13
14 **Abstract**

15 The rate of production of HONO from illuminated TiO₂ aerosols in the presence of NO₂ was
16 measured using an aerosol flow tube system coupled to a photo-fragmentation laser induced
17 fluorescence detection apparatus. The reactive uptake coefficient of NO₂ to form HONO,
18 $\gamma_{NO_2 \rightarrow HONO}$, was determined for NO₂ mixing ratios in the range 34 – 400 ppb, with $\gamma_{NO_2 \rightarrow HONO}$
19 spanning the range $(9.97 \pm 3.52) \times 10^{-6}$ to $(1.26 \pm 0.17) \times 10^{-4}$ at a relative humidity of 15 ± 1
20 % and for a lamp photon flux of $(1.63 \pm 0.09) \times 10^{16}$ photons cm⁻² s⁻¹ (integrated between 290
21 and 400 nm), which is similar to midday ambient actinic flux values. $\gamma_{NO_2 \rightarrow HONO}$ increased as
22 a function of NO₂ mixing ratio at low NO₂ before peaking at $(1.26 \pm 0.17) \times 10^{-4}$ at ~51 ppb
23 NO₂ and then sharply decreasing at higher NO₂ mixing ratios, rather than levelling off which
24 would be indicative of surface saturation. The dependence of HONO production on relative
25 humidity was also investigated, with a peak in production of HONO from TiO₂ aerosol surfaces
26 found at ~25 % RH. Possible mechanisms consistent with the observed trends in both the
27 HONO production and reactive uptake coefficient were investigated using a zero-dimensional
28 kinetic box model. The modelling studies supported a mechanism for HONO production on

29 the aerosol surface involving two molecules of NO_2 , as well as a surface HONO loss
30 mechanism which is dependent upon NO_2 . In a separate experiment, significant production of
31 HONO was observed from illumination of mixed nitrate/ TiO_2 aerosols in the absence of NO_2 .
32 However, no production of HONO was seen from the illumination of nitrate aerosols alone.
33 The rate of production of HONO observed from mixed nitrate/ TiO_2 aerosols was scaled to
34 ambient conditions found at the Cape Verde Atmospheric Observatory (CVAO) in the remote
35 tropical marine boundary layer. The rate of HONO production from aerosol particulate nitrate
36 photolysis containing a photocatalyst was found to be similar to the missing HONO production
37 rate necessary to reproduce observed concentrations of HONO at CVAO. These results provide
38 evidence that particulate nitrate photolysis may have a significant impact on the production of
39 HONO and hence NO_x in the marine boundary layer where mixed aerosols containing nitrate
40 and a photocatalytic species such as TiO_2 , as found in dust, are present.

41

42 **1 Introduction**

43 A dominant source of OH radicals in polluted environments is the photolysis of nitrous acid
44 (HONO) (Platt et al., 1980;Winer and Biermann, 1994;Harrison et al., 1996;Alicke et al.,
45 2002;Whalley et al., 2018;Crilley et al., 2019;Lu et al., 2019;Slater et al., 2020;Whalley et al.,
46 2020). During a recent study in Winter in central Beijing, HONO photolysis accounted for over
47 90 % of the primary production of OH averaged over the day (Slater et al., 2020). Oxidation
48 by OH radicals is the dominant removal mechanism for many tropospheric trace gases, such as
49 tropospheric methane, as well as the formation of secondary species, including tropospheric
50 ozone (Levy, 1971), nitric and sulphuric acids which condense to form aerosols, and secondary
51 organic aerosols. Understanding the formation of HONO in highly polluted environments is
52 crucial to fully understand both the concentration and distribution of key atmospheric radical
53 species, as well as secondary products in the gas and aerosol phases associated with climate
54 change and poor air quality.

55 Atmospheric concentrations of HONO range from a few pptv in remote clean environments
56 (Reed et al., 2017) to more than 10 ppb in highly polluted areas such as Beijing (Crilley et al.,
57 2019). The main gas-phase source of HONO in the troposphere is the reaction of nitric oxide
58 (NO) with the OH radical. HONO has also been shown to be directly emitted from vehicles
59 (Kurtenbach et al., 2001;Li et al., 2008), for which the rate of emission is often estimated as a
60 fraction of known NO_x (NO_2+NO) emissions. Many heterogeneous HONO sources have also

61 been postulated including the conversion of nitric acid (HNO₃) on ground or canopy surfaces
62 (Zhou et al., 2003;George et al., 2005), bacterial production of nitrite on soil surfaces (Su et
63 al., 2011;Oswald et al., 2013) and, more recently, particulate nitrate photolysis, thought to be
64 an important source in marine environments (Ye et al., 2016;Reed et al., 2017;Ye et al.,
65 2017a;Ye et al., 2017b). Rapid cycling of gas-phase nitric acid to gas-phase nitrous acid via
66 particulate nitrate photolysis in the clean marine boundary layer has been observed during the
67 2013 NOMADSS aircraft measurements campaign over the North Atlantic Ocean (Ye et al.,
68 2016). Ground-based measurements of HONO made at Cape Verde in the tropical Atlantic
69 Ocean (Reed et al., 2017) provided evidence that a mechanism for renoxification in low NO_x
70 areas is required (Reed et al., 2017;Ye et al., 2017a).

71 Recent model calculations show a missing daytime source of HONO, which is not consistent
72 with known gas-phase production mechanisms, direct emissions or dark heterogeneous
73 formation (e.g. prevalent at night). It has been suggested that this source could be light driven
74 and dependent on NO₂ (Kleffmann, 2007;Michoud et al., 2014;Spataro and Ianniello, 2014;Lee
75 et al., 2016).

76 It is estimated that between 1604 and 1960 Tg yr⁻¹ of dust particles are emitted into the
77 atmosphere (Ginoux et al., 2001). Titanium dioxide (TiO₂) is a photocatalytic compound found
78 in dust particles at mass mixing ratios of between 0.1 and 10 % depending on the location the
79 particles were suspended (Hanisch and Crowley, 2003). When exposed to UV light ($\lambda < 390$
80 nm) TiO₂ promotes an electron (e_{CB}^-) from the conduction band to the valence band leaving
81 behind a positively charged hole (h_{VB}^+) in the valence band (Chen et al., 2012):

82 which can then lead to both reduction and oxidation reactions of any surface adsorbed gas-
83 phase species such as NO₂ leading to HONO.

84 In previous studies of the reaction of NO₂ on TiO₂ aerosol surfaces, HONO was observed as a
85 major gas-phase product (Gustafsson et al., 2006;Dupart et al., 2014). Gustafsson *et al.*, (2006)
86 observed a yield of gas-phase HONO of ~ 75 % (for each NO₂ removed), and showed the rate
87 of the photoreaction of NO₂ on pure TiO₂ aerosols depended on relative humidity, emphasising
88 the superhydrophilic nature of TiO₂ surfaces under UV irradiation. Dupart *et al.* (2014) also
89 reported a relative humidity dependence of the uptake of NO₂ onto Arizona Test Dust
90 containing TiO₂ with the main gas-phase products measured being NO and HONO, with a
91 HONO yield of 30 % in experiments with 110 ppb NO₂. Dupart et al. (2014) postulated the

92 following mechanism of HONO production, which is consistent with the formation of the NO_2^-
93 anion seen in a previous study on TiO_2 surfaces (Nakamura et al., 2000):

94 In areas with high mineral dust loading, such as desert regions, far from anthropogenic sources,
95 NO_2 concentrations are typically low. However, when dust is transported to urban areas, this
96 source of HONO may become significant. One study reported that TiO_2 composed 0.75-1.58
97 $\mu\text{g m}^{-3}$ when aerosol loadings were 250-520 $\mu\text{g m}^{-3}$ over the same time period in southeast
98 Beijing, when air had been transported from the Gobi desert (Schleicher et al., 2010).

