6 **S1. Positive Matrix Factorization (PMF) analyses**

7 PMF is based on a weighted least-squares fit algorithm following Eq. S1.

8

9

$$[\text{Eq. S1}]: X = (G \times F) + E$$

10

11 where: X is an (n × m) matrix representing the species concentration (m) for each samples (n),
 12 G is the (n × p) matrix representing the source contribution, F is the (p × m) matrix representing
 13 the factor composition and E is the residuals matrix (i.e., difference between measurements and
 14 model output). A condition of non-negativity for G and F matrix is imposed by the algorithm
 15 and PMF find solutions by minimizing the sum of the squared residuals weighted by their
 16 respective uncertainties.

17

18 In order to avoid double counting, OC* was calculated using Eq. S2.

19

20

$$[\text{Eq. S2}]: \text{OC}^* = \text{OC} - (\text{MSA} \times 0.12) + (\text{polyols} \times 0.40) + (\text{levoglucosan} \times 0.44) +$$

$$(\text{mannosan} \times 0.44)$$

21

22

23

24

The uncertainties of the input variables were calculated using Eq. S3 based on Gianini et al. (2012).

25

26

$$[\text{Eq. S3}]: \sigma_{mn} = \sqrt{(\text{DL}_m)^2 + (\text{CV}_m \times x_{mn})^2 + (a_m \times x_{mn})^2}$$

40

41

42

43

44

To resolve the mixing issues, the PMF equation was solved using the ME-2 solver (Paatero, 1999; Paatero and Hopke, 2002) allowing the addition of constraints and expressions to the solved the PMF solution.

45

46

47

48

- the Q/Q_{exp} ratio (<1.5)
- the weighted residuals are normal and between ±4
- the chemical interpretation of the obtained factors
- the information based on the error estimation by bootstrap and displacement method

- the total reconstructed PM₁₀ mass from the PMF-resolved factors

The solutions presented in this study are the optimal solutions from the constrained runs in each site.

The Pearson distance and the Similarity Identity Distance (PD-SID):

In order to evaluate the homogeneity of the chemical profiles in each urban site, the similarity between the factors were assessed by calculating the Pearson distance (PD) and the Similarity Identity Distance (SID), following Belis et al. (2015). The PD and SID defined by Eq. S4 and Eq. S5:

$$[\text{Eq. S4}]: PD = 1 - r^2, \text{ where } r \text{ is the Pearson coefficient}$$

$$[\text{Eq. S5}]: \frac{\sqrt{2}}{n} \sum_{i=1}^n \frac{|a_i - b_i|}{a_i + b_i}$$

where a and b are the relative mass to PM₁₀ of two different factors and n is the number of common specie in a and b. In brief, the PD-SID metric aims to compare profiles based on their relative mass composition. The PD provides information on the sensitivity of a profile to variations in the major mass fractions of PM, while the SID provides information on the sensitivity to all components. PD<0.4 and SID<1 are considered as acceptable criteria for profile similarity, according to Pernigotti and Belis (2018).

S2. PM₁₀ chemical characterization

Table S2. Annual average of PM₁₀ mass concentrations and chemical compositions (in μg m⁻³) at all sites, and individual urban sites in the Grenoble basin.

Species	All sites	CB (urban hyper-center)	LF (urban background)	Vif (peri-urban)
μg m ⁻³

