27 **ABSTRACT**

28 Black carbon (BC) emissions play an important role in regional climate change of the Arctic. It is
29 necessary to pay attention to the impact of long-range transport from regions outside the Arctic as
30 BC emissions from local sources in the Arctic were relatively small. The Task Force Hemispheric
31 Transport of Air Pollution Phase2 (HTAP2) set up a series of simulation scenarios to investigate the
32 response of BC in a given region to different source regions. This study investigated the responses of
33 Arctic BC concentrations and surface temperature to 20% anthropogenic emission reductions from
34 six regions in 2010 within the framework of HTAP2 based on ensemble modeling results. Emission
35 reductions from East Asia (EAS) had most (monthly contributions: 0.2 - 1.5 ng m⁻³) significant
36 impact on the Arctic near surface BC concentrations while the monthly contributions from Europe

37 (EUR), Middle East (MDE), North America (NAM), Russia-Belarus-Ukraine (RBU), and South Asia
38 (SAS) were 0.2–1.0 ng m⁻³, 0.001–0.01 ng m⁻³, 0.1–0.3 ng m⁻³, 0.1–0.7 ng m⁻³, 0.0–0.2 ng m⁻³,
39 respectively. The responses of the vertical profiles of the Arctic BC to the six regions were found to
40 be different due to multiple transport pathways. Emission reductions from NAM, RBU, EUR, and
41 EAS mainly influenced the BC concentrations in low troposphere of the Arctic, while most of the BC
42 in the upper troposphere of the Arctic derived from SAS. The response of the Arctic BC to emission
43 reductions of six source regions became less significant with the increase of the latitude. The benefit
44 of BC emission reductions in terms of slowing down surface warming in the Arctic was evaluated by
45 using Absolute Regional Temperature-change Potential (ARTP). Compared to the response of global
46 temperature to BC emission reductions, the response of Arctic temperature was substantially more
47 sensitive, highlighting the need for curbing global BC emissions.

48 **1. Introduction**

49 Black carbon (BC) is one of the short-lived climate forcers (SLCFs, AMAP, 2015) and was regarded
50 as the second largest contributor to global warming, only inferior to carbon dioxide (Bond et al.
51 2013). BC over the Arctic can perturb the radiation balance in a number of ways. Direct aerosol
52 forcing occurred through absorption or scattering of solar (shortwave) radiation. BC is the most
53 efficient atmospheric particulate species at absorbing visible light (Bond et al., 2013), the added
54 atmospheric heating will subsequently increase the downward longwave radiation to the surface and
55 warm the surface (AMAP, 2011). Radiative forcing by BC can also result from aerosol-cloud
56 interactions that affected cloud microphysical properties, albedo, extent, lifetime, and longwave
57 emissivity (Twomey 1977; Garrett and Zhao 2006). BC has an additional forcing mechanism after
58 depositing onto snow and ice surfaces (Clarke and Noone, 1985). The surface albedo of snow and ice
59 could be reduced and further enhanced the absorption of solar radiation at the surface. In the Arctic,
60 surface temperature responses were strongly linked to surface radiative forcing as the stable
61 atmosphere of the region prevented rapid heat exchange with the upper troposphere (Hansen and
62 Nazarenko, 2004).

63 The Arctic has been warming twice as rapidly as the world in the past fifty years, and has
64 experienced significant changes in its ice and snow covers as well as permafrost (AMAP, 2017).

65 Reductions of carbon dioxide emissions are the backbone of any meaningful effort to mitigate
66 climate forcing. But even if significant reductions of carbon dioxide are made, slow down of the
67 temperature rise in the Arctic and the sea level rise caused by the melting of glaciers may not be
68 achieved in time. Hence, the goal of slowing down the deterioration of the Arctic may best be
69 achieved by also targeting at shorter-lived climate forcing agents, especially those that could impose
70 appreciable surface forcing and trigger regional-scale climate feedbacks pertaining to the melting of
71 sea ice and snow. Modelling studies by UNEP/WMO (2011) and Stohl et al. (2015) suggested that
72 the climate response of SLCFs mitigation was strongest in the Arctic region. AMAP (2011 and 2015)
73 as well as Sand et al. (2016) demonstrated that per unit of emission reductions of SLCFs in the
74 Northern areas had the largest temperature response on the Arctic, with the Nordic countries
75 (Denmark, Finland, Iceland, Norway, and Sweden) and Russia having the largest impact compared to
76 other Arctic countries such as the United States and Canada.

77 The few studies that investigated specific regional aerosol forcing (Shindell and Faluvegi, 2009;
78 Shindell et al., 2012; Teng et al., 2012) typically used a single climate model at a time to investigate
79 the climate response to idealized, historical, or projected forcing. However, different models varied
80 considerably in the representation of aerosols and radiative properties, resulting in large uncertainties
81 in simulating the aerosol radiative forcing (Myhre et al., 2013b; Shindell et al., 2013). When
82 investigating the climate response to regional emissions, such uncertainties were likely to be
83 confounded even further by the variability between models in regional climate and circulation
84 patterns and variation in the global and regional climate sensitivity (the amount of simulated
85 warming per unit radiative forcing). Hence, the Task Force Hemispheric Transport of Air pollution
86 Phase2 (HTAP2, <http://www.htap.org/>) incorporating multiple global models can avoid the great
87 uncertainty of single model to a certain degree, with the aim to improve model estimates of the
88 impacts of intercontinental transport of air pollutants on climate, ecosystems, and human health
89 (Galmarini et al., 2017). To date, the HTAP2 results have been explored from a variety of scientific
90 and policy-relevant perspectives. For instance, by comparing against observations, sulfur and
91 nitrogen depositions during HTAP2 had been significantly improved compared to HTAP1. From
92 2001 to 2010, the global nitrogen deposition increased 7% while the global sulfur deposition
93 decreased 3% (Tan et al., 2018a). The significant impacts of hemispheric transport on the deposition
94 were specifically focused and the deposition over the coastal regions was more sensitive to

95 hemispheric transport than the non-coastal continental regions (Tan et al., 2018b). Jonson et al. (2018)
96 assessed the contributions from different world regions to European ozone levels and contributions
97 from the non-European regions were mostly from North America and eastern Asia, larger than those
98 from European emissions. Hogrefe et al. (2018) found that the simulated ozone over the continental
99 US varied very differently by digesting boundary conditions from four hemispheric or global models.
100 The impact of emission changes from six major source regions on global aerosol direct radiative
101 forcing was estimated (Stjern et al., 2016). In the local source regions, the radiative forcing
102 associated with SO_4^{2-} was strengthened (25%) while that from BC was weakened (37%) due to a
103 20% emission reduction. Liang et al. (2018) estimated global air-pollution-related premature
104 mortality from exposure to $\text{PM}_{2.5}$ and ozone and the interregional transport lead to more deaths
105 through changes in $\text{PM}_{2.5}$ than in O_3 . However, the source region contributions to Arctic BC and the
106 spread among multi-model results have been rarely explored from the perspective of HTAP2
107 initiative.

108 This study aims to investigate the responses of Arctic BC concentrations and surface temperature
109 to 20% anthropogenic emission reductions from different regions in the Northern Hemisphere (NH).
110 A comparison of six global modeling works within the framework of HTAP2 experiments for the
111 Arctic region in 2010 was presented. The ensemble modeling results were used to apportion the
112 contribution from different source regions to the near-surface and vertical black carbon in the Arctic.
113 In addition, the Arctic surface temperature responses to the emission reductions were estimated.

114 **2. Methodology**

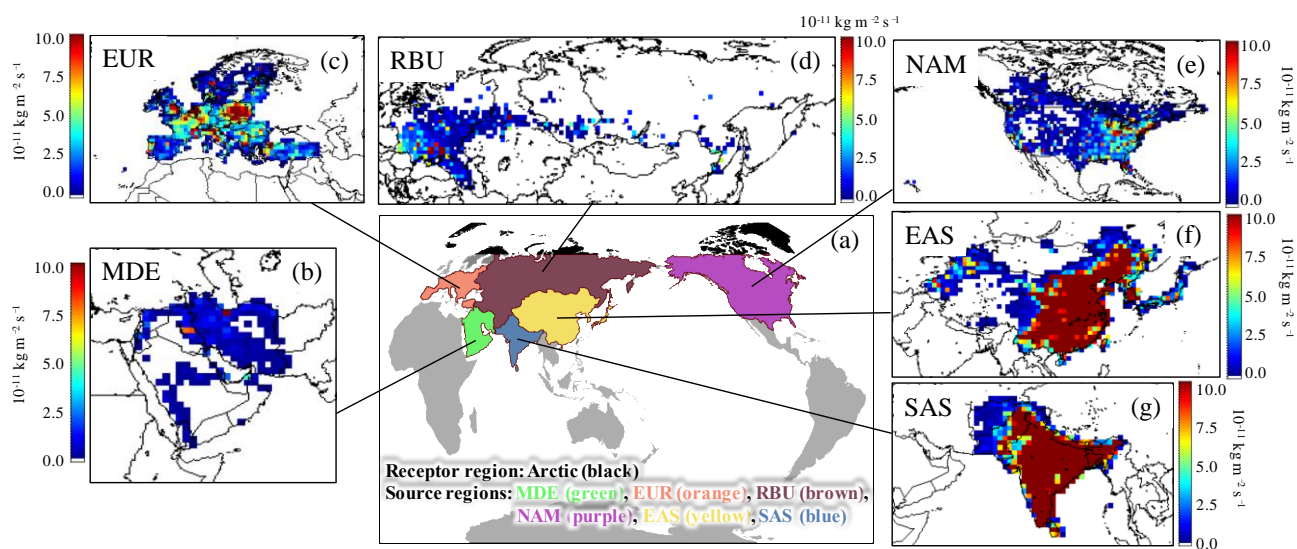

115 **2.1 HTAP2 experiments**

116 HTAP2 developed a harmonized emissions database covering all countries and the major sectors for
117 global and regional modeling from 2008 to 2010. The emissions database was obtained from the
118 nationally reported emissions (e.g., National Emission Inventory for the United States), the regional
119 scientific inventories (e.g., European Monitoring and Evaluation Programme (EMEP), Netherlands
120 Organisation for Applied Scientific Research (TNO) for Europe, Model Inter-Comparison Study for
121 Asia, MICS–Asia III), and the Emissions Database for Global Atmospheric Research data
122 (EDGARv4.3, emissions for South America, Africa, Russia and Oceania). Biomass burning