99 In this study, the production of HONO on the surface of TiO_2 particles in the presence of NO_2
100 is investigated as a function of NO_2 mixing ratio, aerosol surface area density and relative
101 humidity using an aerosol flow tube system coupled to a photo-fragmentation laser induced
102 fluorescence detector (Boustead, 2019). The uptake coefficient of NO_2 to generate HONO is
103 then determined, and a mechanistic interpretation of the experimental observations is
104 presented. The production of HONO directly in the absence of NO_2 from the illumination of a
105 mixed sample of nitrate and TiO_2 aerosol is also presented. Using a similar apparatus, previous
106 work had showed that TiO_2 particles produce OH and HO_2 radicals directly under UV
107 illumination (Moon et al., 2019). The atmospheric implications of these results and the role of
108 photo-catalysts for the formation of HONO are also discussed.

109 **2 Method**

110 **2.1 Overview of the Experimental Setup**

111 The production of HONO from illuminated aerosol surfaces is studied using an aerosol flow
112 tube system coupled to a photo-fragmentation laser induced fluorescence (PF-LIF) cell which
113 allows the highly sensitive detection of the OH radical formed through photo-fragmentation of
114 HONO into OH and NO followed by Laser-Induced Fluorescence (LIF) detection at low
115 pressure. The experimental setup used in this investigation is described in detail in (Boustead,
116 2019), as well as similar systems having been used to measure HONO in the field (Liao et al.,

117 2006;Wang et al., 2020).and therefore only a brief description of the setup is given here. A
118 schematic of the experimental setup is shown in Figure 1.

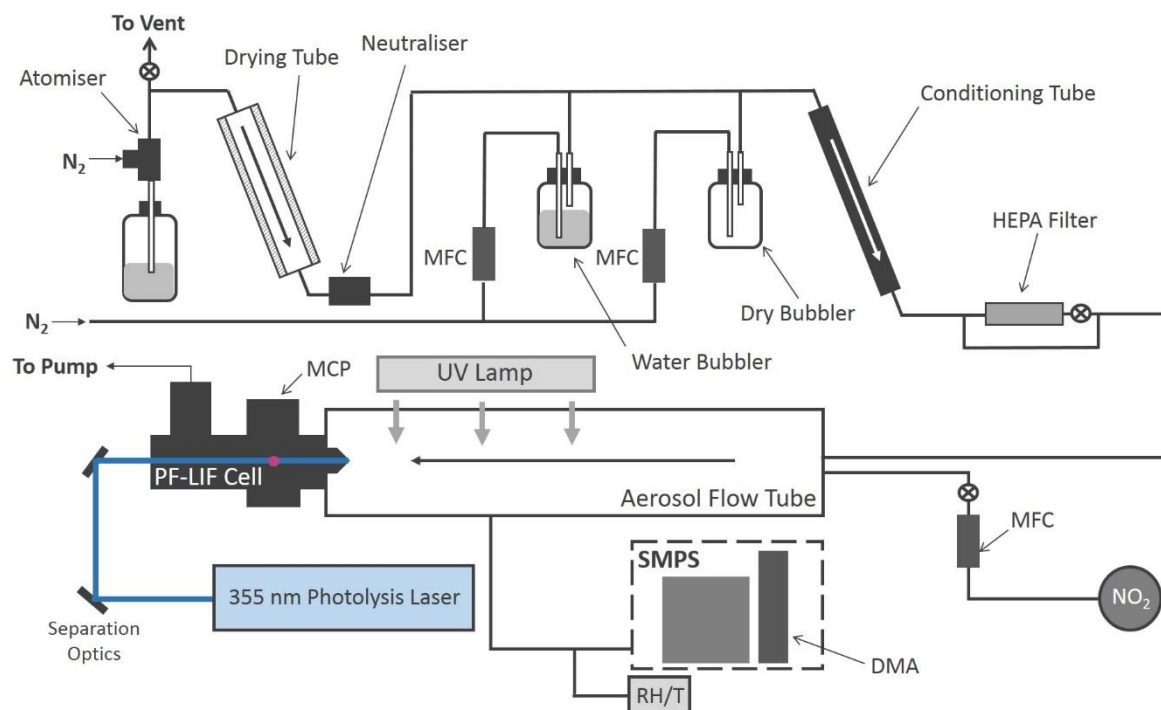

Figure 1. Schematic of the Leeds aerosol flow tube system coupled to a laser-fragmentation laser-induced fluorescence detector for HONO. The paths of the 355 nm (blue) and 308 nm (purple, depicted as travelling out of the page perpendicular to the 355 nm light) light are also shown. CPC: condensation particle counter; DMA: differential mobility analyser; HEPA: high efficiency particle air filter; FAGE: fluorescence assay by gas expansion; MCP: microchannel plate photomultiplier; MFC: mass flow controller; RH/T: relative humidity/ temperature probe; SMPS: scanning mobility particle sizer.

119
120 All experiments were conducted at room temperature (295 ± 3 K) using nitrogen (BOC, 99.998
121 %) or air (BOC, 21 ± 0.5 % O₂) as the carrier gas. A humidified flow of aerosols, ~ 6 lpm (total
122 residence time of 104 s in the flow tube), was introduced through an inlet at the rear of the
123 aerosol flow tube (Quartz, 100 cm long, 5.75×1.5 cm ID) which was covered by a black box to
124 eliminate the presence of room light during experiments. A 15 W UV lamp (XX-15LW Bench
125 Lamp, $\lambda_{\text{peak}}=365$ nm) was situated on the outside of the flow tube to illuminate aerosols and
126 promote the production of HONO (half the length of the flow tube was illuminated leading to
127 an illumination time of 52 s). The concentration of HONO is measured by PF-LIF with
128 sampling from the end of the flow tube via a protruding turret containing a 1 mm diameter
129 pinhole, through which the gas exiting the flow tube was drawn into the detection cell at 5 lpm.
130 The detection cell was kept at low pressure, ~ 1.5 Torr, using a rotary pump (Edwards, E1M80)
131 in combination with a roots blower (Edwards, EH1200). All gas flows in the experiment were

132 controlled using mass flow controllers (MKS and Brooks). The relative humidity (RH) and
133 temperature of the aerosol flow was measured using a probe (Rotronics HC2-S, accuracy ± 1
134 % RH) the former calibrated against the H₂O vapour concentration measured by a chilled
135 mirror hygrometer (General Eastern Optica), in the exhaust from the flow tube.

