 2020), indicating the increase of the oxidizing capacity of the atmosphere (e.g., Huang et al., 2020; Diamond and Wood, 2020; Le et al., 2020; Zhao et al., 2020). The increased oxidizing capacity of
60 the atmosphere resulted in the increase of secondary aerosol formation which in part explains the increase of the aerosol optical depth (AOD) over the North China Plain (NCP), observed from satellites (e.g., Fan et al., 2020a; Huang et al., 2020; Le et al., 2020; Diamond and Wood, 2020), and the concentrations of PM_{2.5} observed in situ by ground-based monitoring networks (e.g., Fan et al., 2020a; Shi and Brasseur, 2020; Le et al., 2020). Over the NCP, aerosol formation was further promoted by meteorological conditions like low wind speed and high
65 relative humidity, conducive of the formation of haze (e.g., Zhao et al., 2020). Furthermore, aerosol emissions were much less affected by the lockdown than NO₂ (Diamond and Wood, 2020). Hence, different species contributing to air pollution were affected by the lockdown in different ways. Several authors concluded that, in spite of the strong reduction of anthropogenic emissions, pollution still occurred over China due to the combination of meteorological influences, economic impacts and complex chemistry (e.g., Shi and Brasseur,
70 2020; Huang et al., 2020; Diamond and Wood, 2020; Le et al., 2020; Zhao et al., 2020; Li et al., 2020). In the current study we examine the evolution of the concentrations of tropospheric NO₂ in China over the last 10 years, until mid-2020. To this end, we extend satellite-derived time series of tropospheric NO₂ vertical column densities (NO₂ TVCDs) derived from satellite observations using the Ozone Monitoring Instrument (OMI) from 2011 to 2019, which provides insights in the effects of pollution control strategies in different parts
75 of China during recent years. The sudden reduction of the concentrations of NO₂ and other atmospheric constituents due to the unfortunate lockdown following the COVID-19 outbreak in China provided another way to look at emission reductions and the recovery of the concentrations when the lockdown was gradually relaxed. The latter extends earlier work presented in Fan et al. (2020a) on the concentrations of trace gases and aerosols during the Chinese Spring Festival (25 January 2020) and the initial phase of the lockdown during the following
80 month. It is noted that the lockdown started during the Spring Festival holidays, during which concentrations of

trace gases and aerosols usually change in response to changing socio-economic conditions during 1-2 weeks. This Spring Festival holiday effect was enhanced and extended over a longer period of time due to the lockdown. In the current study we focus on the variations of NO₂ concentrations both in the years before the 2020 Spring Festival, and during an extended period of 16-20 weeks thereafter, for reasons explained below.

85 In Fan et al. (2020a) we considered all species contributing to the air quality index (AQI, see Appendix A for definition), a measure used in air quality management. However, air quality, or the AQI, was not directly considered in Fan et al. (2020a), we only looked at the change of the concentrations of PM_{2.5}, PM₁₀, NO₂, SO₂, CO and O₃ due to the lockdown. For all species we used satellite data (TROPOMI), except for tropospheric O₃ which is not available over China from TROPOMI, and ground based monitoring observations. TROPOMI data
90 were used for 2019 and 2020, as monthly averages for the period before and after the Spring Festival in these years. The changes resulting from reduced anthropogenic activities during the Spring Festival holidays in 2019 were used as reference to separate the lockdown effect from the overall reduction during the period including both the Spring Festival and the lockdown in the winter of 2020. We concluded that the use of 30-days averages leads to underestimation of the Spring Festival effect and overestimation of the COVID-19 lockdown effect and
95 that for more reliable estimates shorter periods should be used. Therefore, in the current study, weekly maps of tropospheric NO₂ vertical column densities (NO₂ TVCDs) were produced as a compromise between increased time resolution, showing the progressive decrease of the concentrations, and data quality. In Fan et al. (2020a) we concluded that the TROPOMI SO₂ data showed the reduction of SO₂ but the signal was too noisy to deduce a clear quantitative effect, while we also showed that the lockdown did not have a clear effect on the CO TVCDs
100 (except in the south of China). Therefore, and because of the interactions between NO₂, O₃ and aerosols, the current study focuses on these three species, using both satellite data and ground-based data from air quality monitoring stations. Instead of the 26 provincial capitals, 11 areas in different parts of China were selected where satellite data showed large changes in the NO₂ TVCDs.

When the lockdown measures were gradually relaxed, the emissions and thus air pollution increased. Several
105 studies reported that air quality was “back to normal” after 40 days (Bauwens et al., 2020; Filonchyk et al., 2020; Wang and Su, 2020). In the current study we address the question what is “normal”, using satellite observations over the last decade over selected regions, extending to 16-20 weeks after the 2020 Spring Festival. In addition to satellite data, we use ground-based observations from the Chinese air quality monitoring network providing detailed information in different regions, and compare those for 2020 with similar observations in the last 5 years
110 (2015-2019). The reason for this study is the gradual decrease of NO₂ TVCDs and AOD during extended periods in the last decade, as mentioned above, in response to policy measures by the Chinese Government to reduce emissions and improve air quality. In the estimates of the lockdown effects on air pollution such trends were accounted for by comparison of 2020 with the previous year or years. However, the NO₂ TVCDs in early 2020, before the Spring Festival, were much lower than those in 2019 and the question arose whether the trends
115 derived in earlier studies were continued in more recent years. In other words, how well can the expected baseline concentrations, serving as reference to determine the reduction of the concentrations during the lockdown period with respect to the “normal” situation, be determined?

Another question was whether air quality (AQ) was really improved, in spite of the enormous reduction of NO₂ as observed by satellites and confirmed by ground-based monitoring networks. As discussed above, in response
120 to the reduced NO₂ concentrations shifting the oxidizing capacity, surface O₃ concentrations increased, and also

aerosol concentrations were affected, or even increased over the NCP. Taking into account the different behavior of NO₂, O₃ and PM_{2.5}, the question arose what the effect of the lockdown was on the air quality, as expressed by the air quality index and how AQ or AQI reacted to the gradual release of the socio-economic restrictions.

The objectives of the current study are thus (1) to extend the time series from previous studies to evaluate whether earlier trends continued and can be used to determine baseline concentrations; (2) to determine whether the air quality was indeed improved as much as anticipated from the reduction of NO₂ TVCDs deduced from satellite observations; (3) to evaluate whether the pollutant concentrations had returned to normal levels during the study period of 16-20 weeks after the COVID-19 outbreak, i.e. during the gradual relaxation of the lockdown measures when socio-economic life returned to normal. (4) during these 19 weeks, two significant events occurred in China: the Tomb Sweeping Festival (4-6 April) and the May holidays (1-5 May). In addition the Party Congress took place in Beijing (21-28 May). How did these events influence the air quality?

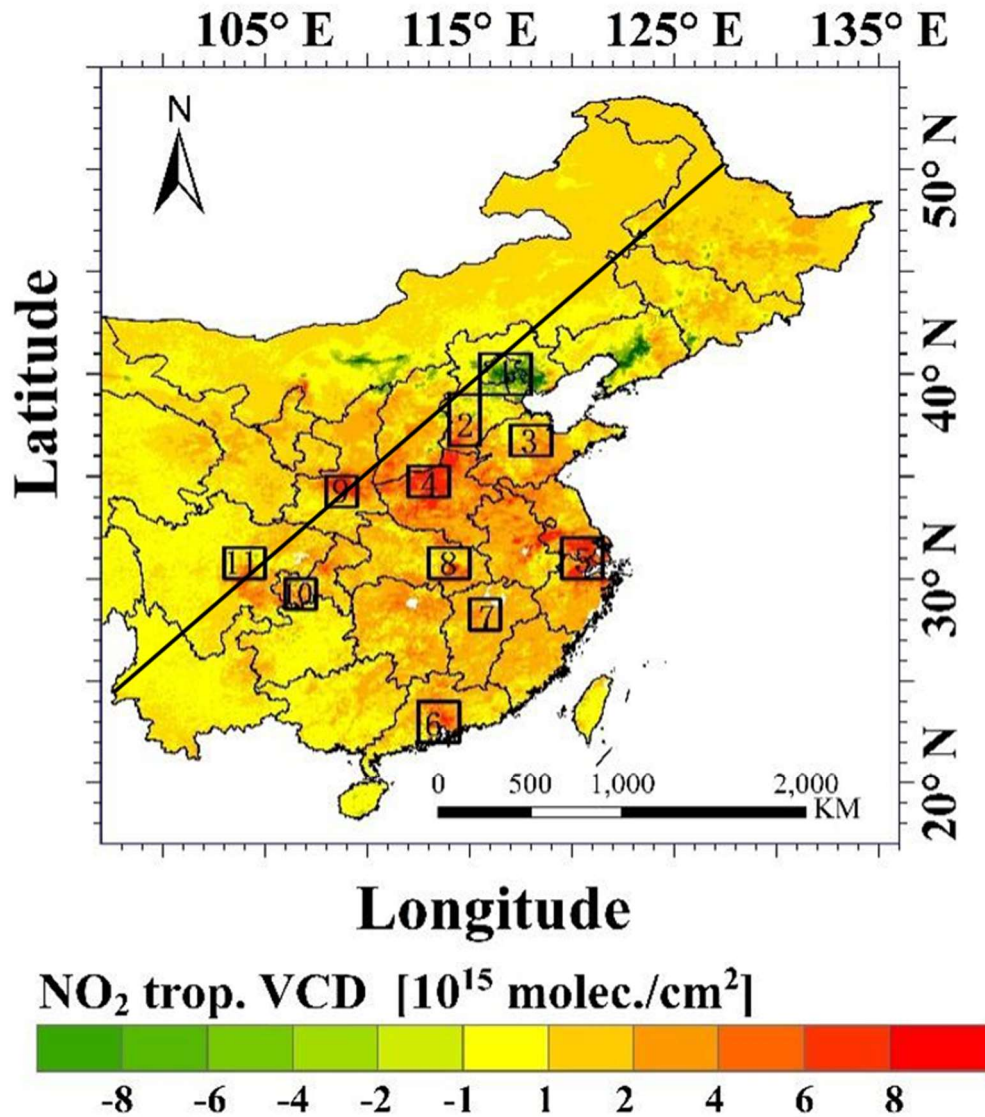

These objectives are addressed by studying satellite measurements of NO₂ TVCDs and ground-based monitoring data of PM_{2.5}, NO₂, and O₃, and the air quality index (AQI). Differences between satellite observations and ground-based monitoring NO₂ data are discussed based on weekly time series during early 2020. Time series of monthly averaged NO₂ TVCDs for the period 2011-2020 are used, and weekly averages in 2020. The study focuses on 11 regions in China, mainly around provincial capitals, selected based on the NO₂ TVCD levels at about 3 months after the 2020 Spring Festival. It is noted that the methodology and part of the ensuing results have generally applicability and do not only apply over China.