123 emissions were not prescribed in HTAP2. It was recommended that modeling groups used the Global
 124 Fire Emissions Database (GFED4, <http://globalfiredata.org/>) with a temporal resolution of daily or
 125 3-hour intervals. The detailed information of different regional inventories can be found in
 126 Janssens–Maenhout et al. (2015).

127 Emission perturbations were conducted in sensitivity simulations to investigate the response of
 128 various air pollutants in a given region to different source regions. In this study, the Arctic region was
 129 the targeted receptor region of interest. Six source regions in HTAP2 experiments, namely, East Asia
 130 (EAS), Europe (EUR), Middle East (MDE), North America (NAM), Russia–Belarus–Ukraine (RBU),
 131 and South Asia (SAS) were selected to demonstrate their influences on the BC concentrations over
 132 the Arctic region (Figure 1a). Two emission scenarios were designed for the HTAP2 simulation to
 133 explore the source/receptor relationships, i.e. the base scenario (BASE) with no emission reduction,
 134 and the control scenario (EASALL, EURALL, MDEALL, NAMALL, RBUALL, and SASALL)
 135 with 20% reduction of all anthropogenic emissions in six regions respectively.

136

137

138 **Figure 1.** (a) The sketch map of receptor and source regions. (b)–(g) Spatial distributions of 20% reduction of
 139 annual BC emission in the six source regions in 2010. MDE: Middle East; EUR: Europe; RBU:
 140 Russia–Belarus–Ukraine; NAM: North America; EAS: East Asia; SAS: South Asia. The unit legends from (b) to (g)
 141 are the same of $10^{-11} \text{ kg m}^{-2} \text{ s}^{-1}$.

142 2.1.1 Anthropogenic emission reductions of BC in HTAP2

143 Anthropogenic BC emission sectors included power plants, industries, transportation, shipping,
 144 aviation, agriculture, and residential sectors. The emission inventory had a monthly temporal

145 resolution and a spatial resolution of $0.1^\circ \times 0.1^\circ$. The total anthropogenic emissions and 20%
 146 emission reductions of BC in six source regions of HTAP2 in 2010 are presented in Table 1. The
 147 higher BC emission reductions were found in the EAS and SAS with the values of 355.6 and 232.5
 148 Gg yr^{-1} , respectively, while were much lower in the MDE and RBU with the values of 5.3 and 18.6
 149 Gg yr^{-1} , respectively. The BC emission reductions in the EAS, EUR, and RBU showed significant
 150 monthly variations with higher values from November to March, while the monthly variations were
 151 not obvious in the MDE, NAM, and SAS.

152

153 **Table 1.** 20% emission reductions and total anthropogenic emissions of BC in different regions of HTAP2 in 2010.

156 Figure 1b–g illustrates the spatial distribution of the 20% reductions of annual BC emissions in six
 157 source regions in 2010. It can be found that the most intense reductions of BC emissions in EAS and
 158 SAS were concentrated in East China and India, respectively, which were mainly attributed to
 159 emissions from residential sectors, followed by transportation and industries. The BC emission
 160 reductions of EUR were widely distributed with high values in central Europe, with residential and
 161 transportation sectors accounting for the largest proportion. The reductions near the Arctic circle
 162 could be found in the north of EUR, NAM, and RBU. For MDE, most BC was emitted from Iran,
 163 which located in the northeast of this region. Overall, the spatial pattern of BC emission reductions in
 164 six regions was closely related to the spatial distribution of the human population.

165 2.1.2 Model description

166 Considering that the simulations should cover all months of 2010 and all emission source regions,

167 five global models (i.e. CAMchem, CHASER_re1, GEOS-Chem, GOCART-v5, and Oslo CTM3-v2)
 168 were incorporated to simulate the responses of BC concentrations in the Arctic to 20% BC emission
 169 reductions from EAS, EUR, MDE, NAM, RBU, and SAS, respectively. The brief information of
 170 model configurations is listed in Table 2. As required by HTAP2, all simulations should include a
 171 spin-up time of 6 months prior to the period of interest. The outputs from all models are available
 172 upon request from <http://aerocom.met.no>. The time resolution of the outputs used in this study is
 173 monthly for all models, although models were run at a finer resolution (e.g., daily or hourly). The
 174 model outputs for air pollutants were originally provided in the unit of mass mixing ratio (MMR, kg
 175 kg⁻¹). To facilitate comparison between model and observation and further data analysis, we
 176 converted the original units into ng m⁻³ based on the ideal gas law (Aamaas et al., 2017).

177

178 **Table 2.** Configurations of models used in this study

Models	Meteorological field	Horizontal resolution	Vertical layers	Convection	Reference
CAMchem	GEOS5 v5.2	1.9° × 2.5°	56	Zhang–McFarlane approach for deep convection	Lamarque et al., 2012; Tilmes et al., 2016
CHASER_re1	ERA-Interim and HadISST	2.8° × 2.8°	32	CCSR/NIES AGCM for advection, convection, and other subgrid-scale mixing	Sudo et al., 2002; Takashi et al., 2018
GEOS-Chem	GEOS-5 (MERRA)	2.0° × 2.5°	47	Convective transport is computed from the convective mass fluxes in the meteorological archive	Henze et al., 2007
GOCART-v5	MERRA	1.3° × 1.0°	72	MERRA for moist convection, Arakawa–Schubert (RAS) algorithm for GCTM	Chin et al., 2000
Oslo CTM3-v2	ECMWF-IFS	2.8° × 2.8°	60	Tiedke mass flux scheme for deep convection	Søvde et al., 2012; Lund et al., 2018

179 2.2 Calculation of the temperature response to BC emissions reduction

180 The climate effects of air pollutants have been the focus of climate change research since the last
 181 century (IPCC, 1990; IPCC, 2001). In the last few years, the metrics for estimating this kind of effect
 182 have been constantly improving (Shindell et al., 2012; Bond et al., 2013; Smith and Mizrahi, 2013;
 183 Stohl et al., 2015). The Intergovernmental Panel on Climate Change (IPCC) used the Global
 184 Warming Potential (GWP) as a method for comparing the potential climate impact of emissions of

185 different greenhouse gases (IPCC, 1990). GWP is the time-integrated radiative forcing due to a pulse
 186 emission of a given species, over some given time horizon (commonly 20, 100, or 500 years) relative
 187 to a pulse emission of carbon dioxide. GWP does not purport to represent the impact of air pollutant
 188 emissions on temperature. Although a short-lived climate pollutant (SLCP) could have the same
 189 GWP as a long-lived climate pollutant, identical (in mass terms) pulse emissions could cause a
 190 different temperature change at a given time, because long-lived climate pollutants accumulate in the
 191 climate system while short-lived climate pollutants can be broken down by various processes.
 192 Consequently, warming caused by long-lived climate pollutants is determined by total cumulative
 193 emissions to date, while the warming due to short-lived climate pollutants is determined more by the
 194 current rate of emissions in any given decade and depends much less on historical emissions. This
 195 means the importance of SLCP emissions is often overstated based on GWP. Shine et al. (2005)
 196 proposed the Global Temperature Change Potential (GTP) as a replacement for GWP to represent the
 197 global-mean surface temperature change for both a pulse emission (GTP_P) and a sustained change in
 198 emissions (GTP_S) of a given air pollutant. The distinction between GTP_P and GTP_S avoids the
 199 overestimation of GWP for the short-lived climate pollutants. Even for a uniform forcing, there will
 200 be differences of spatial patterns in the temperature response. Regional Temperature-change Potential
 201 (RTP) (Shindell and Faluvegi, 2010) was applied to analyze the temperature response on the regional
 202 scale, since both GWP and GTP focused on the global scale. The GWP, GTP, and RTP were
 203 normalized to the corresponding effect of CO₂ as the Absolute Global Warming Potential (AGWP),
 204 Absolute Global Temperature Change Potential (AGTP), and Absolute Regional Temperature-change
 205 Potential (ARTP), respectively. AGWP represented the absolute forms of radiative forcing. AGTP
 206 and ARTP represented the absolute forms of temperature perturbation.