136 **2.2 Aerosol generation and detection**

137 Solutions for the generation of TiO₂ aerosol solutions were prepared by dissolving 5 g of
138 titanium dioxide (Aldrich Chemistry 718467, 99.5% Degussa, 80 % anatase: 20 % rutile) into
139 500 ml of milli-Q water. Polydisperse aerosols were then generated from this solution using an
140 atomiser (TSI model 3076) creating a 1 lpm flow of TiO₂ aerosol particles in nitrogen hereafter
141 referred to as the aerosol flow. This aerosol flow was then passed through a silica drying tube
142 (TSI 3062, capable of reducing 60 % RH incoming flow to 20 % RH) to remove water vapour,
143 then passed through a neutraliser to apply a known charge distribution and reduce loss of
144 aerosols to the walls. After the neutraliser the aerosol flow was mixed with both a dry and a
145 humidified N₂ flow (controlled by MFCs) to regulate the relative humidity of the system by
146 changing the ratio of dry to humid nitrogen flows. A conditioning tube was then used to allow
147 for equilibration of water vapour adsorption and re-evaporation to and from the aerosol surfaces
148 for the chosen RH, which was controlled within the range ~10-70 % RH. A portion of the
149 aerosol flow was then passed through a high efficiency particle filter (HEPA) fitted with a
150 bypass loop and bellows valve allowing control of the aerosol number concentration entering
151 the aerosol flow tube. Previous studies (George et al., 2013; Boustead, 2019) have shown the
152 loss of aerosol to the walls of the flow tube to be negligible. Aerosol size distributions were
153 measured for aerosols exiting the flow tube using a scanning mobility particle sizer (SMPS,
154 TSI 3081) and a condensation particle counter (CPC, TSI 3775) which was calibrated using
155 latex beads. Any aerosol surface area not counted due to the upper diameter range of the
156 combined SMPS/CPC (14.6 – 661.2 nm, sheath flow of 3 lpm, instrumental particle counting
157 error of 10-20 %) was corrected for during analysis by assuming a lognormal distribution,
158 which was verified for TiO₂ aerosols generated in this manner (Matthews et al., 2014).
159 However, the majority of aerosols, >90 %, had diameters in the range that could be directly
160 detected. In addition to the experiments with single-component TiO₂, mixed ammonium
161 nitrate/TiO₂ and single-component ammonium nitrate aerosols were also generated using the
162 atomiser for investigations of HONO production from nitrate aerosols without NO₂ present.
163 An example of an aerosol size distribution from this work for single-component ammonium

164 nitrate aerosols, mixed ammonium nitrate/TiO₂ and single-component TiO₂ aerosols is shown
165 in Figure 2.

Figure 2 Typical aerosol surface area distribution for pure ammonium nitrate aerosols (green) and pure TiO₂ aerosols (red) and 50:50 mixed nitrate/TiO₂ aerosols (purple) measured after the flow tube.

166 **2.3 Detection of HONO**

167 As HONO is not directly detectable via LIF, it was necessary to fragment the HONO produced
168 into OH and NO (Liao et al., 2007), with detection of OH via LIF. A 355 nm photolysis laser
169 (Spectron Laser Systems, SL803) with a pulse repetition frequency (PRF) of 10 Hz and pulse
170 duration ~ 10 ns was used to fragment HONO into OH. This fragmentation wavelength was
171 chosen as HONO has a strong absorption peak at ~ 355 nm leading to the breakage of the HO-
172 NO bond to form NO and OH in their electronic ground states (Shan et al., 1989). A Nd:YAG
173 pumped dye probe laser (JDSU Q201-HD, Q-series, Sirah Cobra Stretch) with a PRF of 5000
174 Hz, was used for the detection of OH via the fluorescence assay by gas expansion (FAGE)
175 technique which employs the expansion of gas through a small pinhole into the detection cell.
176 The OH radical was measured using on-resonance detection by LIF via the excitation of the
177 $A^2\Sigma^+ (v' = 0) \leftarrow X^2\Pi_i (v'' = 0) Q_1(2)$ transition at 308 nm (Heard, 2006). A multi-channel plate
178 (MCP) photomultiplier (Photek, MCP 325) equipped with an interference filter at 308 nm (Barr

179 Associates, 308 nm. FWHM – 8 nm, ~50 % transmission) was used to measure the fluorescence
 180 signal. A reference OH cell in which a large LIF signal could be generated was utilised to
 181 ensure the wavelength of the probe laser remained tuned to the peak of the OH transition at
 182 308 nm. OH measurements are taken both before and after each photolysis laser pulse allowing
 183 measurement of any OH already present in the gas flow to be determined as a background
 184 signal for subtraction. The OH generated from HONO photolysis was measured promptly
 185 (~800 ns) after the 355 nm pulse to maximise sensitivity to OH before it was spatially diluted
 186 away from the measurement region (Boustead, 2019). Offline measurements, with the probe
 187 laser wavelength moved away from the OH transition (by 0.02 nm), were taken to allow the
 188 signal generated from detector dark counts and scattered laser light to be measured and
 189 subtracted from the online signal. To determine an absolute value of the HONO concentration,
 190 [HONO], a calibration was performed, in order to convert from the HONO signal, S_{HONO} , using
 191 $S_{\text{HONO}} = C_{\text{HONO}} [\text{HONO}]$, as described fully in (Boustead, 2019). A glass calibration wand was
 192 used to produce OH and HO₂ in equal concentrations from the photolysis of water vapour at
 193 185 nm:

194 An excess flow of NO was then added to generate HONO which was then detected as OH in
 195 the cell. The excess flow of NO (BOC, 99.5 %) ensures rapid and complete conversion of OH
 196 and HO₂ to HONO. The concentration of OH and HO₂ produced, and therefore the amount of
 197 HONO produced in the wand, is calculated using:

$$[OH] = [HO_2] = [H_2O] \sigma_{H_2O} \phi_{OH} F t \quad (1)$$

198 where [H₂O] is the concentration of water vapour in the humidified gas flow, σ_{H_2O} is the
 199 absorption cross section of H₂O at 185 nm ($7.14 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ (Cantrell et al., 1997),
 200 ϕ_{OH} is the quantum yield of OH for the photo-dissociation of H₂O at 185 nm (=1), F is the
 201 lamp flux and t is the irradiation time (the product of which is determined using ozone
 202 actinometry (Boustead, 2019).

203 A typical value of the calibration factor was $C_{\text{HONO}} = (3.63 \pm 0.51) \times 10^{-9} \text{ counts mW}^{-1}$ for N₂,
 204 leading to a calculated limit of detection of 12 ppt for a 50 s averaging period and a signal-to-
 205 noise ratio (SNR) of 1 (Boustead, 2019). The typical error in the HONO concentration was
 206 15% at 1 σ , determined by the error in the calibration.

207 2.4 Experimental procedure and data analysis

208 The experiments were performed with a minimum flow of 6 lpm through the aerosol flow tube
209 giving a Reynolds number of ~ 150 which ensured a laminar flow regime. The HONO signal,
210 converted to an absolute concentration using a calibration factor, was measured over a range
211 of aerosol surface area densities, both in the presence and absence of illumination, and
212 background measurements without aerosols present, were also performed.

213 The HONO signal originates from several sources: the illuminated aerosol surface; the
214 illuminated quartz flow tube walls; dark reactions on aerosol surfaces; dark reactions on the
215 flow tube surface and finally from impurities in the NO_2 (Sigma Aldrich, $>99.5\%$, freeze pump
216 thawed to further remove any remaining NO or O_2) and N_2 flows (either HONO itself or a
217 species which photolyses at 355 nm to give OH). Of interest here is the HONO production
218 from both dark and illuminated aerosol surfaces which is atmospherically relevant. Following
219 transit through the flow tube, and in the presence of NO_2 , the total concentration of HONO
220 measured by the PF-LIF detector is given by:

$$\begin{aligned} [\text{HONO}] = & [\text{HONO}]_{\text{illuminated aerosols}} + [\text{HONO}]_{\text{illuminated walls}} \\ & + [\text{HONO}]_{\text{dark aerosols}} + [\text{HONO}]_{\text{dark walls}} + [\text{HONO}]_{\text{impurities}} \end{aligned} \quad (2)$$