2. Methods

2.1 Study area

In the current study we focus on the part of mainland China east of the HU line (Figure 1), further referred to in this paper as east China, where 94% of the Chinese population lives (Chen et al., 2016). This part of China is one of the most polluted regions in the world, for which the air quality was much improved during the COVID-19 lockdown. To monitor the rebound of the concentrations when the lockdown measures were gradually released, maps were used of weekly-averages of NO₂ TVCDs derived from TROPOMI (see Sect. 3.1.2, Figure 5) and their differences with respect to week 0, i.e. the Spring Festival week from 25 to 31 January, 2020 (week numbers are listed in Table A1, difference maps are presented in Figure A3). The difference map for week 12 is shown in Figure 1 (week 12 was somewhat arbitrarily selected at the end of a period of 5 weeks when concentrations seemed to be stabilized and undisturbed by other festivals, as discussed in Sect. 3.1.2). The yellow background in this map indicates no changes with respect to week 0, red an increase and green a decrease of the NO₂ TVCD. Based on the occurrence of a strong increase or decrease, 11 regions were selected for the study on regional differences in which satellite data are complemented with ground-based data. The names of the regions shown in Figure 1 are listed in Table 1, together with their geographical locations. These regions include well-known centers such as the Beijing-Tianjin area, Shijiazhuang in west Hebei and Jinan in Shandong, all in the North China Plain (NCP), Shanghai in the Yangtze River Delta (YRD), Guangdong in the Pearl River Delta (PRD), Chongqing and Chengdu, and Wuhan. Each region includes a large city for which monitoring data are available for comparison with the satellite data (Fan et al., 2020a). The selected regions provide a reasonable geographical spread across the study area with the NCP, the YRD and the PRD, as well as mountain areas with large basins such as the Chongqing/Sichuan and the Guanzhong Basins, all with high pollution levels, high

160 population density and high level of industrialization, but different climatological and meteorological influences on air quality.

165 **Figure 1.** Study area showing the NO₂ TVCD difference map for week 12 (i.e. NO₂ TVCD for week 12 minus NO₂ TVCD for week 0). The 11 focus regions are indicated with numbers, corresponding to their names and coordinates which are listed in Table 1. The black diagonal line is the Hu line (Chen et al., 2016).

170 **Table 1.** Focus regions of the current study. The locations corresponding to the numbers in the first column are shown on the map in Figure 1. Coordinates in columns 3 and 4 are the left upper corner of each region, the size around the corner of each region is indicated in columns 5 and 6. Regions are indicated with the name of the central city.

Nr	Name	Longitude(°)	Latitude(°)	Δ Lon(°)	Δ Lat(°)
1	Beijing-Tianjin	108.0	35.0	1.5	1.5
2	Shijiazhuang	114.0	39.0	1.5	2.5
3	Jinan	117.0	37.5	2.0	1.5

4	Zhengzhou	112.0	35.5	2.0	1.5
5	Shanghai	119.5	32.0	2.0	2.0
6	Guangzhou	112.5	24.0	2.0	2.0

8	Wuhan	113.0	31.5	2.0	1.5
9	Xi'an	108.0	35.0	1.5	1.5
10	Chongqing	106.0	30.0	1.5	1.5
11	Chengdu	103.0	31.5	2.0	1.5

2.2. Satellite data

Two satellite products were used in this study, i.e. the tropospheric NO₂ vertical column densities (NO₂ TVCDs) from OMI and TROPOMI. These products are briefly discussed in the following sub-sections. The OMI NO₂ TVCDs were used for time series analysis over the period 2011-2019, during most of which TROPOMI data were not yet available. The TROPOMI NO₂ TVCDs, with better spatial resolution, were used to visualize weekly averaged spatial variations and calculate time series over selected regions, which together show the evolution of NO₂ TVCDs over the study area. OMI and TROPOMI products thus provide complementary information for different periods of time and were used for different purposes.

2.2.1 OMI

The Ozone Monitoring Instrument (OMI) on board NASA's Aura satellite was launched in July 2004 (Schoeberl et al., 2006; Levelt et al., 2018). Aura is in a sun-synchronous polar orbit with an equator-crossing time at 13:30 local time (LT). The OMI instrument employs hyperspectral imaging in a push-broom mode to observe solar radiation backscattered by the Earth's atmosphere and surface at 740 wavelengths over the entire range from 270 to 500 nm with a spectral resolution of about 0.5 nm (<https://projects.knmi.nl/omi/research/instrument/index.php>, last access: 30 January 2021). With a 2600 km wide swath, OMI provides daily global coverage in 14 orbits. In this study the OMI Quality Assurance for Essential Climate Variance (QA4ECV) version 1.1 product (doi:10.21944/qa4ecv-no2-omi-v1.1) with a 13 x 24 km² spatial resolution is used (Boersma et al., 2018). This product was validated by, e.g., Lorente et al. (2017) and Zara et al. (2018). The measurement of NO₂ is one of the explicit objectives of the Aura OMI mission. The monthly mean tropospheric NO₂ column density data are derived from satellite observations based on slant column NO₂ retrievals with the DOAS technique and the KNMI combined modelling/retrieval/assimilation approach (Boersma et al., 2011). NO₂ TVCDs for the years 2011 - 2019 were downloaded from the following website: <http://www.temis.nl/airpollution/no2.html> (last access: 30 January 2021).

2.2.2 TROPOMI

TROPOMI is a passive hyperspectral nadir-viewing imager on board the Sentinel-5 Precursor satellite (also known as Sentinel-5P) launched on 13 October 2017 (Veefkind et al., 2012). Sentinel-5P is a near-polar orbiting sun-synchronous satellite flying at an altitude of 817 km in an ascending node with an equator crossing time at 13:30 LT and a repeat cycle of 17 days. The swath width is approximately 2600 km, resulting in daily global

200 coverage, with an along-track resolution of 7 km (Veefkind et al., 2012). TROPOMI products used in this study are L3 off-line (OFFL) version products (see <http://www.TROPOMI.eu/data-products/> for more detail), in particular tropospheric NO₂ vertical column density data for the period around the 2020 Spring Festival. The spatial resolution at nadir for most products used in this study is 1 km (<https://developers.google.com/earth-engine/guides/scale>; last access: 30 January 2021).

205 The operational validation results are reported every 3 months at the S5P-MOC-VDAF website (<http://mpc-vdaf.TROPOMI.eu/>, last access: 30 January 2021). The TROPOMI/S5P tropospheric NO₂ column is operationally validated by the S5P-MPC-VDAF (S5P–Mission Performance Centre – Validation Data Analysis Facility) using the Pandora NO₂ total columns from the Pandora Global Network (PGN). The comparison shows a negative bias of roughly 30%.

210 2.3 Ground-based data

The ground-based data used in this study were downloaded from <http://www.pm25.in/> (last access: 30 January 2021), which is the National Real-time Air Quality Publishing Platform public website for air quality monitoring data maintained by the China National Environmental Monitoring Center (CNEMC) of the Ministry of Ecology and Environment of China (MEE, see <http://www.mee.gov.cn/>, last access: 30 January 2021, for more detail).

215 This website provides PM_{2.5}, PM₁₀, SO₂, NO₂, O₃, and CO hourly and 24-hour moving averages for each site or city. Measurement techniques used at the stations, reliability of the data and quality control were briefly described by Silver et al., (2018) and Zhai et al., (2019); see also Ministry of Environmental Protection of People’s Republic of China (MEE, 2012). The data from these websites are provided by local governments and have been used in several studies related to air pollution, air quality, and other aspects in China (Xue et al., 2020; 220 Fan et al., 2020a; Fan et al., 2020b) (<http://www.pm25.in/sharer>, last access: 30 January 2021). For the current study, we collected hourly PM_{2.5}, NO₂ and O₃ data for the large cities in the 11 study regions indicated in Sect. 2.1 (Figure 1, Table 1), for up to 20 weeks after the Spring Festival during the years 2015–2020. In the current study, the data collected at different locations in each city were averaged to get a spatially representative number for the whole city, as daily (24 h) averages which subsequently were averaged to weekly values.

225 3. Results

3.1 Satellite Observations

3.1.1 NO₂ TVCD time series and trends for different regions between 2011 and 2019

3.1.1.1 Monthly mean NO₂ TVCD time series

230 Time series of monthly mean TVCDs for tropospheric NO₂ derived from OMI data over the 11 regions defined in Table 1 are presented in Figure 2, for the period from January 1st, 2011 until December 31st, 2019. The NO₂ TVCDs varied strongly by region, with the highest TVCDs in Shijiazhuang, Zhengzhou and Jinan (in 2012), although the relative differences changed from year to year. For each region, the time series show the strong seasonal variations with sharp peaks in the winter and shallow minima in the summer. The winter TVCD maxima were about a factor of 5 larger than the summer minima, with the ratio varying somewhat by region, 235 with higher values in Shijiazhuang (7.2) and Zhengzhou (6.0), and lowest values of about 2.5 in Guangzhou and

Chengdu. These numbers are in reasonable agreement with the factor of 3 reported by Shah et al. (2020) for the NO₂ TVCD averaged over central-east China.

On a monthly scale, the TVCD maximum varies a little between regions and years, but in general the peaks occur in the winter. For the study of lockdown effects (Sect. 3.1.2), the fast decrease of the NO₂ TVCDs from December/January toward the summer implies that, if there would be no restrictions, the NO₂ TVCDs would have decreased by a factor of 2.5-7, depending on the region, from the pre-lockdown period to the time when all measures were released. This needs to be taken into account in any study on the effect on air quality during different stages of the COVID-19 lockdown.

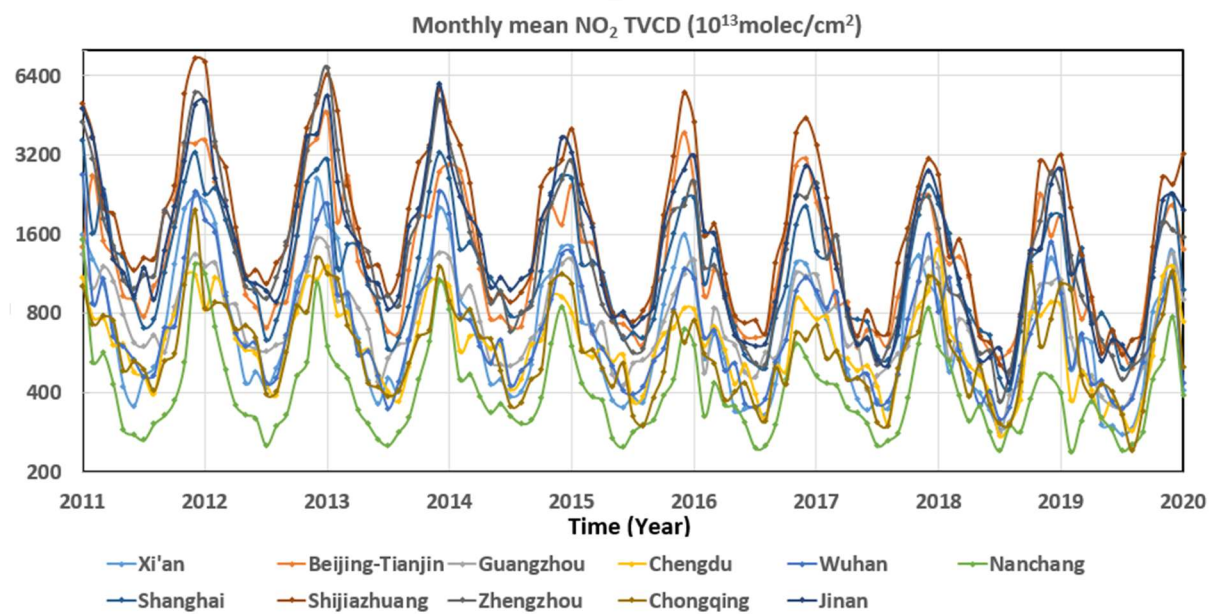

Figure 2. Time series of monthly mean NO₂ TVCDs derived from OMI data, for 11 regions from January 2011 to December 2019. The NO₂ TVCDs are plotted on a logarithmic scale to better visualize the differences between different regions as well as the gradual variation of the TVCDs during the summer months.