105

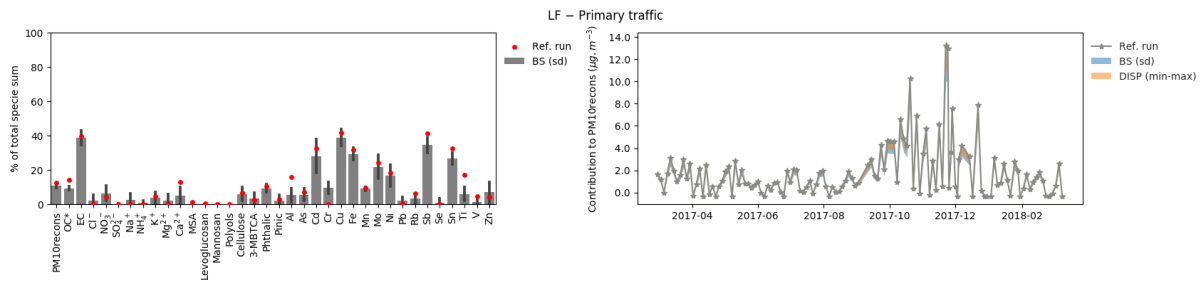

106 **Figure S3.1.1 Comparison of chemical profile between the classic and orga PMF run for the biomass burning factor in**
 107 **LF (top), CB (middle), and Vif (bottom).**

108

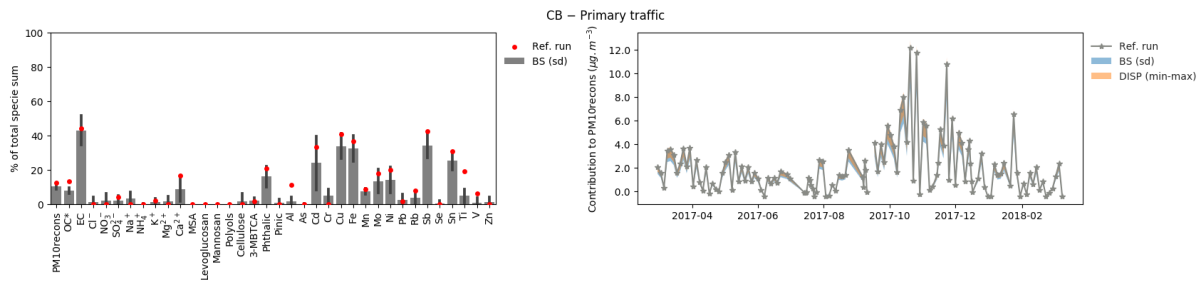

109 The biomass burning factor was identified with high loadings of levoglucosan, mannosan, K⁺,
 110 and Rb. On an annual scale, biomass burning accounted for 17% (2.3 μg m⁻³), 22% (3.5 μg m⁻³), and 26% (3.4 μg m⁻³) of total PM₁₀ mass in LF, CB, and Vif, respectively. Strong correlations
 111 were found across all sites indicating that the influence of this factor on PM₁₀ is on a larger
 112 scale. This factor also showed strong seasonality with highest contributions during the winter
 113 season, ranging according to site from 19-24% (2.2-2.5 μg m⁻³).

114 In CB, a notable contribution was also observed from NO₃⁻ (17%) and NH₄⁺ (10%) in this factor.
 115 These species are commonly associated to secondary formation processes and direct emissions
 116 from biomass burning (Tomaz et al., 2017). Aside from the usual tracers of biomass burning,
 117 contributions from phthalic acid was also seen in the LF (11%) and Vif (16%) sites. Phthalic
 118 acid is a known tracer of naphthalene-derived SOA (Al-Neima and Stone, 2017; Kleindienst et
 119 al., 2012), thereby suggesting the influence of secondary aerosols in the biomass burning factor.
 120

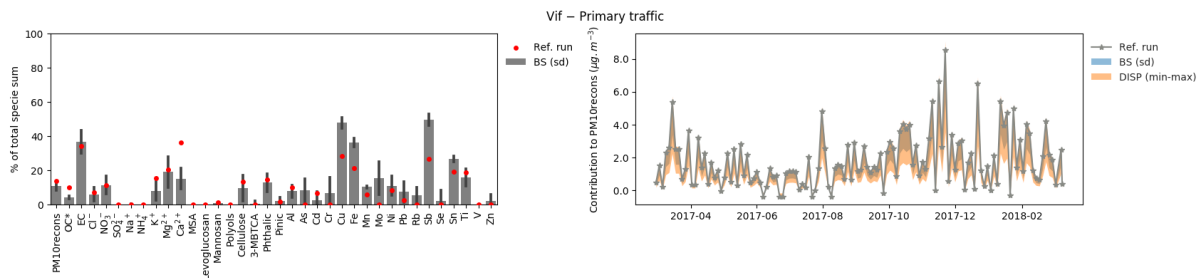

121 **Primary traffic**

122

123

124

125

Figure S3.2. Chemical profile and temporal evolution with error estimates of the primary traffic factor in LF (top), CB (middle), and Vif (bottom).