221 Any HONO seen without the presence of aerosol was therefore due to HONO impurities in the
222 N_2 or NO_2 gas, the dark production of HONO from the flow tube walls or from the production
223 of HONO from the illuminated reactor walls, which may include production from TiO_2
224 aerosols coating the flow tube in the presence of NO_2 . This background HONO concentration
225 depended on the experimental conditions and on how recently the flow tube and PF-LIF cell
226 had been cleaned to remove any build-up of TiO_2 deposits. However, the build-up of TiO_2 on
227 the flow tube walls was relatively slow and back-to-back measurements were made in the
228 presence and absence of aerosols to obtain an accurate background. Additional experiments
229 showed no significant production of HONO on TiO_2 aerosol surfaces without the presence of
230 NO_2 . Even though the aerosol surface area density ($\sim 0.02 \text{ m}^2 \text{ m}^{-3}$) was small compared to the
231 surface area density of the reactor walls ($35 \text{ m}^2 \text{ m}^{-3}$), very little HONO signal was produced
232 without the presence of aerosols, and was always subtracted from the signal in the presence of
233 aerosols. The HONO signal was measured both with the lamp on and off for each aerosol
234 surface area density to investigate the production of HONO from illuminated aerosol surfaces.
235 The HONO signal was averaged over 50 s (average of 500 of the 355 nm photolysis laser pulses
236 with a PRF of 10 Hz). Once aerosols were introduced into the flow tube system a period of \sim

237 30 min was allowed for equilibration and the measured aerosol surface area density to stabilise.
238 In general, the relative humidity of the system was kept constant at RH ~ 15 % for all
239 experiments investigating HONO production as a function of NO₂ mixing ratio over the range
240 34 - 400 ppb. In a number of experiments, however, RH was varied in the range ~12-37 %.

241 The mixing ratio of NO₂ entering the flow tube was calculated using the concentration of the
242 NO₂ in the cylinder and the degree of dilution. The NO₂ mixing ratio within the cylinder was
243 determined using a commercial instrument based on UV-Vis absorption spectroscopy (Thermo
244 Fisher 42TL, limit of detection 50 pptv, precision 25 pptv) For each individual experiment, the
245 mixing ratio of NO₂ was kept constant (within the range 34 – 400 ppb) and the aerosol surface
246 area density was varied from zero up to a maximum of 0.04 m² m⁻³. In order to obtain the
247 HONO produced from illuminated aerosol surfaces in the flow tube for a given mixing ratio of
248 NO₂. As well as subtraction of any background HONO, a correction must be made for any loss
249 of HONO owing to its photolysis occurring within the flow tube.

250 In order to determine the rate of photolysis of HONO, the rate of photolysis of NO₂ was first
251 determined using chemical actinometry, and the known spectral output of the lamp and the
252 literature values of the absorption cross-sections and photo-dissociation quantum yields for
253 NO₂ and HONO were used to determine the rate of photolysis of HONO. When just flowing
254 NO₂ in the flow tube, the loss of NO₂ within the illuminated region is determined only by
255 photolysis and is given by:

$$-\frac{d[\text{NO}_2]}{dt} = j(\text{NO}_2)[\text{NO}_2] \quad (3)$$

256 where $j(\text{NO}_2)$ is the photolysis frequency of NO₂ for the lamp used in these experiments. From
257 the measured loss of NO₂ in the illuminated region, and with knowledge of the residence time,
258 the photolysis frequency, $j(\text{NO}_2)$, was determined to be $(6.43 \pm 0.30) \times 10^{-3} \text{ s}^{-1}$ for the set of
259 experiments using one lamp to illuminate the flow tube. $j(\text{NO}_2)$ is given by:

$$j(\text{NO}_2) = \int_{\lambda_1}^{\lambda_2} \sigma_{\lambda} \phi_{\lambda} F_{\lambda} d\lambda \quad (4)$$

260 where λ_1 and λ_2 represent the range of wavelengths over which the lamp emits, and σ_{λ} and ϕ_{λ}
261 are the wavelength-dependent absorption-cross section and photo-dissociation quantum yield
262 of NO₂, respectively, and F_{λ} is the flux of the lamp at a given wavelength. The flux of the lamp,

263 the spectral intensity of which was measured using a Spectral Radiometer (Ocean Optics QE-
 264 Pro 500) as a function of wavelength, is shown in Figure 3.

Figure 3. UVA emission spectrum for the 15 W bench lamp used in these experiments between 290-400 nm. The integrated photon flux over this wavelength range is $(1.63 \pm 0.09) \times 10^{16}$ photons $\text{cm}^{-2} \text{s}^{-1}$ determined from the measured $j(\text{NO}_2)$ of $(6.43 \pm 0.30) \times 10^{-3} \text{s}^{-1}$.

265 From the measured $j(\text{NO}_2)$, and with knowledge of σ_λ and ϕ_λ for NO_2 , the flux of the lamp was
 266 determined to be $(1.63 \pm 0.09) \times 10^{16}$ photons $\text{cm}^{-2} \text{s}^{-1}$ integrated over the 290 – 400 nm
 267 wavelength range of the lamp. Using this flux, and the known σ_λ and ϕ_λ for HONO over the
 268 same wavelength range, $j(\text{HONO})$ was determined to be $(1.66 \pm 0.10) \times 10^{-3} \text{s}^{-1}$.

269 In the presence of aerosols under illuminated conditions, the rate of heterogeneous removal of
 270 NO_2 at the aerosol surface to generate HONO is given by:

$$-\frac{d[\text{NO}_2]}{dt} = k[\text{NO}_2] \quad (5)$$

271 where k is the pseudo-first order rate coefficient for loss of NO_2 at the aerosol surface, and
 272 which leads to the generation of HONO. The postulated mechanism for HONO production
 273 from NO_2 is discussed in section 3.3.2 below, but for the definition of k it is assumed to be a
 274 first order process for NO_2 . Integration of equation 5 gives:

$$k = -\frac{\ln\left(\frac{[\text{NO}_2]_0 - [\text{HONO}]_t}{[\text{NO}_2]_0}\right)}{t} \quad (6)$$

275 where $[\text{NO}_2]_0 - [\text{HONO}]_t$ is the concentration of NO_2 at time t , assuming that each NO_2
 276 molecule is quantitatively converted to a HONO molecule following surface uptake (see
 277 section 3.3.2 for the proposed mechanism), and $[\text{NO}_2]_0$ is the initial concentration of NO_2 .
 278 Hence k can be determined from equation 6 using the measurement of the concentration of
 279 HONO, $[\text{HONO}]$, that has been generated from TiO_2 aerosol surfaces for an illumination time
 280 of t (and after subtraction of any background HONO produced from other sources and after
 281 correction for loss via photolysis, see above), and with knowledge of $[\text{NO}_2]_0$.

282 The reactive uptake coefficient of NO_2 to generate HONO, $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$, defined as the
 283 probability that upon collision of NO_2 with the TiO_2 aerosol surface a gas-phase HONO
 284 molecule is generated, is given by:

$$\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = \frac{4 \times k}{v \times SA} \quad (7)$$

285 where v is the mean thermal velocity of NO_2 , given by $v = \sqrt{(8RT)/(\pi M)}$ with R , T and M as
 286 the gas constant, the absolute temperature and the molar mass of NO_2 , respectively, SA is the
 287 aerosol surface area density ($\text{m}^2 \text{m}^{-3}$) and k is defined as above. Rearrangement of equation 7
 288 gives:

$$k = \frac{\gamma_{\text{NO}_2 \rightarrow \text{HONO}} \times SA \times v}{4} \quad (8)$$

289 Figure 4 shows the variation of k , determined from equation 6 above with $t = 52$ s (illumination
 290 time in the flow tube), against aerosol surface area density, SA , for $[\text{NO}_2]_0 = 200$ ppb and
 291 $\text{RH} = 15\%$, from which the gradient using equation 8 yields $\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = (2.17 \pm 0.09) \times 10^{-5}$.