3.1.1.2 Trends of annually averaged tropospheric NO₂ TVCDs

Figure 2 shows an overall decrease of the winter-peak TVCDs between 2012 and 2017, whereas in the years 2017-2019 they are of similar magnitude, i.e. the decrease seems to have come to a halt. Similar behavior is observed in the summer months. However, the time series suggest that the period of decreasing NO₂ TVCDs and the occurrence of the maximum and minimum values was not the same for all regions. To further investigate trends in different regions and the differences between them, the time series were de-seasonalized using a centered moving average with a period of 12 months and, to reduce effects of variations due to other influences than the seasonal effects (e.g., due to meteorological conditions), the de-seasonalized data were averaged to annual mean NO₂ TVCDs. Time series of annual mean NO₂ TVCDs are presented in Figure A1. The data in Figure A1 show a grouping with high NO₂ TVCDs in the north of the study area and Shanghai, and a clear separation from the other regions where the TVCDs are lower, as also expected from the maps in, e.g., Figure 4a. Another noticeable difference between the regions is the clear distinction between the temporal behavior in the north and in the south. In each of the regions in the north, i.e. in the NCP (Shijiazhuang, Beijing, Jinan and Zhengzhou), the TVCDs were similar in 2011, 2012 and 2013; from 2013 they decreased exponentially until 2018. In the other regions, i.e. Shanghai and those in the south and west, the TVCDs decreased exponentially

from 2011 until they reached a minimum value in 2015 or 2016 after which they remained low (e.g., Shanghai, Nanchang, Xi'an) or even increased somewhat (Chongqing). Overall, after 2016 the TVCDs in these regions fluctuated from year to year but remained within 10% of the values in 2015 (except in Chongqing). In view of these differences, trend lines to the annual mean NO₂ TVCD data in regions in the north were fitted for the years 2013-2018, whereas for the other regions trend lines were fitted for the years 2011-2015 or 2016. . The trend lines were added to Figure A1 and the result is presented in Figure 3. The trend lines were plotted for the whole period 2011-2019, rather than only for their period of validity, to illustrate that beyond the fit interval the TVCDs do not follow the trend for the region under consideration and level off as discussed above. The trends are presented in Table 2, where the trend (year⁻¹) describes an exponential decrease of the TVCDs following the relationship $y=a \cdot e^{bt}$, where y = TVCD, a is the intercept (TVCD in first year of the fitting period, i.e. year1 = 2011 or 2013), b is the trend (year⁻¹) and t is the number of years after year1. Coefficients of determination (R^2) are all high and the trend lines in Figure 3 show the good fit.

275

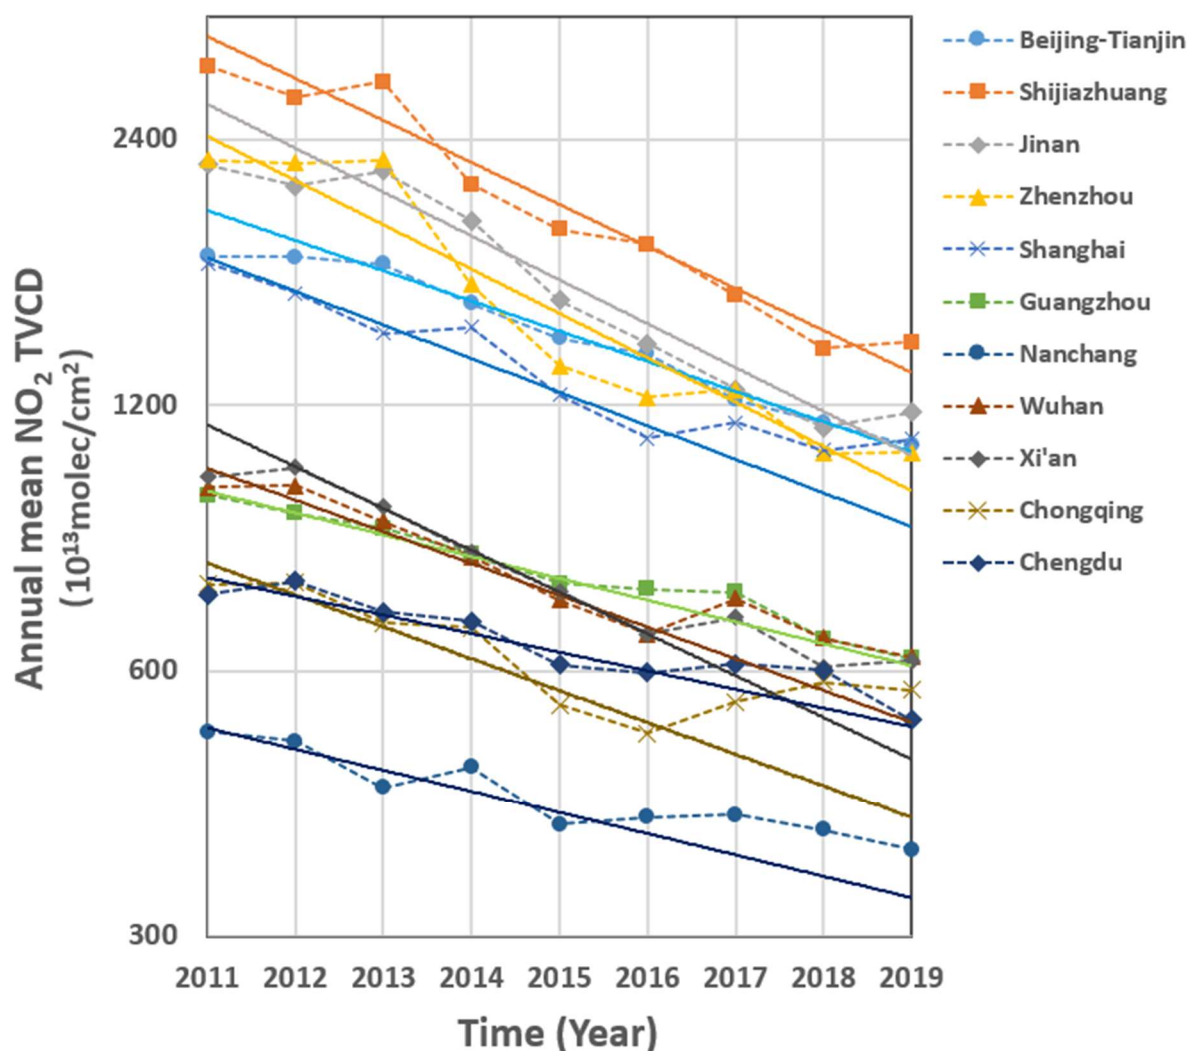

Figure 3. Time series of annual mean NO₂ TVCDs, derived from de-seasonalized monthly OMI data, for each of the 11 regions, plotted on a semi-logarithmic scale and fitted exponential trend lines (solid lines, $y = a \cdot e^{bt}$). The periods and trends (b) are listed in Table 2. The data points for each region are connected with dotted lines for easy identification. Note that the

280 trend lines strictly apply only to the different periods as described in the text and listed in Table 2, but were plotted over the whole period 2011-2019 to demonstrate the deviations from the trends beyond the period of validity.

Table 2. NO₂ TVCD trends determined for the period indicated in the 3rd column. Trends are determined using exponential fits ($y = a \cdot e^{bt}$) to time series of the annual mean NO₂ TVCDs as shown in Figure 3 and described in the text.

Number	Region	Period	Trend (year ⁻¹)	R ²
1	Beijing-Tianjin	2013-2018	-0.08	0.99
2	Shijiazhuang	2013-2018	-0.11	0.93
3	Jinan	2013-2018	-0.11	0.93
4	Zhengzhou	2013-2018	-0.12	0.84
5	Shanghai	2011-2016	-0.09	0.94
6	Guangzhou	2011-2015	-0.06	0.98
7	Nanchang	2011-2015	-0.06	0.80
8	Wuhan	2011-2016	-0.08	0.96
9	Xi'an	2012-2016	-0.11	0.99
10	Chongqing	2011-2016	-0.08	0.90
11	Chengdu	2011-2016	-0.05	0.88

285 3.1.1.3 Tropospheric NO₂ TVCD time series during the winter months

Having established that the annually averaged TVCDs decrease exponentially during a certain period of time and change little during more recent years (after 2015/2016, in the southern regions) or the last year (2019, in the northern regions), we need to determine whether these conclusions also apply to shorter periods of time during which effects of the lockdown on the concentrations of atmospheric trace gases are studied. As a compromise

290 between high time resolution and reducing meteorological effects on concentration differences, monthly averaged NO₂ TVCDs were selected and plotted as time series for the 11 study areas. Because in China the lockdown started in the winter and ended on April 8, 2020, and because the signals in the summer months are relatively weak, this was only done for the winter months. Furthermore, to exclude the effect of the Spring Festival on the NO₂ TVCDs, January and February were not used. This left November, December, March and

295 April for 2011-2019 and the results are presented in Figure A2. The data in Figure A2 show the overall decline of the NO₂ TVCDs, following the yearly trends and variations of the annual mean TVCDs in Figures A1 and 3 and the differences between the 11 regions for different periods. Overall, the periods when the NO₂ TVCDs decreased are similar to those indicated in Table 2. For Beijing and Shijiazhuang a strong minimum is observed in 2014 which may be associated with emission reduction because of the Asia-Pacific Economic Cooperation

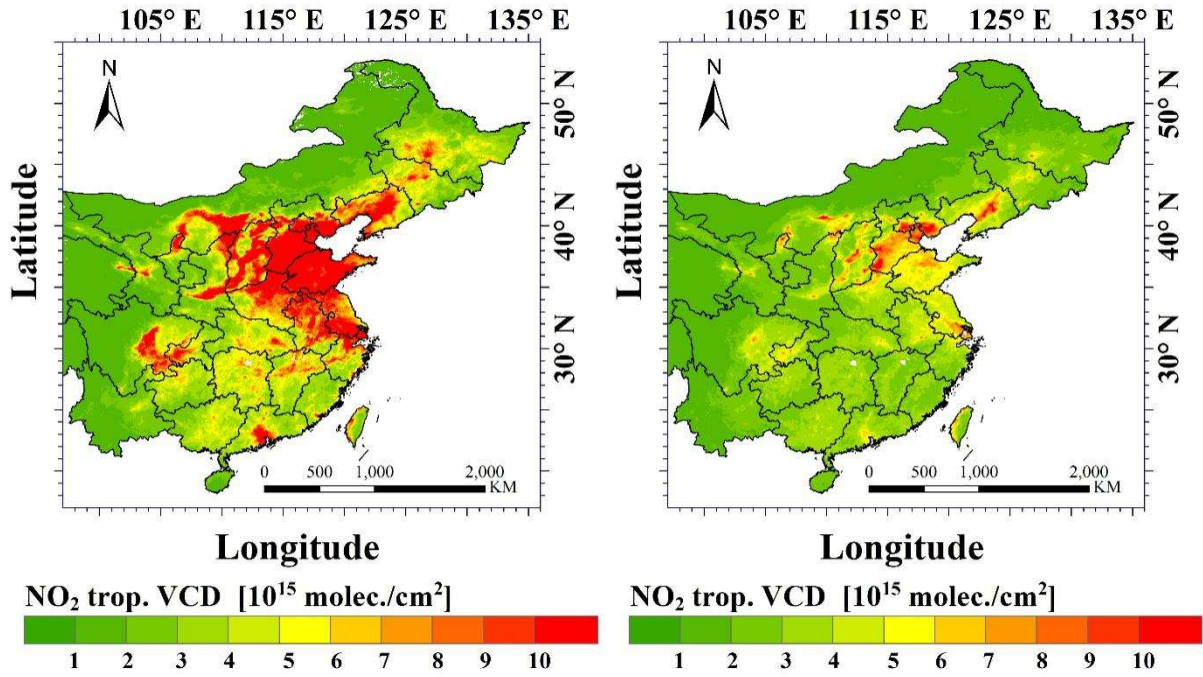

300 (APEC) meeting in Beijing in November 2014 and the China Victory Day Parade in September 2015. Interannual variability is stronger in the monthly mean data than in the annual means, as expected. Because of these variations, trend lines for monthly mean NO₂ TVCDs were not computed. The main message is that the TVCDs follow the tendencies in the annual means with leveling toward the end of the study period.