126

127

128

129

130

131

132 **Figure S3.2.1 Comparison of chemical profile between the classic and orga PMF run for the primary traffic factor in**
 133 **LF (top), CB (middle), and Vif (bottom).**

134

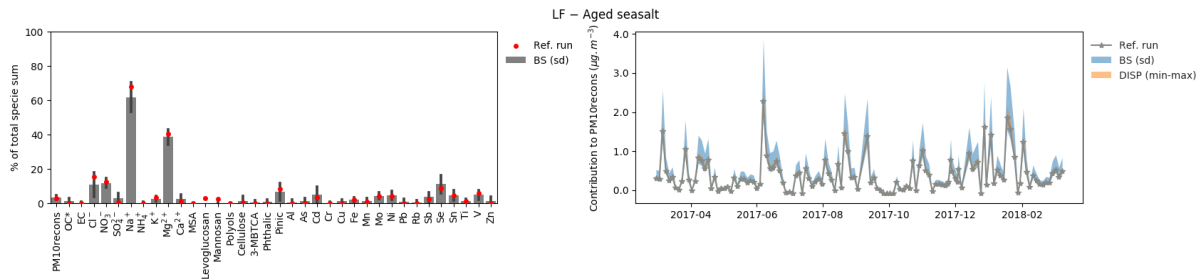

135 The primary traffic factor was identified with high loadings of EC, Cu, Fe, Sn, and Sb. On an
 136 annual scale, the primary traffic factor accounted for 11-14% in LF ($1.8 \mu\text{g m}^{-3}$), CB ($2.0 \mu\text{g m}^{-3}$),
 137 and Vif ($1.8 \mu\text{g m}^{-3}$).

138 A typical tracer of traffic exhaust, EC, contributed 34-44% of its total mass to the primary traffic
 139 factor. Contributions from metals in this factor can be attributed to road dust resuspension due
 140 to road traffic activity such as wear and tear of tires, brake wear, and oil burning (Kulshrestha
 141 et al., 2009; Pant and Harrison, 2013; Pant et al., 2017).

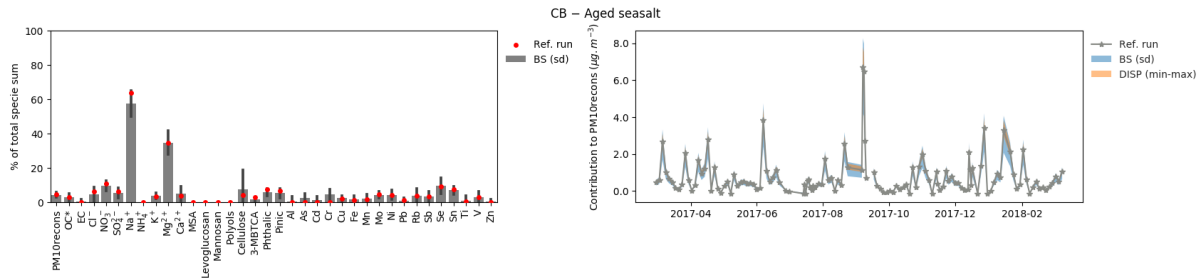

142 The primary traffic factor also showed minimal loadings from Cd in LF and CB sites, a tracer
 143 known to originate from urban traffic soil (Liu et al., 2007, 2011). It is also interesting to note
 144 that phthalic acid, one of the major components of automobile emissions (Kawamura and
 145 Kaplan, 1987) and a known tracer of SOA formation (Al-Neima and Stone, 2017; Kleindienst
 146 et al, 2012), has contributions to primary traffic factor ranging from 11% and 21% of its total
 147 mass in LF and CB.