207 ARTPs is more suitable for this study to calculate the temperature response, considering that the
 208 research object is BC with short lifetime and focus on regional impact of the BC emission reductions
 209 on temperature changes in the Arctic. For SLCPs with atmospheric lifetimes much shorter than both
 210 the time horizon of the ARTP and the response time of the climate system, the general expression for
 211 the ARTP following a pulse emission of BC (E) in region r which leads to a response in latitude band
 212 m is as follows (Fuglestad et al., 2010; Collins et al., 2013; Aamaas et al., 2017):

$$213 \quad \text{ARTP}_{r, m, s}(H) = \sum_l \frac{F_{l, r, s}}{E_{r, s}} \times \text{RCS}_{l, m} \times R_T(H) \quad (1)$$

214 $F_{l,r,s}$ (in W m^{-2}) is the radiative forcing in latitude band l due to emission in region r in season s as
215 a function after the pulse emission $E_{r,s}$ (in Tg). Even though our estimates are based on seasonal
216 emissions, the temperature responses calculated are annual means. Shindell and Faluvegi (2009)
217 analyzed BC climate effect in four different latitudes: southern mid-high latitudes (90°S – 28°S),
218 tropics (28°S – 28°N), northern mid-latitudes (28°N – 60°N), and the Arctic (60°N – 90°N), which gives
219 a better estimate of the global temperature response as it accounts for varying efficacies with latitude.
220 The $RCS_{l,m}$ is a matrix of regional response coefficients based on the RTP concept (unitless; Collins
221 et al., 2013). As these response coefficients are normalized here, they contain no information on
222 climate sensitivity, only the relative regional responses in the different latitude bands. The global
223 climate sensitivity is included in the impulse response function R_T , which is a temporal temperature
224 response to an instantaneous unit pulse of RF (in $\text{K m}^2 \text{W}^{-1}$). This paper refers to the ARTP values in
225 Aamaas et al. (2017). Aamaas et al. (2017) applies two refinements of the forcing-response
226 coefficients for radiative forcing occurring in the Arctic: one for the aerosol effects in the atmosphere
227 (Shindell and Faluvegi, 2010; Lund et al., 2014) and another for the effects due to BC on snow
228 (Flanner, 2013). The ARTP in this study estimated of the direct effect in the Arctic included both the
229 direct radiative forcing from outside the Arctic and within the Arctic, while the ARTP of the
230 semi-direct effect in the Arctic was due to the semi-direct radiative forcing from outside the Arctic.
231 The contribution by radiative forcing within the Arctic to Arctic temperature changes considered the
232 vertical profile of BC concentrations as both $F_{Arctic,r,s}$ and $RCS_{Arctic,Arctic}$ have a dependence on the
233 height of the BC (Lund et al., 2014; Lund et al., 2017). The total response in the Arctic was the sum
234 of the contributions from BC forcing outside of the Arctic and inside of the Arctic.

235 Regional temperature responses at time t of an emission $E(t)$ can be calculated with these ARTP
236 values by a convolution (Aamaas et al., 2016). The temperature response is as follows:

$$237 \Delta T_{r,m,s,t}(t) = \int_0^t E_{r,s,t}(t') \times \text{ARTP}_{r,m,s,t}(t-t') dt' \quad (2)$$

238 $\Delta T_{r,m,s,t}$ refers to the decrease of the Arctic or global surface temperature after 20, 100, or 500 years
239 to 20% BC emission reductions of six regions (namely EAS, EUR, MDE, NAM, RBU, and SAS) in
240 the framework of HTAP2 either during summer or winter in this paper.

241 **3. Results and Discussion**

242 **3.1 Model evaluation**

243 To evaluate the model performance from all five models, the monthly simulated surface BC
244 concentrations of the BASE scenario were compared with the observations at four monitoring sites in
245 the Arctic Circle in 2010. The locations of the four sites, including Alert (82.5°N, 62.3°W) in Canada,
246 Barrow (71.3°N, 156.6°W) in Alaska, Tiksi (71.59°N, 128.92°E) in Russia, and Zeppelin (78.9°N,
247 11.9°E) in Norway, are plotted in Figure S1 in the Supporting Information.

248 Metrics (Text S1) including correlative coefficient (COR), normalized mean bias (NMB),
249 normalized mean error (NME), mean bias (MB), and mean absolute error (MAE) were selected for
250 evaluating the model performance in this study (U.S. EPA, 2007) In addition to the evaluation for
251 each single model, the multi-model ensemble mean (calculated as the average of all participating
252 models) was also evaluated. The statistical results are listed in Table 3 and Table S1. A comparison
253 between the monthly variations of simulated and observed BC concentrations is shown in Figure S2
254 (a).

255 The correlations of the simulated BC concentrations among different models were moderate to
256 high with CORs ranging from 0.33 to 0.98 (Table S1), suggesting the temporal variations of different
257 models were relatively consistent. Overall, CAMchem, GEOS-Chem, GOCART-v5, and Oslo
258 CTM3-v2 underestimated the near-surface BC (Figure S2a), which may be attributed to an
259 underestimation of BC emissions, e.g., gas flaring (Huang et al., 2014, 2015; Stohl et al., 2013) and
260 shipping emissions (Marelle et al., 2016). Also, appropriate temporal allocation of BC emissions
261 from residential combustion was another important factor governing the model performance (Stohl et
262 al., 2013). However, the simulated BC surface concentrations from CHASER_re1 were higher than
263 those of the other four models and observations (Figure S2a), which mainly due to their slow BC
264 aging-rate in remote/polar regions (Sudo et al., 2015).

265 Table 3 shows the model performances at the four Arctic sites. No single model could reproduce
266 the BC concentrations in the Arctic well, and models performed differently at different monitoring
267 sites. Relatively good agreement between the observation and models was found at Zeppelin, with
268 CORs, NME, MB, and MAE of 0.59–0.83, 38.59%–142.64%, –13.53–14.97 ng m⁻³, and 5.40–14.97

269 ng m⁻³, respectively. The best correlation (0.83) was found at Zeppelin from Oslo CTM3, while the
 270 smallest NMB (38.59%) and MAE (5.40 ng m⁻³) were found at Zeppelin from GOCART. On the
 271 contrary, the simulated BC concentrations didn't agree so well with observations at the other three
 272 sites with even negative COR values in some models (e.g., CAMchem, and CHASER_re1), which
 273 may be explained by the uncertainties in emission inventory, the bias in the meteorological
 274 simulations, and chemical mechanisms (Miao et al., 2017; Zhang et al., 2019). All models, except
 275 Oslo CTM3, overestimated the BC concentrations in Barrow in July (Figure S2a), mainly due to the
 276 large contributions of biomass burning from Siberia in the simulations caused by overestimations of
 277 emissions and/or too little removal during transport (Sobhani et al., 2018).

278 The vertical profiles of simulated BC concentrations of the BASE simulation were also compared
 279 with aircraft measurements from HIAPER Pole-to-Pole Observations (HIPPO) during 24 March–16
 280 April 2010 (Figure S2b). Different from comparison between observed and simulated BC
 281 concentrations near the surface, the vertical profiles of BC concentrations were overestimated by
 282 most models. As the aircraft ascended and descended along each flight track, BC concentrations from
 283 HIPPO varied with time, latitude, longitude, and altitude. However, most of the simulation results of
 284 HTAP2 were provided in the temporal resolution of monthly, simulation and observation results
 285 cannot be exactly matched. This partly explained the difference between the simulations and
 286 observations. In general, the model ensemble mean could capture the vertical pattern of observed BC
 287 profiles.

288 Although the single model didn't reproduce the BC concentrations in the Arctic well, the
 289 consistency of the model ensemble mean with the observation was improved to some extent. The
 290 NME and MAE of model ensemble mean was closer to zero compared with the single model.
 291 Therefore, the multi-model ensemble mean was used for further analysis.

292

296 3.2 Near-surface BC concentrations in the Arctic

297 Before analyzing the responses of Arctic BC to emission reductions, it is necessary to understand the
 298 spatial-temporal distribution of BC concentrations in the Arctic region. In this study, months from
 299 May to October were defined as summer and November to April were defined as winter due to the
 300 special geographical location of the Arctic (Aamaas et al., 2017).

301 Spatial distributions of Arctic near surface BC concentrations in summer and winter simulated
 302 from each model are showed in Figure S4. BC simulated by CHASER_re1 showed relatively high
 303 concentrations over the whole Arctic, followed by GEOS-chem and GOCART-v5, while those
 304 simulated by Oslo CTM3-v2 and CAMchem were lower. The difference of simulated BC
 305 concentrations between land and ocean was more obvious in summer than that in winter, especially
 306 for GEOS-chem and GOCART-v5. The mean BC concentrations from the ensemble models near the
 307 surface Arctic (66–90°N) were 18.6 ng m⁻³ in summer and 16.6 ng m⁻³ in winter in 2010,
 308 respectively. Figure 2 shows that the BC concentrations over the polar sea ice region in winter were
 309 higher than that in summer. The coverage of the polar dome expanded more southward in winter
 310 (Bozem et al., 2019; Law and Stohl, 2007), allowing more BC from lower latitudinal regions to be
 311 transported into the Arctic. Turbulent exchange and deposition were reduced during winter as the
 312 meteorological conditions in the Arctic were stable and dry (Bradley et al., 1992; Bozem et al., 2019;

313 Law and Stohl, 2007). In addition, BC emissions in EAS, EUR, and RBU regions showed obvious
314 monthly changes with higher emissions from November to March as mentioned earlier (Section
315 2.1.1), leading to the relatively high BC concentrations over the polar sea ice region in winter. Over
316 the terrestrial areas within the Arctic Circle, summer BC concentrations were higher than winter,
317 especially in Siberia and Alaska, which were attributed to intense BC emissions from biomass
318 burning over these areas from Jun to Aug (Figure S3).
319

320 **Figure 2.** Spatial distribution of near-surface BC concentrations in (a) summer and (b) winter in the Arctic in 2010.