3.1.2 Evolution of NO₂ spatial distributions after the 2020 Spring Festival

305 For the evaluation of the spatial distributions and the short term time series of NO₂ TVCDs over small regions, TROPOMI data were used because of their improved spatial resolution as compared to OMI data (Sect. 2.2). NO₂ TVCDs derived from TROPOMI observations, averaged over 30 days before and after the 2020 Spring Festival, are presented in Figure 4. Figure 4 shows the large difference in the NO₂ TVCDs before and after the 2020 Spring Festival, similar to those used in Fan et al. (2020a) for all China to illustrate and analyze the effect of the COVID-19 containment policy measures. Fan et al. (2020a) concluded that the use of 30-days averages leads to underestimation of the Spring Festival effect and overestimation of the COVID-19 lockdown effect and that for more reliable estimates shorter periods should be used. Therefore, in the current study, weekly NO₂ TVCD maps were produced as shown in Figure 5. Here week numbers relate to the Spring Festival which was on Saturday January 25, 2020, i.e. week 0 is January 25-31, week 1 is February 1-7, etc. (see Table A1 for an overview of week numbers and dates). Weeks -1 to -3 are included as references for the NO₂ TVCDs during the period before the Spring Festival. The comparison of the monthly TVCDs in Figure 4 with the weekly TVCDs in Figure 5 (top row, weeks -3 to -1) clearly illustrates the advantage of using better time resolution to show the advancing decline of the NO₂ TVCDs in east China before the Spring Festival. The first lockdown in Wuhan was on 23 January, toward the end of week -1 and therefore the decline was mainly due to the decreasing economic activity associated with the Spring Festival. The combined effects of the Spring Festival and progressive lockdown in east China (Bao and Zhang, 2020) is visible in weeks 1-3, when the NO₂ TVCDs were lowest. The slight recovery in week 2 in the south of the study area may reflect the progressive nature of the lockdowns in different areas in China, i.e. toward the end of the Spring Festival holidays when people travelled back to their work places when it was still possible.

325 The maps in Figure 5, and the difference plots with respect to week 0 in Figure A3, show that overall the NO₂ TVCDs remained low over the whole study area during the first two weeks. Also in week 3 the NO₂ TVCDs were low, although some increase occurred over industrialized and populated areas north of the Yangtze River and in the Guangzhou area, which intensified every week from week 4 until week 8. In week 8 the NO₂ TVCDs reached high values and the spatial distributions and concentrations changed little during the next 5 weeks, except in week 10 when the NO₂ TVCDs were lower (although not in the YRD and Guangzhou). These reduced concentrations may be a sign of reduced emissions during the Tomb Sweeping Festival on 4-6 April. In week 13 the NO₂ concentrations were substantially lower than in the weeks before, and this continued in week 14. These weeks encompass the May Festival holiday (1-5 May), another very large national festival in China when many people travel home to their families: the associated change in socio-economic activities may explain the lower NO₂ concentrations during that time. After week 14 the NO₂ TVCDs increased in the southern provinces like Hunan and Guizhou as well as in the east around Shanghai, Jiangsu and Shandong, whereas in the northeast the NO₂ TVCDs first decreased, then decreased in week 18. Overall, the spatial patterns during these weeks were similar but the TVCDs changed, likely due to changes in economic activity and meteorological influences, but they did not reach values similar to those before the Spring Festival. However, this would not be expected as discussed in Sect. 3.1.1.

340

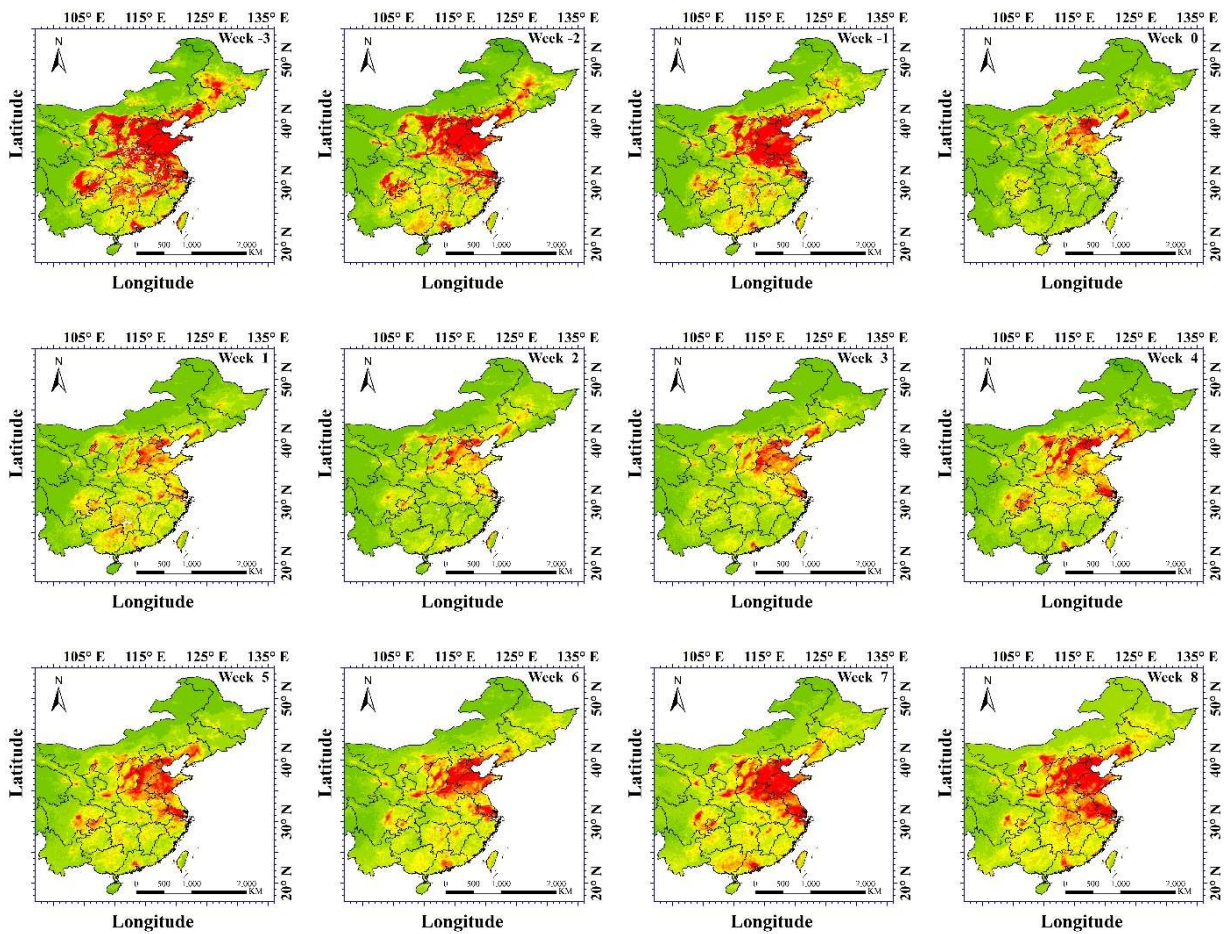

(a)

(b)

Figure 4. NO₂ tropospheric vertical column densities derived from TROPOMI data over east China, averaged over 30 days before (a) and after (b) the 2020 Spring Festival. The 2020 Spring Festival was on 25 January 2020 and thus the 30-days period before started on 26 December and the 30-days period after ended on 24 February 2020.

345

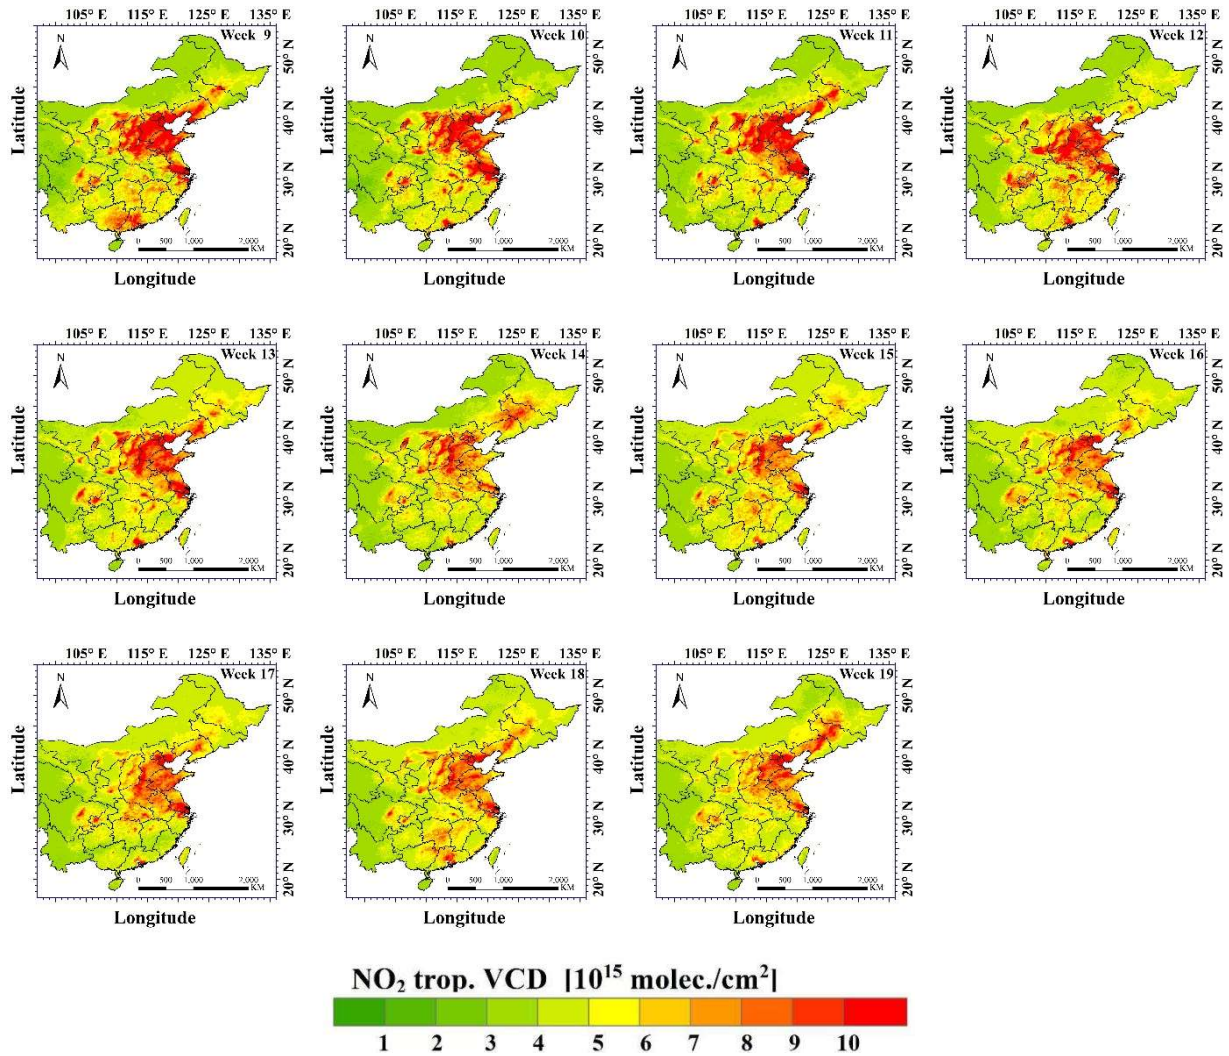

Figure 5. Maps of weekly averages of NO₂ TVCDs derived from TROPOMI data, for weeks -3 to -1 and week 0 (top row) and weeks 1-19 in the following rows. Note that week number refers to the 2020 Spring Festival, i.e. week 0 starts on Saturday 25 January 2020 (see also Table A1).