177

178 **Figure S3.4.1 Comparison of chemical profile between the classic and orga PMF run for the sea/road salt factor in LF**
 179 **(top), CB (middle), and Vif (bottom).**

180

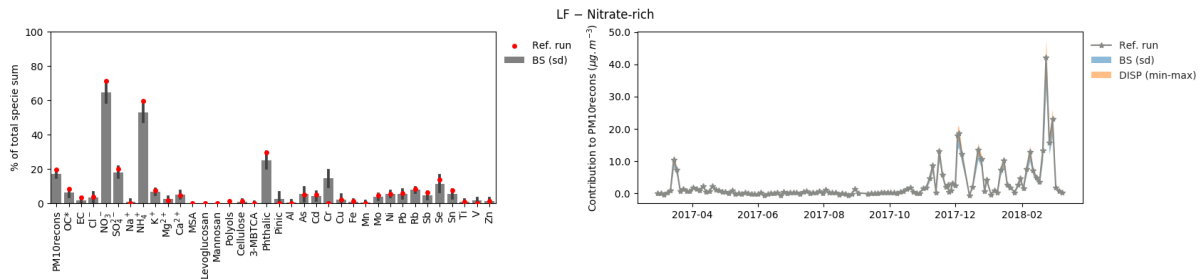

181

182 The aged sea salt factor was identified with high loadings of Na^+ and Mg^{2+} . The strong
 183 correlations of ions across all sites have been reflected in the strong correlations found between
 184 sea salt factors across all sites. On an annual scale, sea salt sources accounted for 3-5% of the
 185 total PM_{10} mass with a steady seasonal contribution. The observed minimal loadings of Cl^- in
 186 the aged sea salt factor resulted from an ageing process by heterogeneous reactions between
 187 particulate sea salt and acidic compounds (e.g., nitric and sulfuric acid) (Seinfeld and Pandis,
 188 2012). On the other hand, the sea/road salt factor was identified with high loadings of Na^+ and
 189 Cl^- accounting for 2-4% of the total mass of PM_{10} . This factor could be attributed to road salting
 190 during colder months as similarly reported by Pere´-Trepas et al. (2007) and Wahlin et al. (2006)
 191 as contributions were also notably higher during winter season.

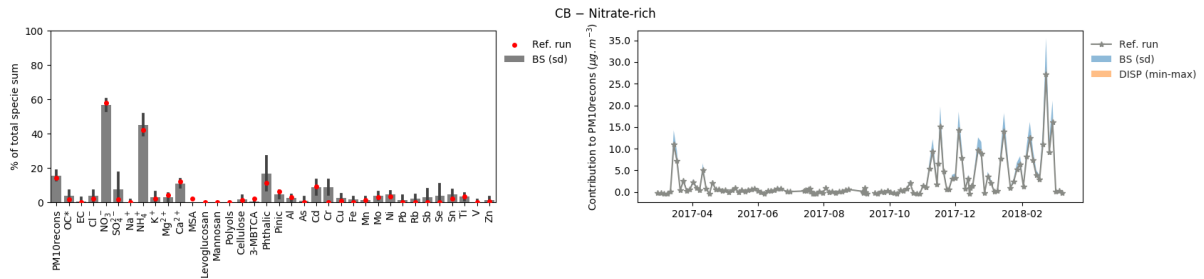

192

193 **Nitrate-rich**

194

195

196

197

198

199

200

Figure S3.5. Chemical profile and temporal evolution with error estimates of the nitrate-rich factor in LF (top), CB (middle), and Vif (bottom).