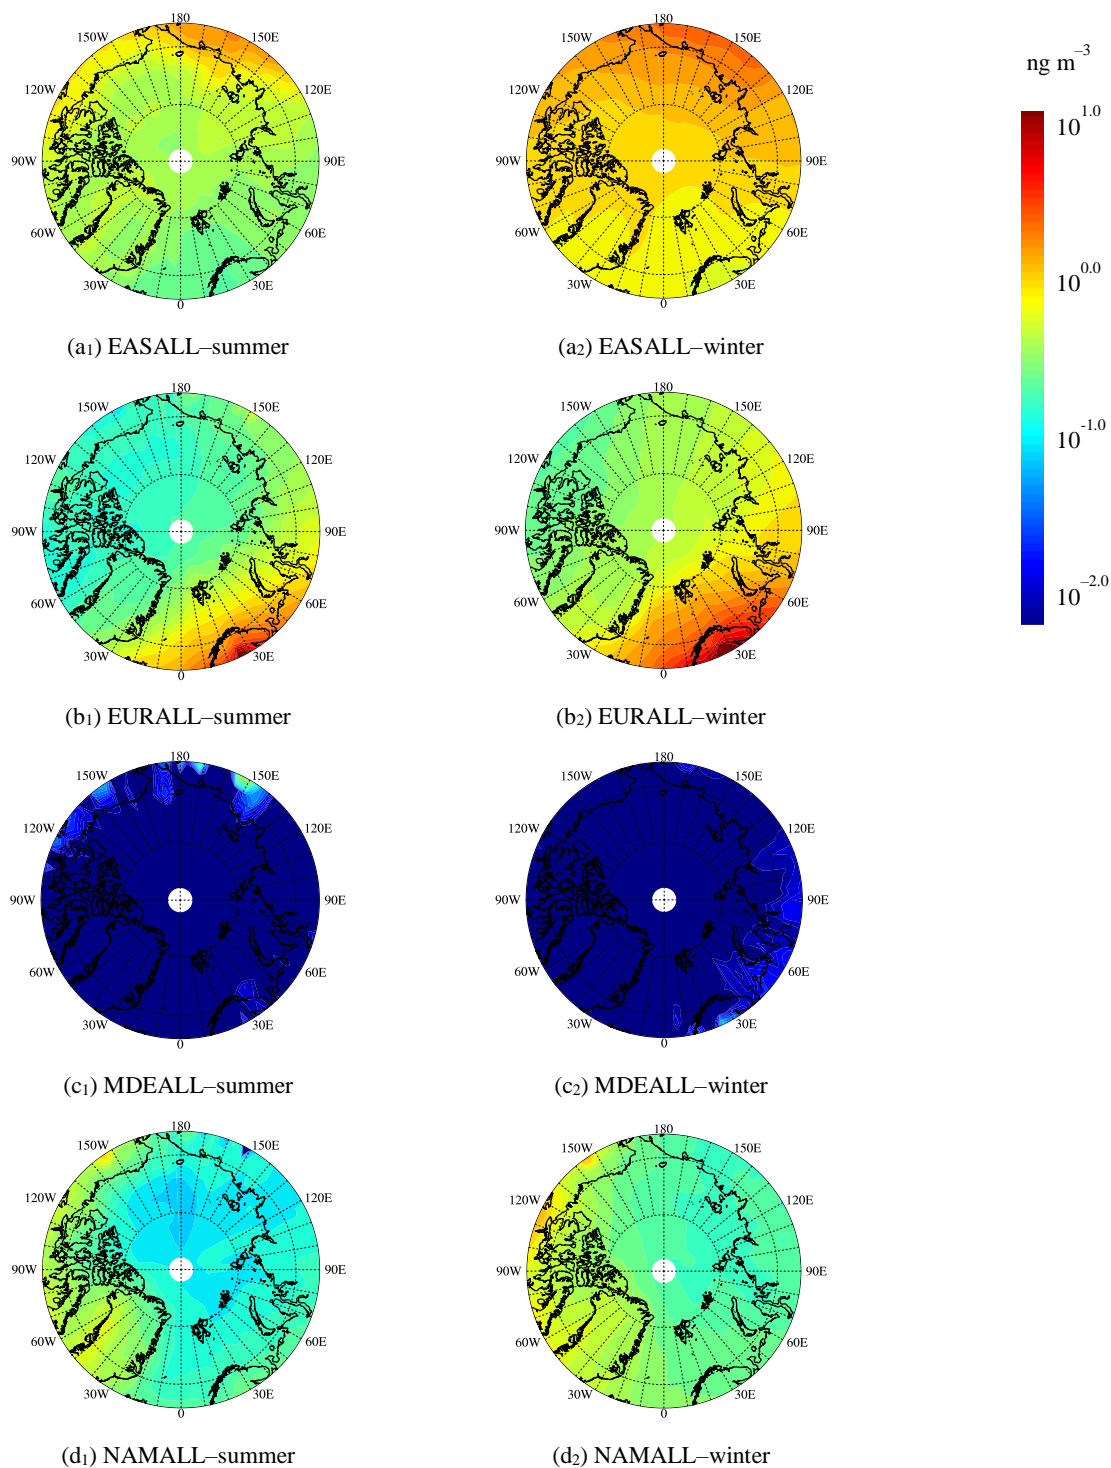

321

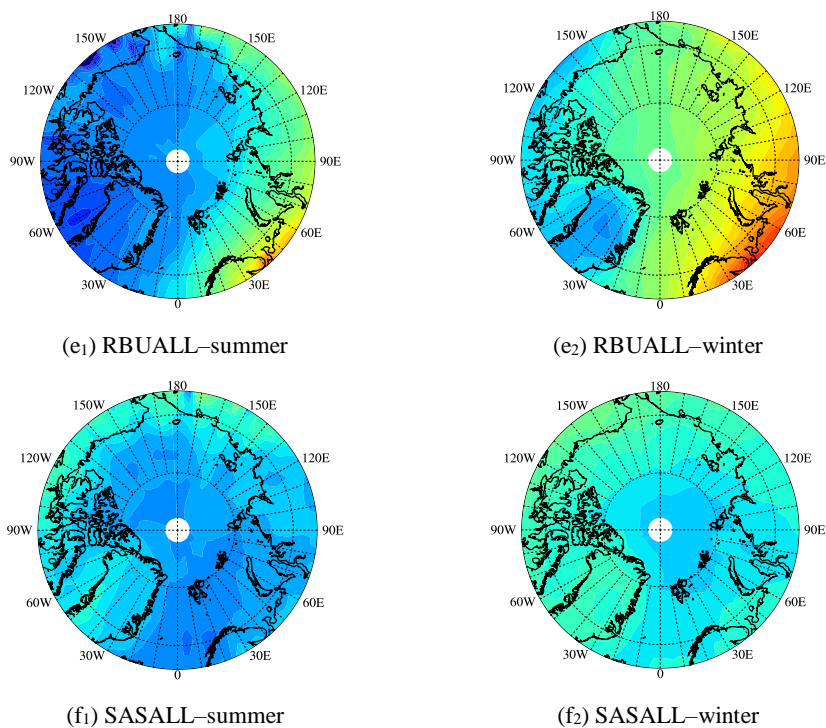

322 **3.3 Response of Arctic BC to 20% emission reductions**

323 **3.3.1 Contributions of regional emission reductions to the Arctic near-surface BC**

324 The response of the Arctic near-surface BC to 20% emission reductions from different source regions
325 was analyzed through emission perturbation simulations. Figure 3 shows the spatial distribution of
326 the referred response above in summer and in winter of 2010 based on multi-model ensemble mean
327 results. The source region contributions to the surface BC concentrations exhibited significant
328 seasonal variability with higher values in winter. The BC emission reductions in EAS almost affected
329 the whole Arctic, especially in winter, indicating the significance of the intercontinental transport of
330 BC. The spatial distribution of the Arctic near-surface BC response to SAS emission reductions was
331 similar to that of EAS, but the extent was much weaker. The emission reductions from EUR, NAM,

332 and RBU mainly affected the local and nearby areas, which was generally consistent with the spatial
333 pattern of emissions (Figure 1). The contribution from MDE emission reductions was very little.
334

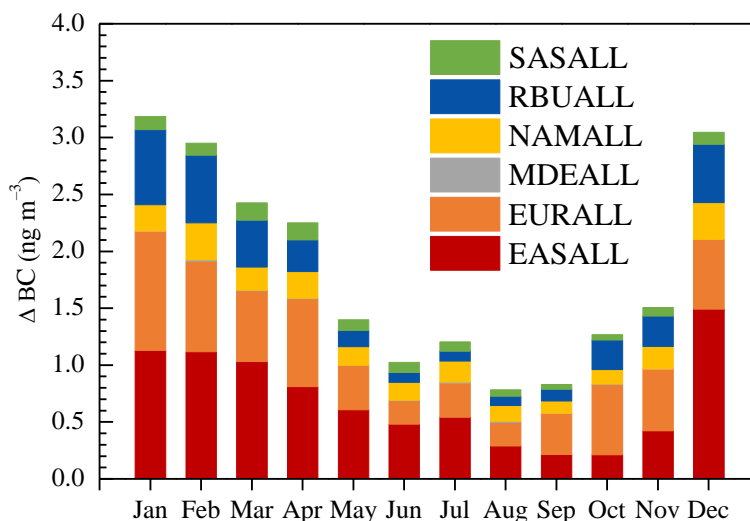

335 **Figure 3.** Spatial distribution of contribution of 20% emission reductions of different source regions to Arctic
 336 near-surface BC in summer and in winter in 2010.