350 3.2 Effects on air quality: ground-based observations

3.2.1 Time series of air quality index for 11 regions

The air quality index (AQI) is based on the mass concentrations of PM_{2.5}, PM₁₀, NO₂, SO₂, CO and O₃ as described in Appendix A. AQI is determined by only one pollutant, i.e. the pollutant with the highest AQI. Time series for the AQI in the 11 cities identified in Table 1 were plotted for the first 16 weeks (weeks 0-15) after the Spring Festival in 2020. Tianjin was added as a second megacity in the metropolitan agglomeration because of its potentially different air quality due to large industrial activities as opposed to the capitol city (Beijing). AQI time series for the same weeks in the five previous years (2015-2019) were plotted to form a plume which serves as reference for the 2020 time series. The results are presented in Figure A4 which shows that there are large variations between the years and there is no specific ordering indicating a systematic temporal variation (tendency). Hence the plume is representative for the range of variations that can be expected in 2020 from other factors influencing the AQI than the lockdown, such as meteorological factors (provided that 2020 is not an exceptional year in regard of these other factors). It is noted, that the AQIs are weekly averages over all measurements in each city, created from 24-hour averages at each site.

Figure A4 shows the similarity between the AQI time series in the five cities in the NCP (Beijing, Tianjin, Shijiazhuang, Jinan and Zhengzhou), for the cities Shanghai, Guangzhou and Wuhan, and for Nanchang, Xi'an, Chongqing and Chengdu. In view of these similarities, one city was selected to represent each group for further analysis, i.e. Shijiazhuang represents the first group (Group 1), Wuhan represents Group 2 and Chongqing represents Group 3. It is noted that in the selection of these cities not only the AQI was considered but also time series of 6 individual pollutants (see below). The AQI time series for these three cities are included in Figures 6-8.

In 2020, the AQI in the cities in Group 1 fluctuated in the first 3 weeks and then stayed low until week 9; increased toward the plume in week 10 and then stayed at the bottom of the plume. Except in the first 3 weeks, the AQI is smaller than 100, indicating good air quality. For Group 2, the AQI fluctuated and the values indicate excellent to good AQ until week 10 when the AQI moved into the plume or occasionally above (Guangzhou) but still indicating good AQ. For Group 3 the AQI indicated good AQ, except in Xi'an (moderate) and decreased somewhat (Xi'an became "good") but remained in the plume throughout the whole study period. In other words, the AQI did not indicate better AQ for these cities in response to COVID-19 containment measures.

3.2.2 Time series of aerosols and trace gases affecting air quality

With the AQI determined by the pollutant with the highest AQI, which may not necessarily be the species observed from satellites such as NO₂, the behavior of individual pollutants contributing to the AQI will be considered using time series similar to those for the AQI. As discussed in the Introduction, we focus here on NO₂, O₃ and PM_{2.5} as the species which were most affected by the lockdown. Time series of the weekly averaged concentrations of these species in Shijiazhuang, Wuhan and Chongqing are presented in Figures 6, 7 and 8, respectively. Note that for some species the vertical scales may be different between the three cities. The concentrations during the five reference years (2015-2019) (further referred to as the plume) are used as reference to determine how the concentrations in 2020 were influenced by the lockdown. Overall, the concentrations of most pollutants in the plume were higher in Shijiazhuang than in Wuhan and Chongqing. This applies to PM_{2.5} (as well as for PM₁₀, SO₂ and CO which are not shown here), but not for NO₂ and O₃ for which the concentrations in the plumes in these three cities were similar. This is remarkable because the satellite NO₂ TVCDs in 2016 were about a factor of 3 higher in Shijiazhuang than in Wuhan which in turn were about 30% higher than in Chongqing (Figures 2 and 3) whereas in 2019 the NO₂ TVCDs were a factor of 2.3 higher in Shijiazhuang than in the other two regions where the TVCDs were similar. However, for an adequate comparison between satellite data and surface concentrations, and thus effects on AQ, factors influencing the relation between near surface concentrations and TVCDs need to be accounted for, such as meteorological factors driving vertical mixing. Also long-term trends, inter-annual variations, seasonal variations, local emissions and meteorological effects influencing (photo) chemical reactions determining the overall concentrations need to be considered. Such detailed quantitative comparison is however out of the scope of the current study; a qualitative comparison between TROPOMI-derived NO₂ TVCDs and surface concentrations of NO₂ will be presented in Sect. 3.3.

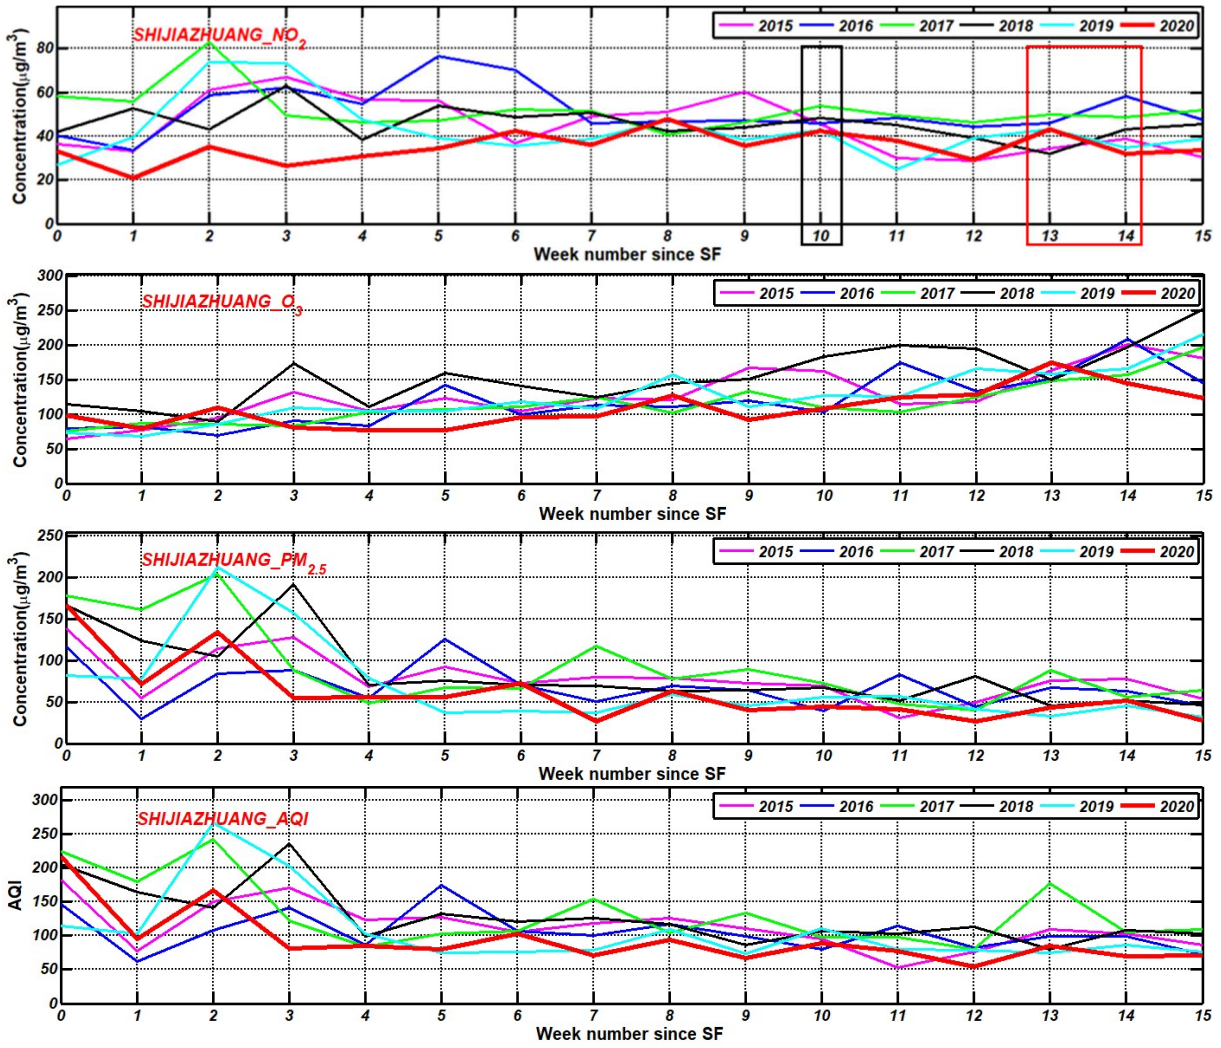

In all three cities the surface NO₂ concentrations are overall decreasing during the study period, following the seasonal variation which is also observed in the satellite data (Figure 2). However, in the satellite data the decrease is largest when concentrations are highest but, as discussed above, for the ground-based data the

concentration differences between the three cities are not large. Yet, the seasonal effect seems more pronounced in Shijiazhuang than in Wuhan than in Chongqing. This is also different from the satellite data (see Figure 2) and may be a life time effect related to lower temperatures in Shijiazhuang than in Wuhan and Chongqing.

Another difference between the three cities is the effect of the lockdown on the evolution of the surface NO₂ concentrations. In Shijiazhuang the plume decreased after week 3 whereas the 2020 concentrations increased steadily from week 0 and the curve joined the plume in week 6 although remaining near the bottom of the plume. In Wuhan the 2020 concentrations were far below the plume (20 µg·m⁻³ vs 40-60 µg·m⁻³) until week 9 after which they suddenly increased in week 10 to remain just below the plume (~40 µg·m⁻³). In Chongqing the NO₂ concentrations were low (20 µg·m⁻³) during the first 3 weeks, then increased and remained close to the plume in weeks 6 to 9 and merged into the plume from week 10.

When NO₂ concentrations decreased, O₃ concentrations increased as observed for all three cities. However, there was no substantial difference between the temporal variation of the O₃ concentrations in 2020 and the other years. The 2020 concentrations were inside the plume during the whole study period and no anomalous behavior was observed in spite of the reduced NO₂ concentrations during the first 6-10 weeks. Rather, in Shijiazhuang and Chongqing both the NO₂ and O₃ concentrations were low in the plume. The O₃ concentrations in Shijiazhuang and Wuhan were similar and a bit higher than in Chongqing.