201

202

203

204 **Figure S3.5.1 Comparison of chemical profile between the classic and orga PMF run for the nitrate-rich factor in LF**
 205 **(top), CB (middle), and Vif (bottom).**

206

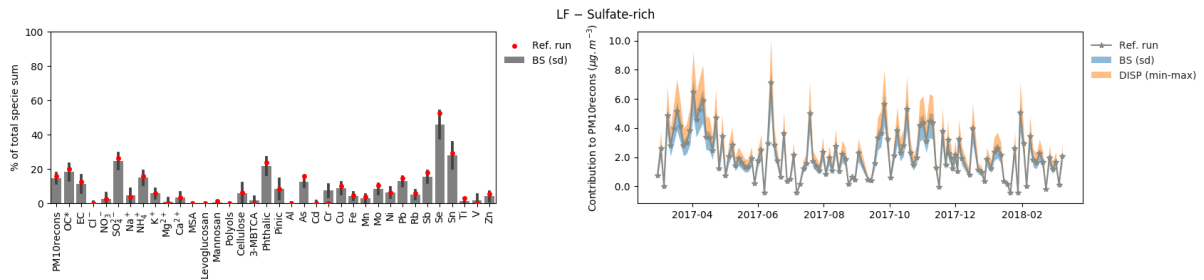

207 The nitrate-rich factor, a secondary aerosol source derived from the presence of NO_3NH_4 in the
 208 atmosphere, was identified with high loadings of NO_3^- and NH_4^+ . The mass concentrations of
 209 these tracers have showed strong correlations across sites possibly indicating similar
 210 atmospheric process affecting the contributions of the nitrate-rich source of PM_{10} in the
 211 Grenoble basin. On an annual scale, nitrate-rich sources accounted for 14-19% of PM_{10} in all
 212 sites.

213 This factor showed strong seasonality with highest contributions during winter season which
 214 can be attributed to increased possibility of atmospheric inversions due to typical atmospheric
 215 dynamics during this season in the area. Additionally, this temporal behaviour can be due to
 216 higher instability of NO_3^- and NH_4^+ during warm seasons (Mariani and De Mello, 2007). These
 217 tracers are also commonly associated to secondary formation processes and long range transport
 218 of aged air masses especially during high PM_{10} concentration levels (Tomaz et al. 2017). The
 219 presence of phthalic acid in the nitrate-rich factor also suggests influence from SOA formation

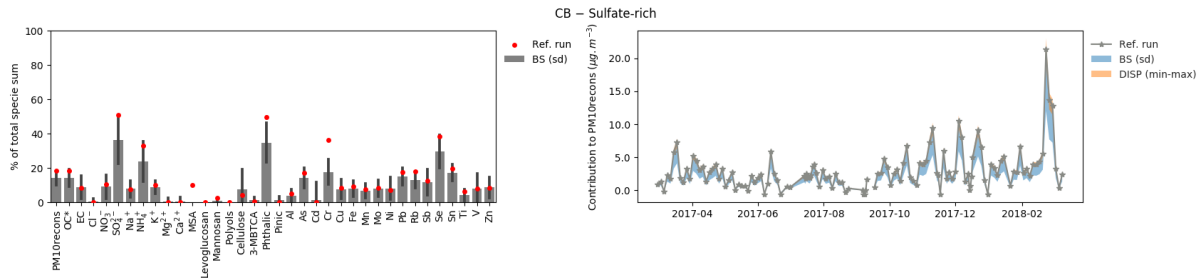

220 (Al-Neima and Stone, 2017; Kleindienst et al, 2012). In fact, a high pollution event (PM₁₀
221 ranging from 44.80-50.0 µg m⁻³) affecting all the sites was noted during winter (February 23,
222 2018) where the concentrations of specific species including NO₃⁻, SO₄²⁻, NH₄⁺, and phthalic
223 acid were elevated in all sites. During this day, the nitrate-rich factor accounted for 83% (in
224 LF), 50% (in CB), and 60% (in Vif) of the total PM₁₀ confirming heavy influence of secondary
225 formation processes possibly due to long range transport of pollutants.