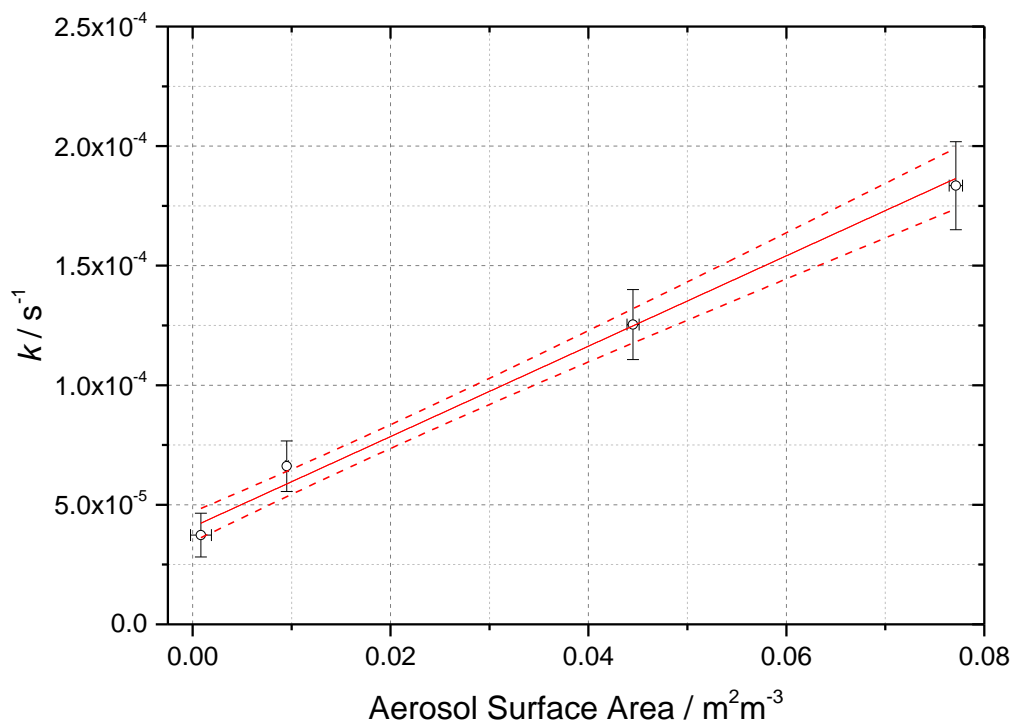

Figure 4. Pseudo-first-order rate coefficient for HONO production, k (open circles) as a function of aerosol surface area for $[\text{NO}_2] = 200$ ppb and $\text{RH} = 15 \pm 1\%$, $T = 293 \pm 3$ K and a photolysis time of 52 ± 2 seconds. The red line is a linear-least squared fit including 1σ confidence bands (dashed lines) weighted to both x and y errors (1σ), the gradient of which yields $\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = (2.17 \pm 0.09) \times 10^{-5}$, with the uncertainty representing (1σ). The non-zero y-axis intercept is due to a background HONO signal owing to the presence of a HONO impurity in the NO_2 cylinder, and which is not subtracted. The total photon flux of the lamp (see Figure 2 for its spectral output) = $(1.63 \pm 0.09) \times 10^{16}$ photons $\text{cm}^{-2} \text{s}^{-1}$.

292 The uncertainty in k ($\sim 20\%$) shown in Figure 4 and determined by equation 6 is mainly
 293 controlled by the uncertainty in the HONO concentration (the HONO signal typically varies
 294 between repeated runs for a given SA by $\sim 10\%$ coupled with the 15% error in calibration
 295 factor), the initial NO_2 mixing ratio (10%), and the photolysis time, t ($\sim 3\%$). The uncertainty
 296 in SA is determined by the uncertainty in the SMPS (15%). The error in the value of
 297 $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$ (typically 20%) is calculated from the 1σ statistical error of the weighted fit shown
 298 in Figure 4. An experiment performed using air yielded an uptake coefficient value within 7%
 299 of the equivalent experiment done in N_2 , which is well within the experimental error.

300 2.5 Box model description

301 A kinetic scheme within the framework of a box model was used together with the differential
 302 equation solver Facsimile 4.3.53 (MCPA software Ltd., 2020) to investigate the mechanism of

303 NO₂ adsorption on TiO₂ in the presence of light to produce HONO. The models were only
304 semi-explicit, focusing on determining the stoichiometric amounts of NO₂ needed to produce
305 a single HONO molecule in the gas-phase for comparison with the experimental dependence
306 of HONO production upon NO₂ mixing ratio, and to provide a predictive framework for
307 parameterising the HONO production rate with NO₂ mixing ratio in the atmosphere. Three
308 model scenarios were designed. The simplest model (Model 1) considered only the adsorption
309 of a single molecule of NO₂ to the TiO₂ surface, the surface conversion to HONO in the
310 presence of light and subsequent desorption of HONO, the latter assumed to occur rapidly. The
311 two further model scenarios investigated the effect of a 2:1 stoichiometric relationship between
312 the NO₂ adsorbed to the surface of TiO₂ and the HONO produced, via the formation of an NO₂
313 dimer. Model 2 incorporated an Eley-Rideal mechanism reliant on the adsorption of one NO₂
314 molecule to the surface followed by the subsequent adsorption of a second NO₂ molecule
315 directly onto the first (Figure 5). Model 3, however, features a Langmuir-Hinshelwood
316 mechanism of adsorption in which two NO₂ molecules adsorb to the surface, then diffuse to
317 one another before colliding on the surface and forming the *cis*-ONO-NO₂ dimer (Finlayson-
318 Pitts et al., 2003; de Jesus Madeiros and Pimentel, 2011; Liu and Goddard, 2012; Varner et al.,
319 2014). The formation of the asymmetric *cis*-ONO-NO₂ dimer followed by isomerisation to
320 form the asymmetric *trans*-ONO-NO₂ dimer has been suggested to have an enthalpic barrier
321 that is ~170 kJ mol⁻¹ lower than for direct isomerisation to *trans*-ONO-NO₂ from the symmetric
322 N₂O₄ dimer (Liu and Goddard, 2012). The dimerisation of NO₂ and subsequent isomerisation
323 to form *trans*-ONO-NO₂ has been suggested under dark conditions to lead to the formation of
324 both HONO and HNO₃ in the presence of water vapour (Finlayson-Pitts et al., 2003; de Jesus
325 Madeiros and Pimentel, 2011; Liu and Goddard, 2012; Varner et al., 2014). Although the
326 interaction of light with TiO₂ with the concomitant production of electron-hole pairs (R1) is
327 central to HONO formation, we do not specify here the exact mechanism by which the electron-
328 hole pairs interact with surface-bound species to generate HONO. We propose that the
329 interaction with light speeds up the autoionisation of *trans*-ONO-NO₂ to form (NO⁺)(NO₃⁻),
330 which is represented by reactions R13 and R15 in Models 2 and 3 respectively. (NO⁺)(NO₃⁻)
331 can then react rapidly with surface adsorbed water leading to HONO formation (Varner et al.,
332 2014).