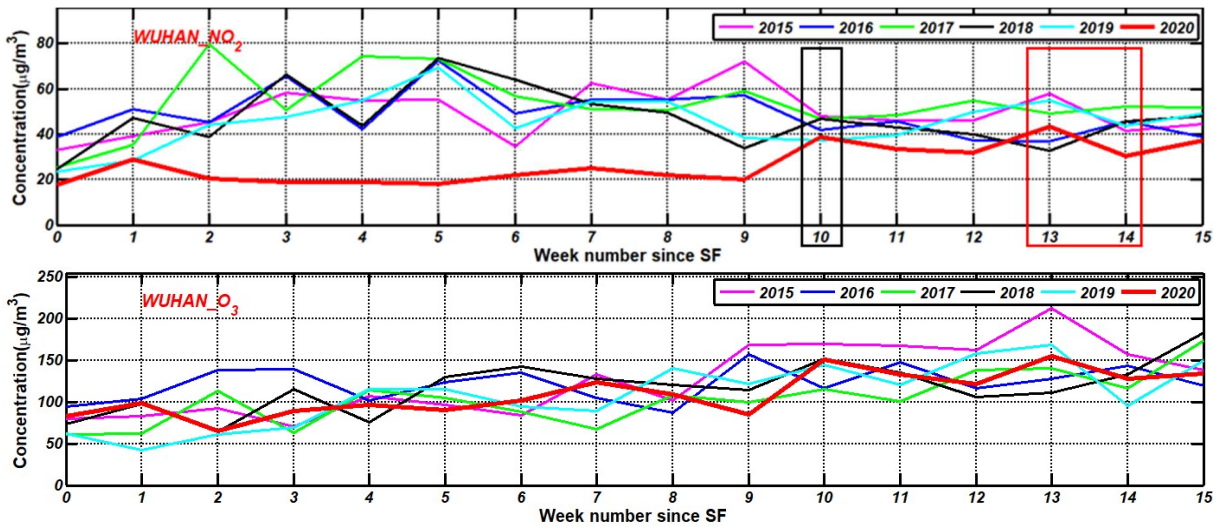

For aerosols the situation was different than for the trace gases. The data in Fig 6 show that in Shijiazhuang PM_{2.5} was relatively high during the first 3-4 weeks during all 5 years, and those in 2020 were well inside the plume. Thereafter the PM_{2.5} concentrations dropped and, apart from some fluctuations, remained low (on average about half of those in the first weeks) and those in 2020 were almost every week near the bottom of the plume. It is noted that the PM_{2.5} concentrations in 2017 and 2019 were substantially higher than in other years. In contrast, the 2020 concentrations of PM_{2.5} in Wuhan were lower in weeks 2 and 3 than in any other week during the study period and also lower than in all 5 years before (about 1/3 of the plume average). In Chongqing the PM_{2.5} concentrations were well inside the plume (around the average) and the plume decreased gradually as expected from the common seasonal behavior of PM_{2.5}. Hence in Chongqing the COVID-19 lockdown measures did not have an evident effect on the aerosol concentrations, in spite of the strong reduction of NO₂ concentrations. The PM_{2.5} concentrations in week 0 were 150 µg m⁻³ in Shijiazhuang, 50 µg m⁻³ in Wuhan and 40 µg m⁻³ in Chongqing.

435

Figure 6. Time series of the concentrations of NO₂, O₃ and PM_{2.5} in Shijiazhuang for weeks 0 to 15 starting from the Spring Festival in 2020 (red line), together with time series for these pollutants for the same weeks in 2015-2019. See legend for identification. Rectangles in the NO₂ time series were added for easy identification of the Tomb Sweeping festival (4 & 5 April, in week 10; red) and the May Festival (1-5 May, in weeks 13-14; black) which are discussed in the text. The Spring Festival date and thus week 0 is determined by the Lunar Calendar, therefore these dates apply only to 2020 and in the other years they may fall in different weeks.

3.3 Comparison of satellite and ground-based weekly observations in 2020 (NO₂)

For the comparison of the temporal evolution of the TROPOMI NO₂ TVCDs (Figure 5) to ground-based observations (Figures 6-8), the satellite data over each of the 11 selected regions were spatially integrated and

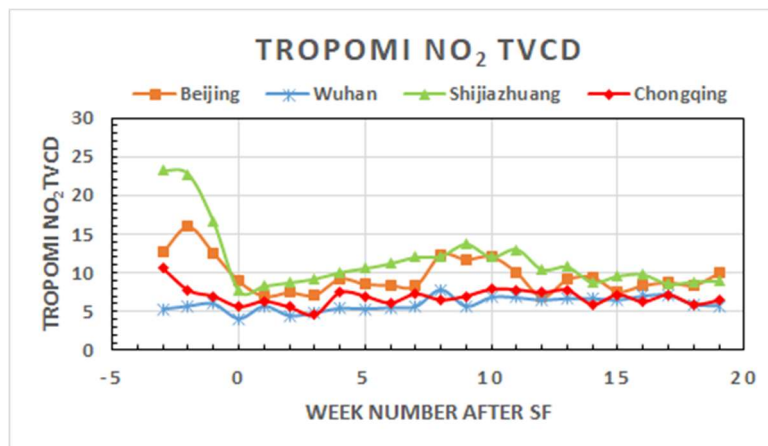

455 also in time, to weekly values. The results for the three representative regions discussed above, i.e. Shijiazhuang, Wuhan and Chongqing, are plotted in Figure 9a as time series for week -3 to week 20 (where week 0 is the Spring Festival in 2020, as above and in Table A1). Beijing data, which are discussed below and presented in Figure 10, are included as well. For easy comparison, the weekly averaged concentrations of NO₂ in 2020 are re-plotted from Figures 6-8 and 10, in Figure 9b, and the time series was extended to cover the same period as the
460 satellite data. The data in Figures 9a and 9b represent different quantities, i.e. column integrated vs near-surface local concentrations of NO₂ which experience different influences of, e.g., meteorological conditions (cf. Sect. 4.2) and thus cannot be quantitatively compared. Hence the comparison here is merely meant to qualitatively discuss the use of satellite data to evaluate the reduction of concentrations near the surface, where they are most important for air quality.

465 The data in Figures 9a and 9b show that overall the temporal behavior of the satellite NO₂ TVCDs and the surface NO₂ concentrations in 2020 was similar, with a strong drop before the Spring Festival (for the ground-based data continuing another week in Shijiazhuang and Beijing), followed by an overall increase. However, where the satellite data show different concentrations before the Spring Festival, the ground-based concentrations were similar, except in Shijiazhuang where they were a factor of 2 higher, and the factors by
470 which the concentrations were reduced are also different. The satellite data for Shijiazhuang show a reduction to a value of 33% from the maximum before the Spring Festival, whereas the ground-based data show a reduction to 24%. For Beijing these values are 55% and 35 %, for Wuhan they are 77% and 40% and for Chongqing they are 53% and 43%. Hence, overall, the reductions derived from satellite data are stronger than those from local monitoring measurements. However, effects of varying meteorological conditions are not included in these
475 estimates and these effects may be different for satellite observations than for local ground-based measurements. It is further noted that these numbers reflect the combined effect of the Spring Festival and the COVID-19 lockdown.

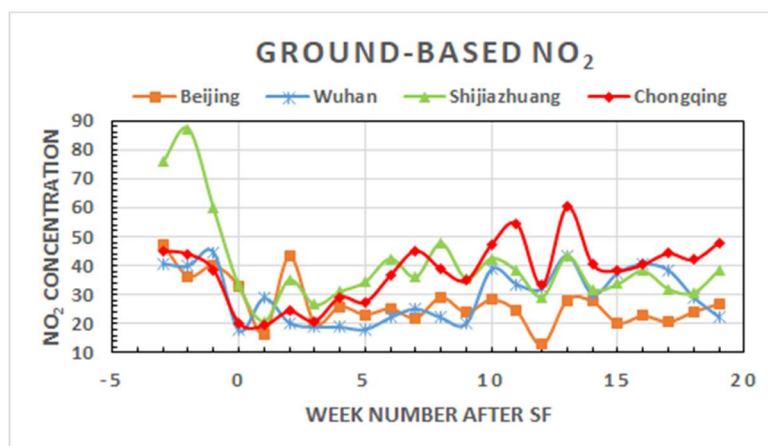

After the Spring Festival, both the satellite and ground-based data show that the concentrations increased, with similar rates in Shijiazhuang (factor 2 between week 0 and week 9) but with much stronger fluctuations in the
480 surface concentrations. However, in other regions the different types of observations show quite different behavior. For instance, in Chongqing the ground-based observations behaved similar to those in Shijiazhuang, whereas the satellite observations show a very small increase. The reverse is true for Beijing, with a rather small increase in the surface concentrations as opposed to a larger increase in the satellite observations. In Wuhan, both types of observations show the strong effect of the strict lockdown with NO₂ concentrations remaining near
485 the lowest values until week 10. However, after the end of the lockdown, the satellite data in Wuhan show a very modest increase whereas the ground-based data show a sudden increase by about a factor 2. Also in other regions, post lockdown large differences are observed in the satellite-derived and ground-based time series.

It is noted that the earlier observed separation in behavior of long-term time NO₂ TVCD series between the north and the south of the study area (Section 3.1.1) is also reflected in the weekly time series in early 2020, i.e. there
490 is a separation between the NO₂ TVCD values over Beijing and Shijiazhuang (north) and those over Wuhan and Chongqing (south). This separation is also reflected in the temporal behavior, but to a lesser extent. However, although in the ground-based time series also a separation can be observed, it is rather due to stronger industrialization (Shijiazhuang and Chongqing) than in the capitol city of Beijing. The time series in Wuhan may

495 have been influenced by the strict lockdown during 10 weeks, whereas after its release many activities suddenly increased which is reflected in the doubling of the ground-based NO₂ concentrations.

(a)

(b)

500 Figure 9. Time series of weekly averages of (a) TROPOMI derived NO₂ TVCDs (10¹³ molec./cm³) over Shijiazhuang, Wuhan, Chongqing and Beijing, for weeks -3 to 19 (b) surface concentrations of NO₂ (µg/m³) over these cities, plotted together in one plot from Figures 6-8 and 10.

4. Discussion

505 The satellite data on tropospheric NO₂ VCDs and ground-based monitoring data for the concentrations of NO₂, O₃, PM_{2.5} and AQI all indicate the different behavior of atmospheric composition in the north and south of China and the selected regions have been grouped to discuss the characteristic behavior within each group. This relates both to long-term variations (trends in the satellite data) and the influence of the COVID-19 lockdown. Hence the answers to the questions we set out with for this study at the end of Sect. 1 will be different for each of the regional clusters which emerged in the course of the study.

4.1 Estimation of lockdown effects: effects of temporal resolution

Many studies on the COVID-19 lockdown effect on atmospheric concentrations are based on comparison of a period before and after the start of the lockdown or on comparison with the same period in previous years. The

lockdown occurred during the Spring Festival holidays during which the concentrations of NO₂, often used in studies on the effect of the COVID-19 lockdown, were substantially reduced. Hence, in many studies the Spring Festival effect was separated from the total effect to determine the effect of the lockdown only. One way to do this was presented in Fan et al. (2020a) for tropospheric NO₂ TVCDs. In contrast, AOD was observed to increase. The AOD increase was anticipated to be due to meteorological factors conducive to the formation of haze. Also the ratio of the PM_{2.5} concentrations before the Spring Festival to those thereafter was higher than in previous years (in Beijing PM_{2.5} even increased by a factor of 2.2) and these ratios were higher in north China than in the south. In their estimates of the lockdown effects from satellite data, Fan et al. (2020a) (and others) used averages over the months before and after the Spring Festival. The current study clearly shows that during the weeks before the lockdown the NO₂ TVCDs gradually decreased and varied also after the lockdown. The post Spring Festival variations are also observed in the surface concentrations of NO₂ which varied by more than a factor of 2. This also applies to aerosols, and to a lesser extent to O₃. Hence the actual effect of the lockdown on the concentrations of aerosols and trace gases will be influenced by the separation from the Spring Festival effect, the temporal resolution chosen for the data analysis, as well as the correction for meteorological and other factors such as reduction of emissions and related concentration trends, as well as chemistry. The influence of emissions and the impact of the lockdown on different economic sectors on NO₂ and aerosol concentrations was discussed by Diamond et al. (2020).