226 **Sulfate-rich**

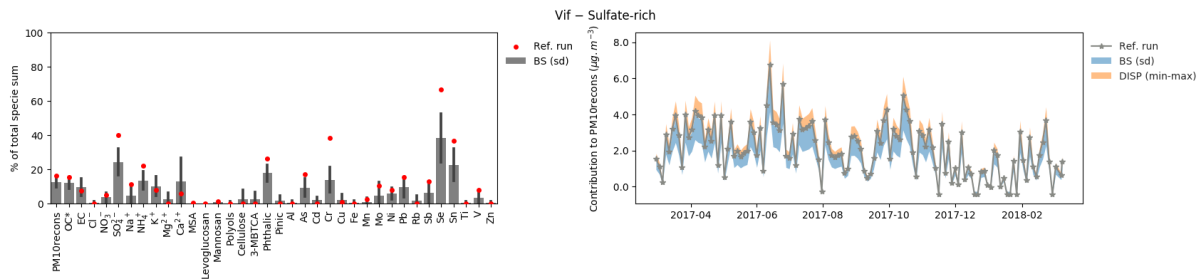

227

228

229

230

231

232

233

Figure S3.6. Chemical profile and temporal evolution with error estimates of the sulfate-rich factor in LF (top), CB (middle), and Vif (bottom).

234

235

236

237 **Figure S3.6.1 Comparison of chemical profile between the classic and orga PMF run for the sulfate-rich factor in LF**
 238 **(top), CB (middle), and Vif (bottom).**

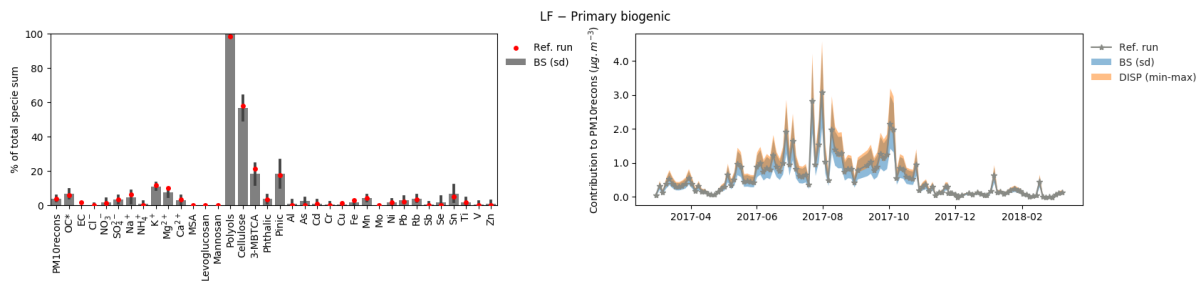

239

240 The sulfate-rich factor, a secondary aerosol source from $\text{SO}_4(\text{NH}_4)_2$, was identified with high
 241 loadings of SO_4^{2-} , NH_4^+ , and Se. In Vif, this factor also had minimal loadings of metal species
 242 including Cr and Sn. On an annual scale, sulfate-rich factor accounted for 16-18% of PM_{10}
 243 across the urban sites in Grenoble.