337 The monthly variations of the response of the Arctic near-surface BC concentrations to 20%
 338 emission reductions from six source regions are presented in Figure 4. Results from the ensemble
 339 simulations are averaged over the Arctic covering latitudinal areas from 66°N to the north pole. The
 340 emission reductions from the total six source regions were 329.6 Gg during May to October, lower
 341 than that of 411.9 Gg during November to April (Table 1). Correspondingly, the contributions of 20%
 342 BC emission reductions from all six regions to Arctic near-surface BC concentrations were 0.8–1.4
 343 ng m^{-3} during May to October and 1.5–3.2 ng m^{-3} during November to April. Arctic sensitivities
 344 (Arctic concentration change per unit source region emission change) for BC typically maximized
 345 from December to February for EUR and RBU and from March to May for EAS and NAM (Shindell
 346 et al., 2008; AMAP, 2008). The enhanced sensitivity from December to May resulted from faster
 347 transport and slower removal during winter as the meteorological conditions in the Arctic were stable
 348 and dry (Law and Stohl, 2007). The results of deposition changes also proved this result well (Figure
 349 S5). The wet deposition in summer was higher than that in winter, which was 7–13 times of dry
 350 depositions. Sharma et al. (2013) found that the Arctic region (north of 70°N) was very dry during
 351 winter with an average daily precipitation rate between 0 and 1 mm day^{-1} . Precipitation rates over
 352 some of the BC source regions such as Eurasia were at the same order of magnitude as the Arctic.

353 Less wet deposition and a shallow boundary layer resulted in higher BC concentrations near the
354 surface during winter. In the summertime, the Arctic region experienced 2 to 3 times higher
355 precipitation rates as well as wet depositions of BC relative to wintertime, thus resulting in lower
356 contributions to the near-surface BC concentrations.

357 The annual contribution of 20% emission reductions from EAS, EUR, MDE, NAM, RBU, and
358 SAS to the Arctic near-surface BC concentrations reached 0.70, 0.54, 0.01, 0.20, 0.29, and 0.09 ng
359 m⁻³ in 2010, respectively. Correspondingly, the annual reduced column BC loadings over the Arctic
360 were 8521.7, 2789.1, 28.8, 1762.1, 998.6, and 3640.2 ng m⁻² in 2010, respectively.

361 The response of Arctic near-surface monthly BC concentration was found strongest to the 20%
362 emission reductions from EAS with the contribution of 0.2–1.5 ng m⁻³, accounting for 16.8%–49.0%
363 of the total reduced BC concentrations resulting from all six source regions (Figure 4). On one hand,
364 the BC emission reductions in EAS were the largest among the six source regions (Table 1). On the
365 other hand, BC emission reductions in EAS can influence the Arctic lower troposphere via two
366 pathways (Bozem et al., 2019; Stohl, 2006). BC from northern regions of EAS can enter into the
367 polar dome of the Arctic in winter, as the air masses have cooled during transport. BC from eastern
368 regions of EAS fast uplifted due to convection and then followed by high altitude transport in
369 northerly directions. Radiative cooling eventually led to a slow descent into the polar dome area after
370 air masses arrived in the high Arctic. It occurred both in summer and winter. In addition to EAS, BC
371 emission reduction from EUR also showed significant impacts on the Arctic near-surface monthly
372 BC concentration with the contribution of 0.2–1.0 ng m⁻³, accounting for 20.1%–49.0% of the total
373 reduced BC concentrations resulting from all six source regions (Figure 4). Among the three regions
374 in the Arctic Circle (i.e. EUR, NAM, and RBU), EUR region had the largest BC emission reductions.
375 Also, the relatively short distance between EUR and the Arctic made EUR the second most important
376 source region to the Arctic. As for NAM and RBU, their 20% emission reductions induced moderate
377 reductions of the monthly Arctic near-surface BC concentrations by 0.1–0.3 and 0.1–0.7 ng m⁻³,
378 respectively. The contribution of 20% emission reductions from SAS to the Arctic near-surface BC
379 concentrations was much lower of 0.0–0.2 ng m⁻³ as a significant portion of BC originating from
380 SAS accumulated in the upper troposphere (Section 3.3.2). Compared to the five source regions
381 discussed above, the response of Arctic BC concentrations to emission reductions from MDE was
382 negligible, owing largely to the low emissions there and long distance from the Arctic.

384 **Figure 4.** Monthly mean reduced concentrations of the near-surface Arctic BC due to 20% emission reductions
 385 from six source regions in 2010.

386 Figure S6 compares the contributions of 20% emission reductions to Arctic near surface BC
 387 concentrations simulated by different models. All five models showed similar monthly variations, of
 388 which CHASER_re1 simulated high BC concentrations compared to the other models due to slow
 389 aging-speed (Sudo et al., 2015). All models showed the major source regions of Arctic BC from EAS,
 390 EUR, and RUB. NAM and SAS contributed moderately while the contribution from MDE was
 391 negligible.

392

393 3.3.2 Contributions of regional emission reductions to the vertical BC profiles

394 To assess the contributions from various source regions to the BC profiles based on the model
 395 ensemble mean, the vertical stratification needed to be unified as most participating models had
 396 different vertical settings. Since CHASER had a relatively coarse vertical resolution of 32 layers, the
 397 other models were unified to the same vertical stratification, as detailed in Table S2.

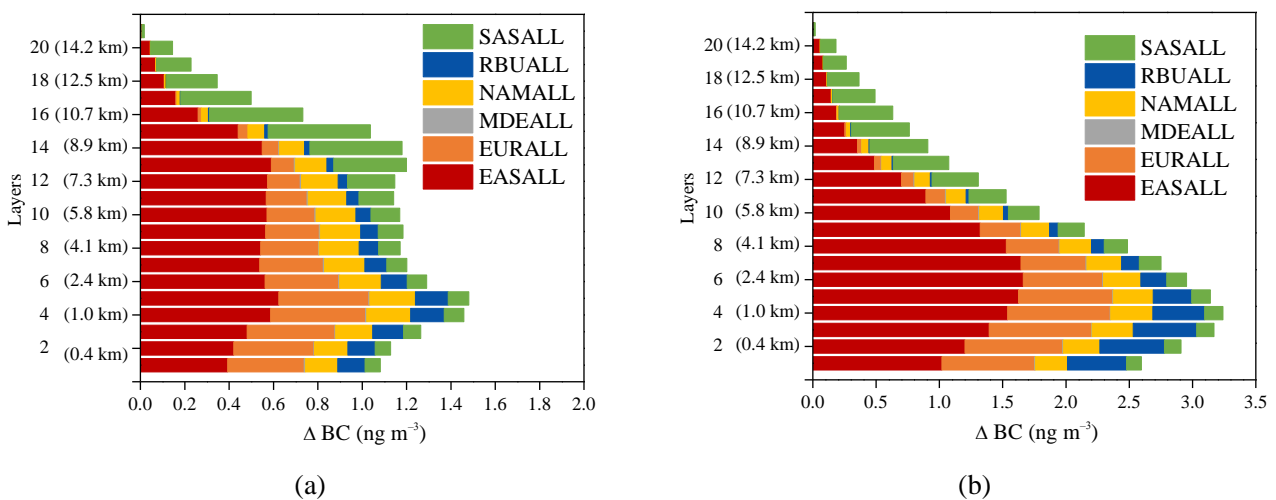

398 As shown in Figure 5, the contributions of regional emission reductions to BC exhibited strong
 399 vertical gradients over the Arctic. In general, the BC profiles displayed a bimodal pattern in summer,
 400 showing peaks at around 1.0–1.6 km a.s.l. (4th and 5th layers) and 8.0–8.9 km a.s.l. (13th and 14th
 401 layers). While in winter, the BC profiles showed a unimodal pattern with peaks around 0.6–1.6 km
 402 a.s.l. (3rd – 5th layers). Long-range transport of air pollutions may occur near the planetary boundary
 403 layer (Eckhardt et al., 2003; Stohl et al., 2002). High contributions in the low layers (e.g., 3rd – 5th

404 layers) were consistent with the height of the planetary boundary layer in the Arctic (Zhang, et al.,
405 2018; Cheng, 2011).