333 A schematic of the proposed mechanism investigated with Models 2 and 3 is shown in Figure
334 5, and consists of (i) the adsorption of NO₂ onto a surface site, (ii) the conversion of NO₂ to
335 form HONO via the formation of an NO₂ dimer intermediate on the surface via either a Eley-

336 Rideal or Langmuir Hinshelwood- type mechanism, (iii) subsequent desorption of HONO from
 337 the surface, and finally (iv) competitive removal processes for HONO both on the surface and
 338 in the gas-phase that are either dependent or independent on the NO_2 mixing ratio. The model
 339 includes the gas-phase photolysis of NO_2 and HONO and the gas phase reactions of both
 340 HONO and NO_2 with OH and $\text{O}(^3\text{P})$ atoms.

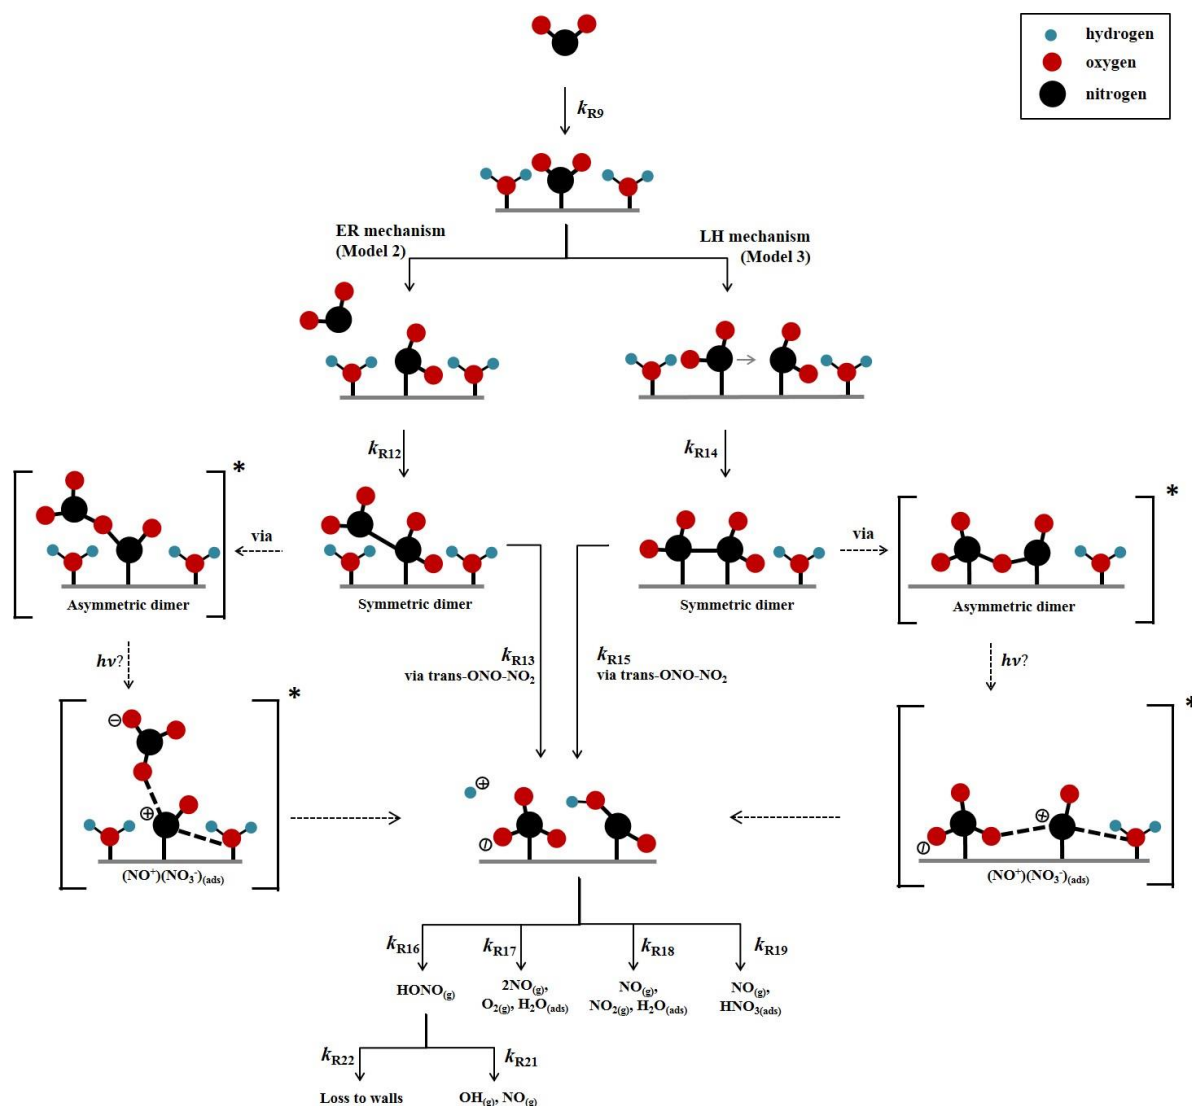

Figure 5. Schematic diagram of proposed mechanism of uptake of NO_2 on an aerosol surface in the presence of water to form HONO. Both Eley Rideal, Model 2, and Langmuir Hinshelwood, Model 3, mechanisms are shown with relevant estimated and calculated rate coefficients used in the models. NO_2 dependent and independent loss reactions of HONO are also depicted. Nitrogen shown in black, oxygen shown in red and hydrogen shown in blue. * denotes intermediate steps of the isomerisation of symmetric N_2O_4 to *trans*-ONO- NO_2 which is then predicted to form HONO.

341 To the best of our knowledge the enthalpy of adsorption of NO_2 onto a TiO_2 surface has not
 342 been determined, nor the bimolecular rate coefficients for the chemical steps on the surface

343 shown in Figure 5. Hence, for each of the steps a rate coefficient (s^{-1} or $cm^3 \text{ molecule}^{-1} s^{-1}$) was
 344 assigned, as given in Table 1, and with the exception of the experimentally determined $j(\text{NO}_2)$
 345 and the calculated $j(\text{HONO})$, and the gas-phase rate coefficients which are known, the rate
 346 coefficients were estimated, with the aim of reproducing the experimental NO_2 dependence of
 347 the HONO production and NO_2 reactive uptake coefficient; justification of chosen values is
 348 given below.