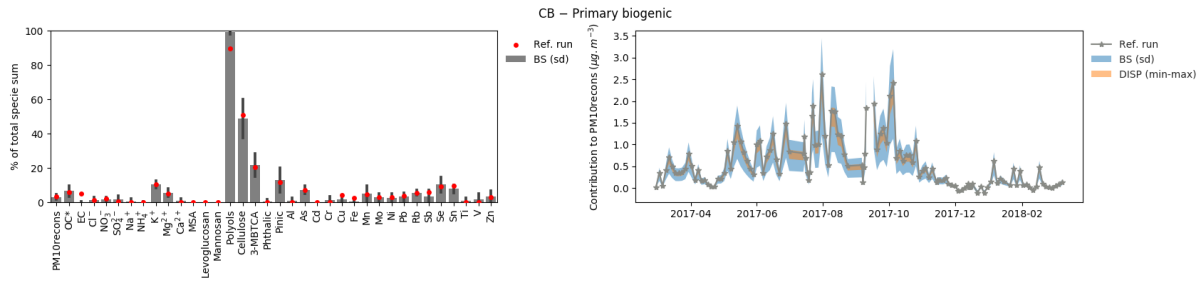

244 This factor remained relatively steady due to the influence from long-range transport but did
 245 not show seasonality that was previously found in the nitrate-rich factor. Most of the tracers,
 246 SO_4^{2-} , NH_4^+ , and phthalic acid, in this factor have showed strong correlations across sites,
 247 except for Se. The presence of Se in this factor may suggest a contribution from gasoline and
 248 diesel emissions (De Santiago et al., 2014) which can be highly localized in nature affecting the
 249 over-all temporal correlation of the sulfate-rich source across sites. The presence of phthalic
 250 acid in this factor also suggests influence from SOA formation as reported in other studies (Al-
 251 Neima and Stone, 2017; Kleindienst et al., 2012).

309

310

311

Figure S3.10.1 Comparison of chemical profile between the classic and orga PMF run for the industrial factor in LF (top), CB (middle), and Vif (bottom).

The industrial factor was identified with high loadings of trace elements including As, Cd, Cr, Mn, Mo, Ni, Pb, and Zn. On an annual scale, this factor only accounted for 1-2% of the total mass of PM. It is interesting to note that LF and CB showed comparable chemical profiles suggesting possible similarity in origin of this factor resulting to mild correlations between these two sites. However, only weak correlations were seen in the industrial factor when compared to Vif. In fact, Vif showed much higher contribution of Cd compared to other metals in this factor. Nevertheless, this further highlights the robustness of the PMF model in discriminating the chemical profiles of PM₁₀ sources in spite of diversity at a fine-scale resolution.

One of the possible sources of Cd and Ni in the city of Grenoble are modern municipal waste incinerators (Boudet et al., 1999). The elevated contributions of Cd in Vif may also be due to additional influence from a nearby chemical industrial area (<6 km of the sampling location) in the southeast of Grenoble.

312 **Mineral dust**

313

314

315

316

317

318

Figure S3.11. Chemical profile and temporal evolution with error estimates of the mineral dust factor in LF (top), CB (middle), and Vif (bottom).

319

320

321

322 **Figure S3.11.1 Comparison of chemical profile between the classic and orga PMF run for the mineral dust factor in LF**
 323 **(top), CB (middle), and Vif (bottom).**

324

325 The mineral dust factor was identified with high loadings of Ca^{2+} , Al, Ti, and V. In Vif, this
 326 factor did not show as much loading of Ca^{2+} (see Fig. S3.11). The temporal evolution of Ca^{2+}
 327 showed strong correlations across all sites, however good correlations from Al, Ti, and V were
 328 only found between LF and CB which has further resulted to strong correlations of the mineral
 329 dust factor in these two sites. This highlights the capability of PMF to analyse and differentiate
 330 the chemical profiles of sources even at high proximity of receptor locations. The loadings from
 331 metal tracers suggests natural dust, and fossil fuel or industrial origins of this factor, especially
 332 in Vif (Luo et al., 2008; Pan et al., 2015).

333 The presence of Fe, a good indicator of road traffic emissions, also suggests possible influence
 334 from road dust resuspension in the mineral dust factor. On an annual scale, mineral dust sources
 335 accounted for 9%, 10%, and 2% in LF, CB, and Vif, respectively.

336

337 **S4. Comparison between the PMF results from Srivastava et al. (2018b) and our study**

338 One of the sites in our study, LF (urban background site), has been previously reported using a
 339 one-year dataset collected in year 2013 (Srivastava et al., 2018b). The comparison of PMF
 340 results obtained including the sources and its corresponding tracers and percentage contribution
 341 are summarized in Table S4.

342 However, there are some differences in the input variables used resulting to differences in the
 343 identified sources. The sources that are common to both studies are biomass burning, primary
 344 traffic, mineral dust, and aged sea salt. The nitrate-rich and sulfate-rich sources were obtained
 345 separately in our study while it was combined into one factor as the secondary inorganics in
 346 Srivastava et al. (2018b). Although the tracers are available, sea/road salt and industrial sources
 347 were not identified in Srivastava et al. (2018b). Due to the specific organic tracers used in our
 348 study, we have also additionally obtained primary biogenic, MSA-rich, and secondary biogenic
 349 oxidation sources.