406 It has been summarized that there were several major transport pathways for BC into the Arctic
407 troposphere (Stohl, 2006). i) BC transported rapidly at low-level, followed by uplifting at the Arctic
408 front when it is located far north. Significant deposition of BC in the Arctic occurs mostly north of
409 70°N for this transport route. This transport route derived often from the high BC emission areas in
410 northern EUR but seldom from the NAM and RBU. That was mainly due to that the BC emissions
411 exist at high enough latitudes in EUR, which can be north of the polar front. However, the BC
412 emissions in NAM and RBU were concentrated south of the polar front (Figure 1), thus BC emitted
413 from these two regions can't be easily transported into the Arctic through this pathway. ii) Cold air
414 masses into the polar dome transport at low-level. This pathway derived mainly from EUR and
415 high-latitude areas of EAS during winter. The contribution of 20% emission reductions from EUR to
416 the Arctic BC concentrations peaked at around 1.0 km a.s.l. with the multi-model ensemble mean
417 value of 0.4 ng m⁻³ in summer, while peaked at lower altitude of around 1.6 km a.s.l. with the value
418 of 0.8 ng m⁻³ in winter. iii) BC could also ascend south of the Arctic followed either by high-altitude
419 transport or by several cycles of upward and downward transport, and finally slowly descended into
420 the polar dome due to radiative cooling. This was the frequent transport route from source regions
421 such as NAM, RBU, and east EAS. The contribution from NAM and RBU to the Arctic BC peaked
422 at about 1.6 km a.s.l. (0.2 ng m⁻³) and 1.0 km a.s.l. (0.2 ng m⁻³) in summer, and peaked at about 1.0
423 km a.s.l. (0.3 ng m⁻³) and 0.4 km a.s.l. (0.5 ng m⁻³) in winter. The contribution from EAS including
424 pathways ii and iii, to the Arctic BC peaked at about 1.6 km a.s.l. (0.6 ng m⁻³) in summer and peaked
425 at about 2.4 km a.s.l. (1.6 ng m⁻³) in winter. The contribution from MDE was negligible.

426 As shown in Figure 5, BC can also be transported into the upper troposphere of the Arctic. Air
427 masses preferably kept their potential temperature almost constant during transport as the
428 atmospheric circulation can be well described by adiabatic motions in the absence of diabatic
429 processes related to clouds, radiation, and turbulence. The potential temperature was low within the
430 polar dome area, and thus only air masses experienced diabatic cooling were able to enter the polar
431 dome (Stohl, 2006). That is to say, the air masses from SAS and low-latitude regions of EAS were
432 not easy to penetrate the polar dome but can be lifted and transported to the Arctic in the middle and
433 upper troposphere along the isentropes (AMAP, 2011; Barrie, 1986; Law and Stohl, 2007; Stohl,

434 2006). This agreed well with the previous study of Koch and Hansen (2005) and Stohl (2006). The
 435 contribution from SAS to the Arctic BC concentrations peaked at about 9.7 km a.s.l. (0.4 ng m^{-3}) in
 436 summer and 9.7 km a.s.l. (0.5 ng m^{-3}) winter. This was also consistent with the vertical profiles of
 437 BC shown in Stjern et al. (2016). The polar dome boundary was variable in time and space and was
 438 not zonally symmetric. The range of polar dome expanded southward to about 40°N over Eurasia in
 439 winter as the temperature difference of different latitudes became smaller (Bozem et al., 2019; Law
 440 and Stohl, 2007), resulting in the contribution of EAS to the Arctic BC concentrations in upper
 441 troposphere only peak in summer at 13th layer (8.0 km a.s.l.) with the value of 0.6 ng m^{-3} .
 442

443 **Figure 5.** Contribution of 20% emission reductions from six source regions to BC concentrations in different
 444 vertical layers (a) in summer and (b) in winter in the Arctic in 2010.

445 3.3.3 Contributions of emission reductions to BC in different latitudinal bands

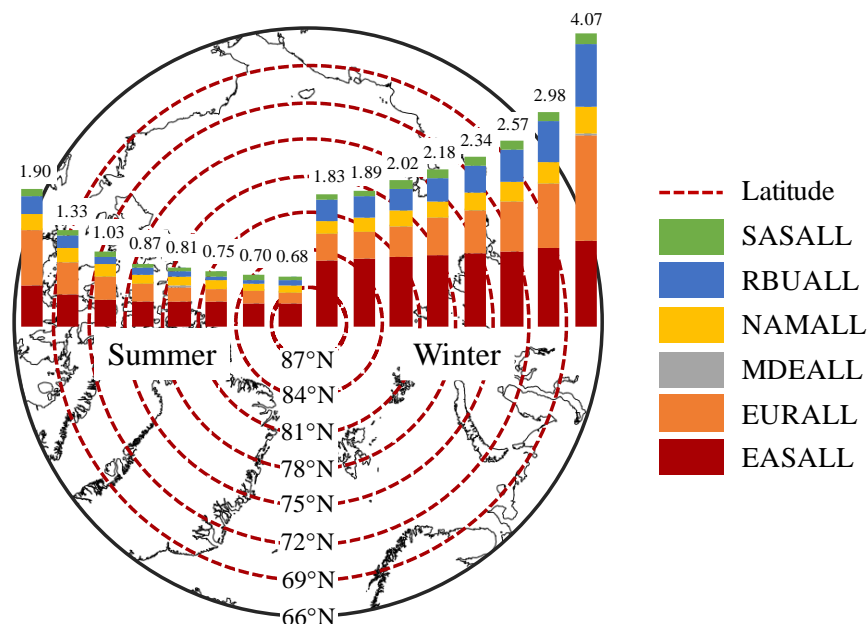

446 To further analyze the response of the Arctic BC concentrations to emission reductions of six source
 447 regions in HTAP2, the contribution of 20% emission reductions to BC concentrations at different
 448 latitudes of the Arctic were calculated (Figures 6 and 7). In regard to the different horizontal
 449 resolution of participating models, the Arctic region ($66\text{--}90^\circ\text{N}$) was divided into eight latitudinal
 450 bands with a 3-degree interval, which was based on the coarsest resolution of all models.

451 The response of the Arctic BC concentrations to emission reductions of six source regions became
 452 weaker with the increase of the latitude due to the continuous loss of BC during transport (e.g., dry
 453 and wet depositions) (Figure 6). The difference of contributions between two adjacent latitudinal
 454 bands became smaller as closer to the north pole. The contributions of 20% emission reductions to

455 the Arctic BC concentrations near surface were the highest between 66–69°N both in summer (1.9 ng
 456 m⁻³) and winter (4.1 ng m⁻³), which were 1.4–2.8 times higher than the other latitudinal bands.

457 The contributions from EAS and EUR were higher than those from the other four regions in each
 458 latitudinal band. In detail, the contributions from EUR (0.8 ng m⁻³ in summer and 1.5 ng m⁻³ in
 459 winter) were higher than those from EAS (0.6 ng m⁻³ in summer and 1.2 ng m⁻³ in winter) in the
 460 latitudinal band of 66–69°N as the BC concentrations near surface there were more sensitive to the
 461 local emission sources. In contrast, the contributions from EAS (0.3–0.4 ng m⁻³ in summer and
 462 0.9–1.1 ng m⁻³ in winter) were higher than those from EUR (0.2–0.4 ng m⁻³ in summer and 0.4–0.9
 463 ng m⁻³ in winter) in the other high latitudinal bands where long-range transport played the dominant
 464 role.

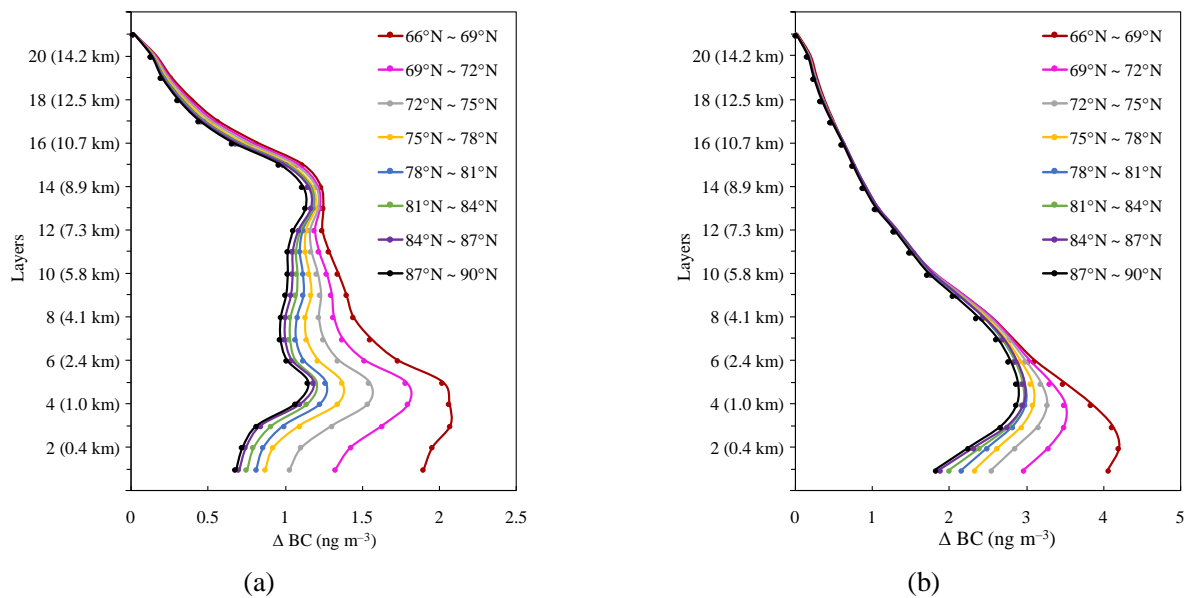

465 The downward trends of the response of the Arctic near surface BC to emission reductions with
 466 the increase of latitude from EUR and RBU were more obvious than that of other regions (Figure 6).
 467 Dry and wet depositions of BC decreased with the increase of transport distance, and the decreasing
 468 rates became slower (Figure S7). The changes of dry and wet depositions caused by emission
 469 reductions from EUR and RBU were still obvious in the Arctic region (66°N–90°N), while
 470 depositions caused by emission reductions from the other regions tended to be gentle (Figure S7).
 471 This explains why the contribution from EAS to BC at different latitudes remained almost constant
 472 while that from EUR and RBU decreased obviously from lower latitudes to the Arctic pol
 473