Reactions	Rate coefficient ^d
Model 1	
R9 $\text{NO}_{2(g)} + \text{surface} \rightarrow \text{NO}_{2(ads)}$	1×10^{-3}
R10 $\text{NO}_{2(ads)} \rightarrow \text{HONO}_{(ads)}$	1×10^{-3}
R11 $\text{HONO}_{(ads)} \rightarrow \text{HONO}_{(g)}$	1×10^{-2}
Model 2 and 3	
<i>Model 2 only – Eley-Rideal mechanism</i>	
R12 $\text{NO}_{2(g)} + \text{NO}_{2(ads)} \rightarrow \text{NO}_2 - \text{NO}_{2(ads)}$	1×10^{-2}
R13 $\text{NO}_2 - \text{NO}_{2(ads)} \xrightarrow{\text{via trans-ONO-NO}_2} \text{HONO}_{(ads)} + \text{HNO}_3_{(ads)}$	5×10^{-3}
<i>Model 3 only – Langmuir-Hinshelwood mechanism</i>	
R14 $\text{NO}_{2(ads)} + \text{NO}_{2(ads)} \rightarrow \text{NO}_{2(ads)} - \text{NO}_{2(ads)}$	1×10^{-3}
R15 $\text{NO}_{2(ads)} - \text{NO}_{2(ads)} \xrightarrow{\text{via trans-ONO-NO}_2} \text{HONO}_{(ads)} + \text{HNO}_3_{(ads)}$	5×10^{-3}
<i>Common to both Models 2 and 3</i>	
R9 $\text{NO}_{2(g)} + \text{surface} \rightarrow \text{NO}_{2(ads)}$	1×10^{-1}
R16 $\text{HONO}_{(ads)} \rightarrow \text{HONO}_{(g)}$	5×10^{-2}
R17 $\text{HNO}_3_{(ads)} + \text{HONO}_{(ads)} \rightarrow 2\text{NO}_{(g)} + \text{O}_{2(g)} + \text{H}_2\text{O}_{(ads)}$	1×10^{-3}
R18 $\text{HONO}_{(ads)} + \text{HONO}_{(ads)} \rightarrow \text{NO}_{(g)} + \text{NO}_{2(g)} + \text{H}_2\text{O}_{(ads)}$	1×10^{-3}
R19 $\text{NO}_{2(g)} (\text{or species such as } \text{NO}_2^+) + \text{HONO}_{(ads)} \rightarrow \text{NO}_{(g)} + \text{HNO}_3_{(ads)}$	5×10^{-3}
R20 $\text{NO}_{2(g)} + h\nu \rightarrow \text{NO}_{(g)} + \text{O}({}^3P)_{(g)}$	6×10^{-3a}
R21 $\text{HONO}_{(g)} + h\nu \rightarrow \text{OH}_{(g)} + \text{NO}_{(g)}$	2×10^{-3b}
R22 $\text{HONO}_{(g)} \rightarrow \text{wall loss}$	1×10^{-4}
R23 $\text{HONO}_{(g)} + \text{OH}_{(g)} \rightarrow \text{NO}_{2(g)} + \text{H}_2\text{O}_{(g)}$	4.5×10^{-12c}
R24 $\text{NO}_{2(g)} + \text{OH}_{(g)} \xrightarrow{M} \text{HNO}_3_{(g)}$	1×10^{-11c}
R25 $\text{O}({}^3P)_{(g)} + \text{NO}_{2(g)} \rightarrow \text{O}_{2(g)} + \text{NO}_{(g)}$	1×10^{-11c}
R26 $\text{O}({}^3P)_{(g)} + \text{O}_{2(g)} \xrightarrow{M} \text{O}_3$	1.5×10^{-14c}
R27 $\text{O}({}^3P)_{(g)} + \text{NO}_{(g)} \xrightarrow{M} \text{NO}_{2(g)}$	1.7×10^{-12c}

349 **Table 1.** Reactions included in the chemical mechanism used to model NO_2 uptake onto TiO_2 aerosols. All rate
 350 coefficients are estimated, as described in Section 2.5, with the exception of the NO_2 and HONO photolysis rate
 351 coefficient and the gas phase rate coefficient which are known. ^aMeasured using chemical actinometry with the

352 knowledge of the experimentally determined spectral output of the lamp and the cross-sections and quantum
353 yields of NO₂ and HONO, see section 2.4 for more detail. ^bCalculated using a photon flux of $(1.63 \pm 0.09) \times$
354 10^{16} photons cm⁻² s⁻¹. ^c(Sander et al., 2003). ^dRate coefficients are in the units of s⁻¹ for first-order processes or
355 cm³ molecule⁻¹ s⁻¹ for second-order processes. *T* for all *k* values is 298 K.

356 The modelled Gibbs free energy barrier for the isomerisation of N₂O₄ to form the asymmetric
357 ONO-NO₂ isomer (*cis* or *trans* conformation not specified) was estimated by Pimental et al.,
358 (2007) to be 87 kJ mol⁻¹ with a rate coefficient as large as 2×10^{-3} s⁻¹ in the aqueous phase at
359 298 K, stated in the study to confirm the Finlayson-Pitts model for the hydrolysis of NO₂ on
360 surfaces via the asymmetric *trans*-ONO-NO₂ dimer (Finlayson-Pitts et al., 2003). Using this
361 study as a guide, we estimated k_{R13} and k_{R15} as 5×10^{-3} s⁻¹, slightly larger than that estimated
362 by Pimental et al., (2007) due to the presence of light. A study into the decomposition of HONO
363 on borosilicate glass surfaces suggested a rate coefficient for the loss HONO on the non-
364 conditioned chamber walls to be $(1.0 \pm 0.2) \times 10^{-4}$ s⁻¹ increasing to $(3.9 \pm 1.1) \times 10^{-4}$ s⁻¹ when
365 HNO₃ was present on the walls (Syomin and Finlayson-Pitts, 2003). From this we estimated a
366 light-accelerated loss rate coefficient of 1×10^{-3} s⁻¹ for the loss of HONO_(ads) by reaction with
367 itself, k_{R18} , and through reaction with HNO_{3(ads)}, k_{R17} . Both these reactions will occur on the
368 surface of the aerosol. We make the assumption that the rate of loss of HONO to the walls of
369 the chamber for this experiment is less than that of the heterogeneous loss reactions on the
370 photo-catalytic aerosol surface leading to a k_{R22} of 1×10^{-4} s⁻¹ as reported by (Syomin and
371 Finlayson-Pitts, 2003). For k_{R12} - k_{R15} , initial values were adopted and were then adjusted to fit
372 the shape of the trend in experimental results of [HONO] and $\gamma_{NO_2 \rightarrow HONO}$ versus [NO₂],
373 discussed fully in Section 3.3.2. For completeness, gas-phase loss reactions of HONO and NO₂
374 with OH and the reactions of O(³P) with NO, NO₂ and O₂ were also included in the model,
375 R23-R27, though their inclusion had no effect on the HONO concentration. The rates of R23-
376 R27 within the model are much smaller than HONO loss reactions on the surface (R17-R19)
377 and the photolysis reactions (R21). For both Models 2 and 3, the adsorption of an NO₂ molecule
378 to the surface, k_{R9} , was assumed to be rapid and not the rate determining step. Likewise, the
379 desorption of HONO was also assumed to be rapid, faster than the loss rates of adsorbed HONO
380 but slower than the adsorption of NO₂; this was necessary for the model to reproduce the trend
381 in the experimental results of [HONO] versus [NO₂], discussed fully in Section 3.3.2.

382 3 Results and Discussion

383 3.1 HONO production from TiO₂ aerosol surfaces in the presence of NO₂

384 The production of HONO on TiO₂ aerosol surfaces was measured as a function of the initial
385 NO₂ mixing ratio. Figure 6 shows the dependence of the HONO concentration, measured at
386 the end of the flow tube, on the initial NO₂ mixing ratio for an aerosol surface area of $(1.6 \pm$
387 $0.8) \times 10^{-2} \text{ m}^2 \text{ m}^{-3}$. A sharp increase in HONO production at a low mixing ratio of NO₂ was
388 seen followed by a more gradual reduction in HONO production after a peak production at \sim
389 $54 \pm 5 \text{ ppb NO}_2$.