350 It should be noted that Srivastava et al. (2018b) have identified a fungal spores source identified
 351 by high loadings of polyols, which is one of the tracers that was similarly used to identify the
 352 primary biogenic source in our study. This is only a question of naming the profile, fungal
 353 spores emissions being one type of primary biogenic emissions. On the other hand, the plant
 354 debris factor (another type of primary biogenic emissions) from their study using alkane tracers
 355 were considered to be accounted in the primary biogenic factor in our study through the
 356 contributions of cellulose in this factor. Although different organic acids were used, Srivastava
 357 et al. (2018b) was able to obtain a biogenic SOA source identified by contributions from α -
 358 methylglyceric acid (α -MGA and 2-methylerythritol (2-MT), hydroxyglutaric acid (3-HGA),
 359 while our study have obtained a secondary biogenic oxidation source identified by 3-MBTCA
 360 and pinic acid. Both of these factors are identified as a secondary biogenic oxidation source and
 361 are very close in terms of percentage contribution. Lastly, Srivastava et al. (2018b) was able to
 362 obtain an anthropogenic SOA source that was not identified in our study but may be considered
 363 to be mixed in multiple sources through the contributions of phthalic acid.

364 **Table S4. The comparison of PMF-resolved sources, tracers, and annual average percentage contribution between**
 365 **Srivastava et al. (2018b) and our study.**

Sources	Our study (LF only)			Srivastava et al. (2018b)	
	Tracers	Percentage contribution (%)	Average \pm std ($\mu\text{g m}^{-3}$)	Tracers	Percentage contribution (%)
Biomass burning	Levoglucosan, mannosan, K ⁺ , Rb, Cl ⁻	17	2.3 \pm 3.2	Levoglucosan, coniferaldehyde, vanillic acid	20
Primary traffic	EC, Ca ²⁺ , Cu, Fe, Sb, Sn	12	1.8 \pm 2.4	EC, hopanes (H5 to H8)	14
Nitrate-rich	NO ₃ ⁻ , NH ₄ ⁺	20	2.8 \pm 5.7	N/A	N/A
Sulfate-rich	SO ₄ ²⁻ , NH ₄ ⁺ , Se	16	2.2 \pm 1.6	N/A	N/A
Mineral dust	Ca ²⁺ *, Al, Ti	9	1.3 \pm 1.6	Ca, Al, Ti	21
Sea/road salt	Na ⁺ , Cl ⁻	4	0.5 \pm 1.1	N/A	N/A
Aged sea salt	Na ⁺ , Mg ²⁺	3	0.4 \pm 0.4	Na ⁺ , Mg ²⁺	2

Industrial	As, Cd, Cr, Mn, Mo, Ni, Pb, Zn	1	0.1±0.2	N/A	N/A
Primary biogenic	Polyols, cellulose	4	0.5±0.6	N/A	N/A
MSA-rich	MSA	4	0.5±0.6	N/A	N/A
Secondary biogenic oxidation	3-MBTCA, pinic acid	11	1.6±2.3	N/A	N/A
Fungal Spores	N/A	N/A	N/A	Polyols	5
Secondary inorganics	N/A	N/A	N/A	NO ₃ ⁻ , NH ₄ ⁺ , SO ₄ ²⁻ , Cl ⁻	13
Plant debris	N/A	N/A	N/A	alkanes (C27 to C31)	11
Biogenic SOA	N/A	N/A	N/A	α-methylglyceric acid (α-MGA and 2-methylerythritol (2-MT), hydroxyglutaric acid (3-HGA)	12
Anthropogenic SOA	N/A	N/A	N/A	acenaphthenequinone, 6H-dibenzo[b,d]pyran-6-one, 1,8-naphthalic anhydride, DHOPA	2