474

475 **Figure 6.** Contributions of 20% emission reductions of different regions to near-surface BC concentrations in each
476 latitudinal band of the Arctic. The results of summer and winter correspond to the left and right panel in the figure.

477 Figure 7 further depicts the response of the vertical Arctic BC profiles in different latitudinal bands
478 to 20% emission reductions. The contributions of eight latitudinal bands showed a typical bimodal
479 pattern in summer with peaks at 0.6–1.6 km a.s.l. (3rd – 5th layers) and 8.0–8.9 km a.s.l. (13th and 14th
480 layers), while the contribution displayed a single peak at the 0.4–1.0 km a.s.l. (2nd – 4th layers) in
481 winter. Similar to section 3.3.2, the peak value of the contribution at the low layers was due to the
482 transport of EAS, EUR, NAM, and RBU emission reductions to the Arctic through different
483 pathways both in summer and winter. The peak value in the high layers in summer was due to the
484 transport of EAS and SAS. However, a high contribution of 20% emission reductions to BC
485 concentrations in SAS was found in the high layers, while the contribution was low in other regions,
486 leading to a single peak in winter. The statistical results of SAS indicated that the contribution in
487 vertical appeared one peak at the 15th layer (9.7 km a.s.l.) with a value of 0.45–0.48 ng m⁻³ in
488 summer and winter (Figure S8).
489

490 **Figure 7.** Contributions of 20% emission reductions from all six source regions to the vertical BC concentrations of
491 the Arctic in different latitude bands varies with vertical layers in (a) summer and (b) winter in 2010.

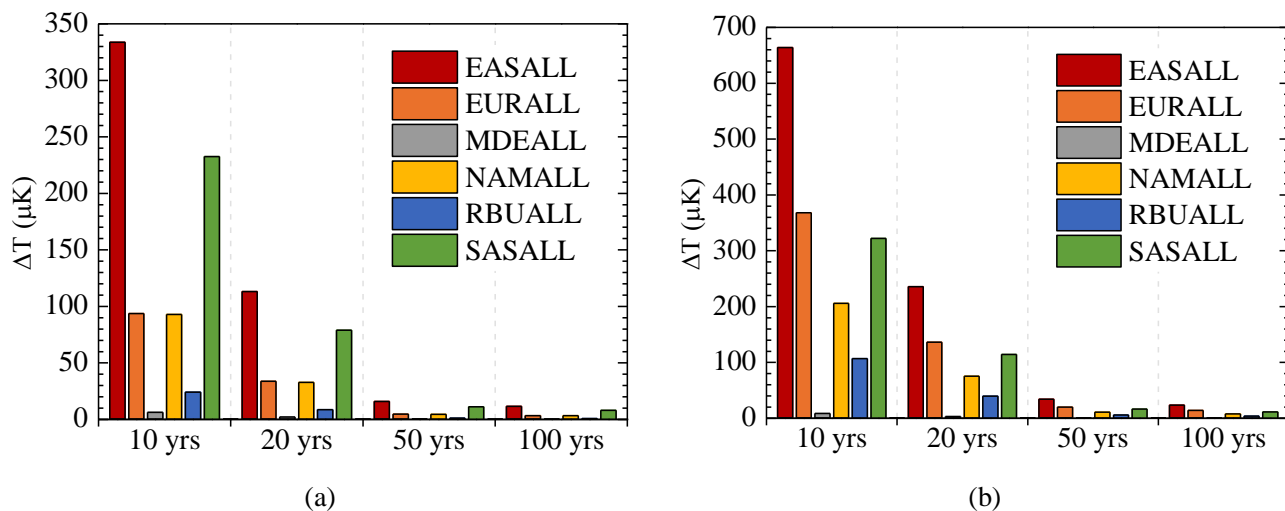

492 As same as the whole Arctic region (Section 3.3.1 & 3.3.2), the contributions of 20% emission
493 reductions to BC concentrations in eight latitude bands were higher in winter than in summer,
494 whether near surface or in vertical. The contribution of 20% emission reductions from all six source
495 regions to BC concentrations in eight latitude bands of the Arctic near surface was 0.7–1.9 ng m⁻³ in

496 summer and 1.8–4.1 ng m⁻³ in winter, respectively (Figure 6). The high BC peak at around 0.6–1.6
497 km a.s.l. (3rd – 5th layers) was 1.1–2.1 ng m⁻³ in summer, and 2.9–4.2 ng m⁻³ in winter (Figure 7).

498 **3.4 Benefit of BC emission reductions on the decrease of Arctic temperature**

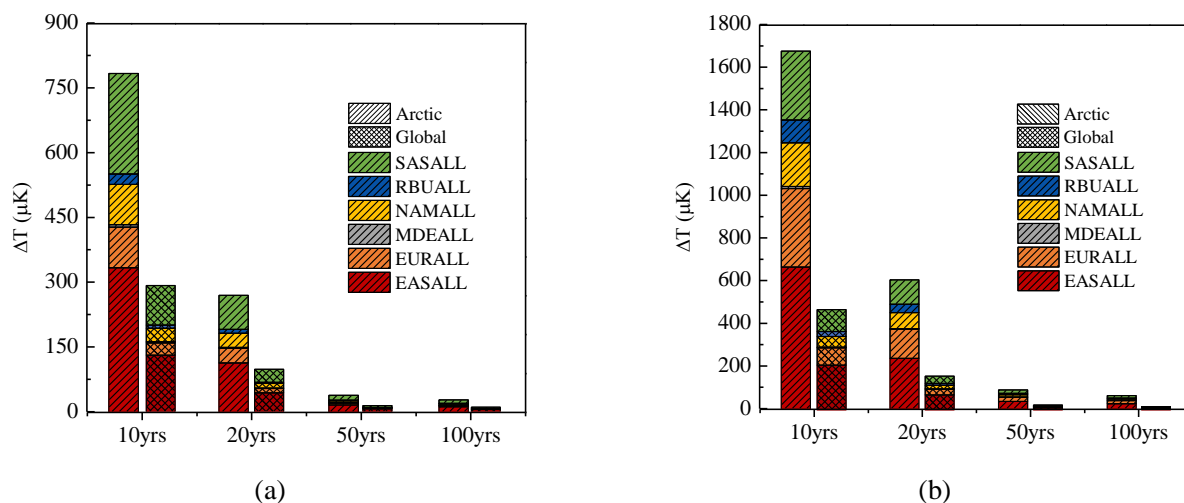

499 The impact of BC emission reductions on decreasing the Arctic (60–90°N) surface temperature was
500 assessed by using ARTP (See methods in Section 2.2). Aerosol effects, BC deposition on snow, and
501 BC semi-direct were considered in the calculation of ARTP (Aamaas et al., 2017). As shown in
502 Figure 8, the response of Arctic surface temperature to emission reductions was the most significant
503 at the time scale of 10 years and then gradually decreased with the passage of time. For each source
504 region, the Arctic temperature response was significantly higher in winter than in summer as ARTP
505 was seasonal dependent with higher values in the colder seasons. Obviously, the Arctic surface
506 temperature benefited the most from BC emission reductions from EAS with more than 300 and 660
507 μK decreases in summer and winter after 10 years, respectively. The influences of EUR and NAM
508 emission reductions on the temperature decrease were similar in summer, reaching about 3–90 μK
509 after 10, 20, 50, and 100 years. However, in winter, the influence of emission reductions from NAM
510 on temperature decrease (8–200 μK) was weaker than that from EUR (14–370 μK). This was mainly
511 due to the difference of ARTPs between EUR and NAM was not obvious compared with the
512 difference of emission reductions from NAM and EUR in summer and winter. The responses of the
513 temperature decrease to emission reductions from RBU were 9–20 μK in summer and 4–100 μK in
514 winter after 10-100years, respectively, which were smaller than that from EUR and NAM. This can
515 be explained by the low BC emission reductions from RBU (Table 1). The response of the
516 temperature decrease to emission reductions from SAS in winter (10–320 μK) was similar to that
517 from EUR, while this response in summer (8–230 μK) was more than twice that of EUR. Although
518 the ARTP of EUR was higher than that of SAS, the BC emission reductions from SAS were much
519 higher than that from EUR and the difference between emission reductions from the two regions was
520 more obvious in summer (Table 1). In spite of the higher Arctic temperature response to EAS than
521 SAS in the target year of this study, a number of studies have shown that BC emissions in South Asia
522 were increasing in recent years (Sahu et al., 2008; Paliwal et al., 2016; Sharma et al., 2019) while the
523 emissions of East Asia were exhibiting a downward trend especially from China (Chen et. al., 2016),
524 thus it should be given more attention to the impact assessment of South Asia on the Arctic in the

525 future. The minimum temperature response was found from MDE due to the least emission
 526 reductions and small ARTP.
 527

528 **Figure 8.** Arctic surface temperature response to 20% regional BC emission reductions in (a) summer and (b)
 529 winter after 10, 20, 50, and 100 years.