4.2 Long term trends, trend reversal and meteorological influences on the estimation of lockdown effects

Decadal time series of monthly and annual mean NO₂ TVCDs for the 11 regions and the annual trends derived from these were presented in Sect. 3.1.1 (Figures 2, 3 and A1, Table 2). For the calculation of the baseline concentrations in 2020, i.e. the concentrations expected if there would not have been a lockdown, the seasonal variation needs to be taken into account. However, monthly trendlines are difficult to determine with some accuracy due to interannual variations and due to the Spring Festival effect which occurs at different dates in the solar calendar. Therefore trends for January and February were not considered. Furthermore, as Figures 2 and 3 show, the decline in the NO₂ TVCDs seems to level off in recent years, i.e. from 2015/2016 in the south of China and possibly after 2018 in the north. The years when the trends were changing are similar for the monthly and annual mean data. Hence the baseline could be determined using an average over the years after the trend change. The uncertainty in these averages is about 10% (Figure 3). Ignoring the trend change, i.e. assuming that the trend would continue to 2020, would result in an underestimation of the baseline for 2020. Extrapolation of the trend for Wuhan to 2020 would result in an estimated baseline of 4.4×10^{15} molec·cm⁻² and for Chongqing 3.6×10^{15} molec·cm⁻², whereas using the average over 2016-2019 for 2020, i.e. assuming that the decrease has halted as suggested by the data in Figure 3, would provide a baseline of 6.6×10^{15} molec·cm⁻² for Wuhan and 5.6×10^{15} molec·cm⁻² for Chongqing. In other words, ignoring the trend change would result in a baseline lower by about 35% and thus in an overestimation of the lockdown effect on the NO₂ TVCD. Similar considerations may apply to Shijiazhuang, but considering that a change in the annual trend did not occur until 2018, the variation in following years is difficult to estimate.

In view of this discussion, the use of a climatology over recent years for comparison with the 2020 concentrations may be a good strategy for regions in the south of China, whereas for the north, where concentrations were decreasing until 2018, the climatological concentrations may be too high. The use of

ground-based data leads to larger uncertainties. As the ground-based data in Figures 7 and 8 for Wuhan and Chongqing show, the NO₂ concentrations in the plumes vary strongly from week to week and the plume width is therefore rather large, with an uncertainty which is much larger than the 10% uncertainty in the trend since 2015/2016.

Meteorological influences may be twofold. Meteorological conditions may be conducive of the formation of haze in stagnant air as often observed in north China during the winter (e.g., Li et al., 2018; Wang et al., 2019; Wang et al., 2018a; Wang et al., 2020a). On the other hand, large scale weather systems influence the transport of air masses from different origins transporting either clean air or pollution contributing to local air quality (e.g., Wang et al., 2019; Li et al., 2018; Hou et al., 2020). Another aspect to be considered are the influences of air temperature, humidity and radiation on chemistry, which affects NO₂, O₃ and aerosols, in particular for the situation during the COVID-19 lockdown with the strong reduction of NO₂ concentrations. A reduction of NO₂ (or NO_x = NO + NO₂, where NO is only a small fraction of NO_x) leads to an increase in O₃, as observed in the ground-based data. The enhanced O₃ concentrations result in the increase of the oxidizing capacity of the atmosphere which in turn leads to the production of secondary organic aerosol (SOA) as explained in, e.g., Diamond et al. (2020) and Le et al. (2020). The increased aerosol concentrations result in the attenuation of solar irradiation due to more scattering and absorption which in turn may further influence the meteorology (Zhong et al., 2018) and photochemical reactions.

In view of the decisive role of meteorology in haze formation in north China (Le et al., 2020) it is surprising that both Le et al. (2020) and Diamond et al. (2020) used meteorological data averaged over 1 month (February 2020). Haze occurs episodically and less than 25% of the episodes last longer than 4 days (Wang et al., 2018b; Wang et al., 2020b).

4.3 Lockdown effect on air quality and rebound

The similarity in the temporal behavior of the air quality index (Figure A4) was the basis for the subdivision of the regions in three groups. In Group 1 (NCP) the AQI fluctuated in the first 3 weeks and reached a peak value in week 2, then remained low. The peak was highest (170, moderately polluted) in Beijing where it exceeded the value of previous years. Obviously, this was due to a haze episode with strongly enhanced PM_{2.5} with respect to the period before the Spring Festival (Fan et al., 2020a) and a concentration of ca. 140 µg·m⁻³, almost double the 24-h class 2 (for cities) air quality standard in China specified in GB 3095-2012 (<https://www.transportpolicy.net/standard/china-air-quality-standards/>, last access 30 January 2021). In other cities in Group 1 (not shown) the peak values were lower, decreased with distance to Beijing, and were also lower than in 2017 and 2019. Only in Jinan and Zhengzhou the PM_{2.5} values were within the 24-h class 2 (for cities) air quality standard. After week 3 the PM_{2.5} concentrations were within air quality standard limits and the AQI was between 50 and 100 (good) and lower than in the previous years, for all cities in Group 1. However, closer inspection shows that the O₃ concentrations exceeded the air quality standard of 100 µg·m⁻³ (1-hour mean value) between weeks 5 (in the south of the NCP) and 7 (in the north). Furthermore, in all cities in the NCP the O₃ concentrations in 2020 were well inside the plume. Hence, in the NCP the strong emission reduction during the lockdown and the strong decrease of NO₂ concentrations observed both from space and from the surface monitoring network, were offset by the increase of other pollutants. Early in the lockdown the aerosol concentrations were high due to meteorological conditions and complex chemical influences, and later the O₃

concentrations exceeded the limiting values. However, the latter were not reflected in the AQI, which followed the variations in PM_{2.5} but remained low when O₃ concentrations were high. In fact, for all cities in the NCP the AQI was below or just inside the plume during the whole study period, whereas the NO₂ concentrations moved into the plume toward the end, except in Beijing. The relatively low NO₂ concentrations might be expected based on both the decreasing trends in the NO₂ TVCDs until 2018 in the north of China and from the seasonal decrease. With these considerations, it is hard to determine whether the pollutant concentrations in the NCP returned to their normal levels, which in regard of seasonal variations are expected to be lower than before the lockdown and in regard of their decreasing trends are expected to be lower than in other years or, considering that the trends level off, similar to those in the last couple of years.

For the Group 2 cities, Shanghai, Guangzhou and Wuhan, the AQI during the lockdown varied and AQ was good until week 10, with the largest effect in Wuhan. NO₂ concentrations in Wuhan were very low with 20 µg·m⁻³ during the first 9 weeks (3 times lower than the plume average). In Shanghai and Guangzhou the concentrations were initially similar but increased slowly. In all three cities the NO₂ concentrations merged into the plumes after week 10, more or less coincident with the end of the lockdown after 76 days, on April 8, 2020. PM_{2.5} was not reduced as much as NO₂ but was also below the plume and overall traced the NO₂ concentrations, moving into the plume after week 10. Being further south than the NCP, O₃ concentrations were close to the air quality standard of 100 µg·m⁻³ and exceeded that limit around week 5, as in the NCP. Hence, also in the Group 2 cities the reduction of other pollutant concentrations was offset by the increase of O₃ which is not reflected in the AQI. The rebound at the end of the lockdown period is clear with all indicators returning to levels similar to those in the earlier years, i.e. inside or close to the plume.

Group 3 includes three cities in the Sichuan/Chongqing and Guanzhong Basins and Nanchang. In these cities the AQI was not substantially affected by the lockdown, except in the very beginning when it was low inside (or even below) the plume but overall remained inside the plume. Yet, the NO₂ concentrations were around 20 µg·m⁻³ during the first 3 weeks, initially some 40-60% lower than the plume for which the concentrations actually increased during these 3 weeks and then gradually decreased. Between week 3 and 7 the NO₂ concentrations in 2020 increased in all 4 cities to about 50 µg·m⁻³ in week 7, close to the plume, and later merged into the plume. PM_{2.5} was not much different from the plume throughout the whole period and in all three cities. Decreasing somewhat in the basins and fluctuating around 40 µg·m⁻³ in Nanchang. O₃ concentrations were lower than 100 µg·m⁻³ (50 µg·m⁻³ in Chongqing) and gradually increased to above 100 µg·m⁻³ around week 7. Overall, the lockdown had little effect on the air quality in Group 3 cities in spite of the significant reduction of the NO₂ concentrations. The latter returned to normal levels after about 9 weeks.

The differences between the lockdown effects on the air quality in the three clusters have not been analyzed in detail. In general, the reduction of concentrations of pollutants such as NO₂ was offset by the increase of O₃ which is not reflected in the AQI which seems to be mostly influenced by PM_{2.5}. The duration of the lockdown was not exactly the same in each city. For instance, in Xi'an peoples' lives gradually returned to normal during a period of 1 month ending on 27 March (Zhang et al., 2020b) whereas in Wuhan the lockdown ended on 8 April. The effects of the gradual increase of activities depends on the kind of activity and resulting emissions. The effect of the emissions on the concentrations depends on meteorological conditions and other factors influencing

630 dispersion of the pollutants such as the local topography in the basin area which limits transport as well as effects
on atmospheric chemistry.

4.4 Effects of national holidays and other events

The 16 weeks study period covered the lockdown from the beginning (week 0) to the end of the lockdown in
Wuhan on 8 April (week 10) and the last weeks were included to monitor the rebound of the pollutant
635 concentrations. For Beijing, four more weeks were included because of the Party Congress which took place
during 21-28 May, 2020 (i.e. during weeks 16-17). During the study period, also two national holidays occurred,
the Tomb Sweeping Festival (4-6 April, i.e. in week 10) and the May holidays (1-5 May, i.e. during weeks 13-
14). These periods are marked in Figures 6-8 with rectangles for easy identification. The Tomb Sweeping
Festival was just before the end of the lockdown in Wuhan when NO₂ concentrations were observed to rise from
640 very low to close to the values observed in previous years (Figure 7) and also concentrations of other pollutants
as well as AQI peaked, as discussed in Sect. 3.2. As shown in Figures 6-8, in most other cities the AQI was a
little higher in week 10 but the effect was not strong. Also during the May holidays in weeks 13-14 the AQI and
the concentrations of other pollutants did not stand out. Although during these holidays families usually get
together there was no significant effect on AQ, possibly because the concentrations were already lower and had
645 not fully recovered, while also travel was still restricted.

The situation in Beijing was different. With the regular occurrence of large (inter)national meetings, emission
control measures are often enforced in Beijing and, except during the haze event in the first weeks of the
lockdown, the AQI was low (around 50), well below the plume, until week 13 (Figure 10). In weeks 13 and 14
the AQI merged into the plume as did the concentrations of some of the contributing pollutants (only shown for
650 PM_{2.5}; O₃ was already inside the plume), except NO₂ which however also increased in that period. The
subsequent decrease of the concentrations resulted in minima in the concentrations in week 17. This is illustrated
in Figure 10 showing time series of the AQI and ground-based concentrations of NO₂, O₃ and PM_{2.5} in Beijing
from week 0 to week 19.