530 In addition, the impacts of BC emission reductions from six source regions on the Arctic and
 531 global surface temperature were compared in this study (Figure 9). Due to the BC emission
 532 reductions from the six source regions, the surface temperature in the Arctic decreased 27–780 μK in
 533 summer and 61–1675 μK in winter after 10, 20, 50, and 100 years, which were higher than that of
 534 the global with the values of 10–290 μK in summer and 16–470 μK in winter. It can be seen that the
 535 difference of the temperature response between the Arctic and the globe was more obvious in winter.
 536 Overall, the response of the Arctic surface temperature was more sensitive to emissions perturbation
 537 than that of the globe surface temperature.
 538

539 **Figure 9.** Global and Arctic surface temperature responses to 20% regional BC emission reductions in (a) summer
540 and (b) winter after 10, 20, 50, and 100 years.

541 It should be noted the estimation of temperature response was subject to large uncertainties for the
542 following reasons. On the one hand, even though the HTAP2 emissions database were all constructed
543 by bottom-up methods, the different inventories and spatiotemporal distributions were constructed
544 with sub-regional (country, state, county or province level) activity data and emission factors, which
545 lead to inconsistencies at the borders between two adjacent inventories. The version 5 of Evaluating
546 the Climate and Air Quality Impacts of Short-Lived Pollutants (ECLIPSEv5, <http://eclipse.nilu.no>)
547 estimated a 2010 emission inventory, that serves also as a reference point for all projections
548 (Janssens-Maenhout et al., 2015). At the global level, a relatively good agreement was found with
549 small relative emission differences compared with the ECLIPSEv5 emission inventory for the
550 aggregated sectors in 2010. However, larger differences of 29% between HTAP2 and ECLIPSEv5
551 emissions was present for BC since ECLIPSEv5 relied on provincial statistics for China which
552 resulted from higher coal consumption than reported national statistics. Hoesly et al. (2018) provided
553 a sectoral and gridded historical (1750–2014) anthropogenic emission inventory for use in the
554 Coupled Model Intercomparison Project phase 6 (CMIP6). The amount of global BC anthropogenic
555 emissions was 7.7 Tg/year in 2010 from the CMIP6 emissions, which was larger than that from
556 HTAP2 emissions (5.5 Tg/year). This was mainly due to the energy, transportation, and international
557 shipping sectors of CMIP6 were higher than those of HTAP2.

558 On the other hand, the time evolution of R_T , a parameter in the calculation of ARTP was also one
559 factor causing the uncertainty of temperature response calculation. This impulse response function
560 was only based on one coupled atmosphere-ocean climate model GISS-ER in this study, while Olivé
561 and Peters (2013) have found a spread in the GTP (20) value of BC of about -60 to +80% due to
562 variability of R_T among various models. However, the uncertainty in R_T was less relevant for the
563 regional patterns. Forcing-response coefficients didn't exist on a seasonal basis since emissions
564 occurring during Northern Hemisphere summer and winter season were differentiated (Aamaas et al,
565 2017). Hence, the seasonal differences presented here in the ARTP values were not due to potential
566 differences in the response sensitivities, but due to differences in the RF. The temperature response
567 will vary by species and location, such as between land surface and ocean surface. These differences
568 are not accounted for in this study, but the increased efficacy in the RCS matrix towards the NH can

569 be partly attributed to a larger land area fraction in the NH (Shindell et al., 2015). Besides, recent
570 studies have found that the positive radiation budget of BC being largely compensated for by rapid
571 atmospheric adjustment, this means that the responses of surface temperatures to BC tends to be
572 weaker than expected (Stjern et al., 2017; Takemura and Suzuki, 2019).

573 Although the HTAP2 emissions database contain uncertainties and ARTP calculations are
574 simplifications, these emission metrics are useful, simple, and quick approximations for calculating
575 the temperature response in the different latitude bands for emissions of BC.

576 **4. Conclusions**

577 The CAMchem, CHASER_re1, GEOS-Chem, GOCART, and Oslo CTM3 in HTAP2 experiment
578 were used in this study to estimate the responses of Arctic BC to multi-region emission reductions in
579 2010. Six regions (e.g., EAS, EUR, MDE, RBU, NAM, and SAS) were selected as the source
580 regions and the Arctic was the receptor region. HTAP2 set up the base scenario with all BC
581 emissions, and also simulated BC concentrations with 20% reduction of anthropogenic emissions.
582 The AGPT was further used to calculate the benefit of BC emission reductions on the decrease of
583 Arctic temperature.

584 The statistical results of 20% BC emission reductions showed that emission reductions in EAS
585 were the largest with the values of 355.6 Gg yr⁻¹, followed by SAS (232.5 Gg yr⁻¹), EUR (65.3 Gg
586 yr⁻¹), NAM (62.2 Gg yr⁻¹), RBU (18.6 Gg yr⁻¹), and MDE (5.3 Gg yr⁻¹). The BC emission
587 reductions in the EAS, EUR, and RBU were higher from November to March.

588 The temporal variations of simulations from different models were relatively consistent as the
589 correlations of the simulated BC concentrations among different models ranged from 0.33 to 0.98.
590 However, the simulated BC concentrations didn't agree so well with observations at monitoring sites
591 except Zeppelin. In order to reduce the difference of simulation performance of each model in
592 different areas of the Arctic, the model ensemble mean was used for analysis.

593 The contribution of 20% BC emission reductions from EAS, EUR, MDE, NAM, RBU, and SAS
594 to the Arctic near-surface BC concentrations reached 0.70, 0.54, 0.01, 0.20, 0.29, and 0.09 ng m⁻³,
595 respectively. Correspondingly, the reduced column BC loadings from the six regions above over the
596 Arctic was 8521.7, 2789.1, 28.8, 1762.1, 998.6, and 3640.2 ng m⁻², respectively.

597 The response of Arctic near-surface BC concentrations to 20% emission reductions from EAS and
598 EUR was larger than other four source regions, with the monthly value of 0.2–1.5 ng m⁻³ and 0.2–1.0
599 ng m⁻³, accounting for 16.8%–49.0% and 20.1%–49.0% of the total contributions from all six
600 regions, respectively. The BC profiles displayed a bimodal pattern in summer with peaks at around
601 1.0–1.6 km a.s.l. (4th and 5th layers) and 8.0–8.9 km a.s.l. (13th and 14th layers). While the BC profiles
602 showed a unimodal pattern with peaks around 0.6–1.6 km a.s.l. (3rd – 5th layers) in winter.

603 The response of Arctic BC to emission reductions from source regions in winter was higher than
604 that in summer. The contributions of 20% emission reductions to the Arctic BC concentrations near
605 surface were the highest between 66–69°N both in summer (1.9 ng m⁻³) and winter (4.1 ng m⁻³), and
606 became weaker with the increase of the latitude.

607 The response of Arctic temperature to BC emission reductions was the most significant at the time
608 scale of 10 years and then gradually decreased with the passage of time. The Arctic had benefited the
609 most from emission reduction in EAS with more than 300 and 660 μK decreases in summer and
610 winter after 10 years, respectively. The Arctic temperature response was more sensitive to the whole
611 globe in regard of the same emissions perturbation. The estimation of temperature response was
612 subject to large uncertainties due to the uncertainties in the calculation of ARTP and emissions of BC
613 in source regions.

614 Overall, this study provided insights on the source regions and seasonal contributions of Arctic BC
615 from the most recent international ensemble modeling efforts. The discrepancy between model
616 results and observations and the spread among different HTAP models may be attributed to various
617 factors such as emissions in the remote Arctic, physical parameterizations, and convection and
618 deposition processes. This would subsequently result in large uncertainties of the climatic effects of
619 air pollutants. More observation sites on the typical transport pathways from sources regions to the
620 Arctic should be planned to improve the model capability of simulating the transport behavior of
621 black carbon.

622 **Data availability**

623 All data used in this paper can be obtained through the AeroCom servers and web interfaces,
624 accessible at <http://aerocom.met.no>.

625

626 **Author contributions**

627 KH and JSF designed this study. ML, KS, DH, TK, MC, and ST performed modeling. NZ analyzed
628 data and wrote the paper. All have commented on and reviewed the paper.