655

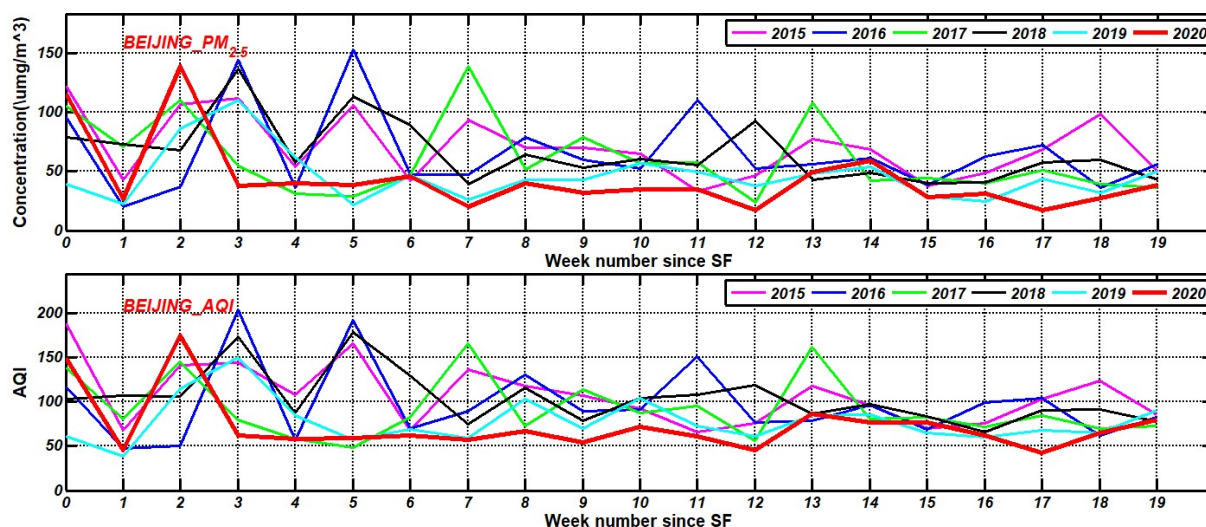

Figure 10. As Figure 6, but for Beijing and from week 0 to week 19.

5. Summary and conclusions

660 China is a fast developing country with a high degree of urbanization and industrialization, especially in the east of China (here defined as east of the Hu line, Figure 1). China also offers a large variety of meteorological, climatic and geographical conditions with fast plains, large mountainous terrain and desert areas. The country can roughly be divided by the Yangtze River, with different influences on atmospheric processes in the north than in the south. These effects came out in the analysis of both the satellite and ground-based monitoring data of

665 trace gases and aerosols affecting air quality. In addition, the Sichuan and Guanzhong basins have their own characteristics due to the influence of the surrounding mountains. The focus of the current study was the evolution of the concentrations of the pollutants during the last decade in response to emission reduction policies, and in particular the effect of the sudden reduction in economic activities and peoples' mobility during the lockdown in response to the COVID-19 outbreak in China in January 2020. The study area was mainland China east of the Hu line (Figure 1). On a decadal scale, column-integrated concentrations of tropospheric NO₂ were analyzed, using OMI TVCD data, showing the difference in both the variation of the concentrations and the response to emission reduction policies in regions north and south of the Yangtze River. This analysis was made for 11 regions (Figure 1, Table 1) selected using weekly averaged TROPOMI NO₂ TVCD data, showing the spatial variations over the whole study area during the first 16-20 weeks after the Chinese New Year (25 January

670 2020). Ground-based monitoring data were collected for a large city in each of the 11 study areas, i.e. NO₂, O₃ and PM_{2.5}, which were most affected by the lockdown as shown in our earlier study (Fan et al., 2020a). Differences between these two types of observations were qualitatively discussed based on weekly time series of NO₂ TVCDs and surface concentrations encompassing a short period before the Spring Festival and 20 weeks thereafter. Based on the similarities in the evolution of the AQI and pollutant concentrations, the 11 regions were

675 divided in three groups: Group 1 in the NCP, Group 2 in the south, and Group 3 including two major basin areas. The large reduction of the concentrations of NO₂ was observed, in both the surface and satellite data, whereas the concentrations of O₃ were observed to increase and for the concentrations of PM_{2.5} the behavior varied by region. Hence the question came up whether the air quality was really improved as much as suggested from the NO₂ data, or that this reduction was offset by the increase of the concentrations of other pollutants? To answer these

685 questions, satellite and ground-based data were analyzed for the selected 11 regions in east China, leading to the following conclusions.

1. The effect of the lockdown is often determined by comparison of the concentrations before and after the lockdown, averaged over a certain period of time, which often is taken as 1 month, to average out short-term effects. However, as shown in Figure 5, the concentrations evolved over much shorter time scales and, for NO₂, decreased from week to week, both before and after the lockdown. A complicating factor for the determination of the lockdown effect was that the lockdown happened during the Spring Festival holidays during which the NO₂ concentrations already decreased substantially. The lockdown added more severe reductions during a much extended period of time. Hence, for a proper determination of the evolution of the concentrations a temporal resolution of 1 week is more suitable than 1 month. The choice of shorter time scales is even more important when episodic events occur, such as the haze event early in the lockdown in the north of China, and for the use of meteorological data.
2. Time series of annual mean tropospheric NO₂ VCDs for 2011-2019 for the 11 regions show the decreasing trend in the north between 2013 and 2018, and in the south between 2011 and 2015/2016. After these periods, the decrease was halted and concentrations fluctuated but remained within 10% of the 2015 values. Trends vary between -0.05 and -0.14 per year (see Table 2).
3. To determine the effect of the lockdown on the concentrations, a baseline must be determined. This baseline depends on both long term trends and short term variations. Ignoring the trend change in the south would result in an underestimation of the baseline concentrations of the order of 35% as compared to using the average of the concentrations in 2016-2019 as baseline. In the north the baseline is difficult to determine because the NO₂ TVCDs continued to decrease until 2018. Using the average of the concentrations in 2016-2019 as baseline would result in an overestimate of the baseline concentrations.
4. The effect of the strong reduction of the NO₂ concentrations on the air quality is offset by the increase of O₃ concentrations and, in some part of China, aerosols (PM_{2.5}). The increase of aerosols in the north of China has two reasons: the meteorological conditions conducive of the formation of haze and the complicated chemistry involving NO₂ and O₃, leading to the formation of secondary aerosols (e.g., Huang et al., 2020; Diamond and Wood, 2020; Le et al., 2020; Zhao et al., 2020).
5. The effect of the lockdown is different in cities in Groups 1, 2 and 3, with an AQI increase in the first weeks in the Group 1 (NCP) and improved AQ later. The concentrations did not return to the levels in the previous four years (the plume). In Group 2 the AQ was substantially improved during about 10 weeks, although after week 5 the effect of the reduced concentrations was offset by the increase of O₃ exceeding National Ambient Air Quality Standards. After the lockdown the concentrations returned to levels similar to those in the plume. For Group 3 cities the concentrations were initially reduced but after a few weeks increased to inside the plume. Hence, apart from the first weeks, the lockdown did not have a significant effect on the AQ in the Group 3 cities, in spite of the substantial reduction of the NO₂ concentrations which returned to normal levels after about 9 weeks. The AQI seems to be mostly influenced by PM_{2.5}. The use of AQI is questionable because its definition is not following a physical quantity: even when AQI indicates good AQ, limits may be exceeded.

6. Holidays like the Tomb Sweeping Festival and the May holidays are expected to have some effect on the air quality, but in 2020 this was hardly noticeable. However, in Beijing the air quality during the Party Congress, at the end of May, was better than during the weeks before. It is noted that throughout the whole study period of 19 weeks, the NO₂ concentrations in Beijing were strongly reduced with respect to those in the preceding 4 years.

This study was undertaken for China, but the methodology and results can in part also be applied to other areas. In particular this applies to the temporal resolution, which in this study was taken as 1 week, as opposed to 1 day or 1 month in earlier studies such as Fan et al. (2020a). As discussed above, meteorological variations influencing air quality, such as formation and dissipation of haze, take place on rather short time scales. Whereas, for the determination of effects of sudden changes in emissions on pollutant concentrations such short term meteorological effects need to be considered, as well as interannual changes. The baseline correction using multi-annual data also needs to account for (changes in) long term trends and seasonal variations as discussed in detail for NO₂.

Appendix A.

The air quality index (AQI) is based on measured mass concentrations of aerosols and trace gases. The method to determine the AQI is described in (Yuan and Yang, 2019) and is calculated according to the National Standards on Air Quality Measurement published by the Chinese Ministry of Environmental Protection on 29 February 2012 -Ambient air quality standards (GB 3095-2012) (Ministry of Environmental Protection of the People's Republic of China, MEE, 2012) and the Technical Regulation on Ambient Air Quality Index (on trial) (HJ 633-2012) (MEP(Ministry of Environmental Protection of the People's Republic of China), 2012) that became effective on January 1st, 2016). The aerosol mass concentrations considered are PM_{2.5} and PM₁₀ and the trace gases are NO₂, SO₂, O₃ and CO. The AQI is calculated using the method described in (MEP(Ministry of Environmental Protection of the People's Republic of China), 2012). The individual AQI of each of these 6 pollutants (IAQI_P) is calculated using (Yuan and Yang, 2019):

$$IAQI_P = \frac{IAQI_{Hi} - IAQI_{Lo}}{BP_{Hi} - BP_{Lo}} (C_P - BP_{Lo}) + IAQI_{Lo}. \quad (A1)$$

Where C_P is the mass concentration of pollutant P, BP_{Hi} and BP_{Lo} are the higher and lower threshold of pollutant concentration near C_P corresponding to specified IAQI (Individual Air Quality Index) regulated by government policy. $IAQI_{Hi}$ and $IAQI_{Lo}$ are the corresponding IAQI to BP_{Hi} and BP_{Lo} , respectively. The AQI is the highest of the 6 individual IAQI_P:

$$AQI = \max \{IAQI_1, IAQI_2, \dots, IAQI_6\} \quad (A2)$$

Eq (A2) shows that the AQI reflects only one pollutant, with the highest IAQI, and is not a combination of all 6 (Yuan and Yang, 2019).

An AQI of 50 means that the air quality is excellent, and AQI between 50 and 100 means it is good. When $100 < AQI < 150$ the AQ is lightly polluted, for $150 < AQI < 200$ AQ is moderately polluted and for $200 < AQI < 300$ AQ is heavily polluted. $AQI > 300$ indicates severe pollution (MEP(Ministry of Environmental Protection of the People's Republic of China), 2012).

Table A1. Definition of the weeks around the Chinese Spring Festival, as used in this study, from 2015 to 2020. The first day of week 0 in each year is defined as the first day of the Lunar New Year, which in the solar calendar changes from year to year.

Data availability statement

QA4ECV data are available at <https://doi.org/10.21944/qa4ecv-no2-omi-v1.1>.

The OMI data are available via <https://www.temis.nl>.

The TROPOMI data are available via <http://www.TROPOMI.eu/data-products/>.

800 The ground-based monitoring data are available via <http://www.mee.gov.cn/>.

Author contributions

CF, YL and GdL designed the study which was conducted by CF and YL. JTD contributed to the data presentation. CF, YL and GdL prepared the manuscript, ZQL and RvdA provided extensive comments and suggestions for the manuscript. All authors discussed the results and read and commented on the paper.

805 Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

800 The authors thank the TEMIS team for maintaining the website and the free use of tropospheric NO₂ column data from the OMI sensor from www.temis.nl and the NASA Earth Science Division for the free use of tropospheric products from the TROPOMI (Sentinel-5P) sensor. We also acknowledge the China National Environmental Monitoring Center (CNEMC) of the Ministry of Ecology and Environment of China (MEE) for the provision of the ground-based monitoring data at <http://www.mee.gov.cn/>. We thank Abdelrazek Elnashar of Cairo University for the Google Earth Engine technical support. The authors thank anonymous reviewers for their effort to critically review the manuscript and providing constructive comments.

815 Financial support

This work was supported by the National Outstanding Youth Foundation of China (Grant No. 41925019) and the National Natural Science Foundation of China (Grant No. 41671367).