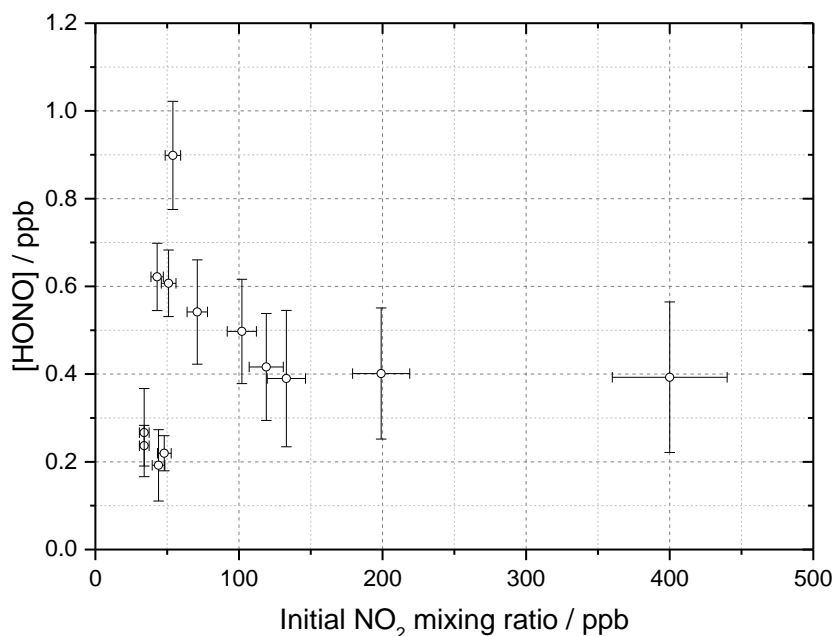

Figure 6. HONO concentration measured at the end of the flow tube as a function of the initial NO₂ mixing ratio, for the aerosol surface area density of $(1.6 \pm 0.8) \times 10^{-2} \text{ m}^2 \text{ m}^{-3}$, relative humidity $15 \pm 1 \%$, photon flux $(1.63 \pm 0.09) \times 10^{16} \text{ photons cm}^{-2} \text{ s}^{-1}$ (290-400 nm wavelength range), reaction time of 52 seconds and N₂ carrier gas. Each point is an average of up to 20 measurements at the same aerosol surface area and mixing ratio of NO₂. The highest concentration of HONO measured was $0.90 \pm 0.12 \text{ ppb}$ at $[\text{NO}_2] = 54 \pm 5 \text{ ppb}$. The y error bars represent 1σ while the x error bars represent the sum in quadrature of the errors in the N₂ and NO₂ gas flows and the NO₂ dilution. The SA varied over the experiments at different NO₂ mixing ratios leading to a larger error in the quoted SA.

390 Figure 7 shows the HONO concentration measured at the end of the flow tube over a range of
391 RH values for a fixed aerosol surface area density of $(1.59 \pm 0.16 \times 10^{-2} \text{ m}^2 \text{ m}^{-3})$ and at two

392 NO₂ mixing ratios, displaying a peak in HONO production between 25 – 30 % RH. Above ~
 393 37 % RH, for experiments including single-component TiO₂ aerosols, it was found that
 394 significant aerosols were lost from the system before entering the flow tube, speculated to be
 395 due to loss to the walls of the Teflon lines. As such the RH dependence was only studied up to
 396 37 % RH, however a clear drop off in HONO production was seen for both NO₂ mixing ratios
 397 studied after ~ 30 % RH.

Figure 7. RH dependence of HONO production from illuminated TiO₂ aerosol surfaces at 295 K in N₂ at 71 (black) and 170 (red) ppb initial NO₂ mixing ratio. The aerosol surface area density was kept constant at $(1.59 \pm 0.16) \times 10^{-2} \text{ m}^2 \text{ m}^{-3}$ with a photon flux of $(1.63 \pm 0.09) \times 10^{16} \text{ photons cm}^{-2} \text{ s}^{-1}$ and an illumination time of 52 ± 2 seconds. The error bars represent 1σ .

398 A dependence of HONO production upon RH was expected due to the potential role of water
 399 as a proton donor in the production mechanism of HONO on TiO₂ surfaces (R2) and (R5), as
 400 shown in Figure 5 (Dupart et al., 2014). The fractional surface coverage of water on the TiO₂
 401 aerosol core, V/V_m , at 15 % RH and above was calculated using the parameterisation below,
 402 which was determined using transmission IR spectroscopy (Goodman et al., 2001):

$$\frac{V}{V_m} = \left[\frac{c \left(\frac{P}{P_0} \right)}{1 - \left(\frac{P}{P_0} \right)} \right] \left[\frac{1 - (n+1) \left(\frac{P}{P_0} \right)^n + n \left(\frac{P}{P_0} \right)^{n+1}}{1 + (c-1) \left(\frac{P}{P_0} \right) - c \left(\frac{P}{P_0} \right)^{n+1}} \right] \quad (9)$$

403 where V is the volume of water vapour adsorbed at equilibrium pressure P , V_m is the volume
 404 of gas necessary to cover the surface of TiO_2 particles with a complete monolayer, P_0 is the
 405 saturation vapour pressure, c is the temperature dependent constant related to the enthalpies of
 406 adsorption of the first and higher layers (taken as 74.8 kJ mol^{-1} for TiO_2 (Goodman et al., 2001))
 407 and n is the asymptotic limit of monolayers (8 for TiO_2 (Goodman et al., 2001)) at large values
 408 of P/P_0 .

409 At 15 % RH, a fractional water coverage of 1.09 was calculated to be present on the surface,
 410 increasing to 1.50 at 35 % RH. It has been shown in previous work that HONO can be displaced
 411 from a surface by water, leading to an increase in gas-phase HONO with RH (Syomin and
 412 Finlayson-Pitts, 2003). The increase in HONO with RH to ~25-30 % RH could therefore be
 413 attributed to both an increase in the concentration of the water reactant leading to more HONO
 414 formation and the increase in displacement of HONO from the surface due to preferential
 415 adsorption of water. A decrease in HONO production seems to occur above ~ 30 % RH, which
 416 could be due to the increased water adsorption inhibiting either NO_2 adsorption or the
 417 electron/hole transfer process (Gustafsson et al., 2006). H_2O vapour adsorption is likely
 418 enhanced by the superhydrophilic properties of TiO_2 surfaces under UV radiation meaning that
 419 water monolayers form more quickly on the surface of TiO_2 owing to light-induced changes in
 420 surface tension (Takeuchi et al., 2005; Gustafsson et al., 2006).

421 At the higher initial concentration of $\text{NO}_2 = 170 \text{ ppb}$, the RH dependence showed a similar
 422 peak in HONO production between ~25 - 30 % RH but less HONO was produced overall, as
 423 expected from Figure 6 given the higher NO_2 . Previous work on the production of HONO from
 424 suspended TiO_2 aerosols reported a strong RH dependence of the uptake coefficient, γ , of NO_2
 425 to form HONO with a peak at ~ 15 % RH and decreasing at larger RH (Gustafsson et al., 2006).
 426 The same trend for the NO_2 uptake coefficient was observed by Dupart et al., 2014 on Arizona
 427 test dust (ATD) aerosols with a peak in γ at ~ 25 % RH. This increase in the RH at which the
 428 uptake coefficient for NO_2 in going from TiO_2 to ATD aerosols was ascribed to the lower
 429 concentration of TiO_2 present in ATD aerosols as opposed to single-component TiO_2 aerosols
 430 used by Gustafsson et al., 2006 as well as by differences in particle size distribution. Gustafsson
 431 et al., 2006 reported a larger aerosol size distribution with a bimodal trend with mode diameters

432 of ~ 80 and ~ 350 nm for single-component TiO₂ aerosols whereas Dupart et al., 2014 reported
433 a smaller unimodal aerosol size distribution for ATD aerosols with a mode diameter of ~110
434 nm. In this work we also see a larger aerosol size distribution, with a lower mode diameter of
435 ~ 180 nm similar to Dupart et al., 2014 but for pure TiO₂ aerosols; aerosol size distribution
436 shown in Figure 2. Similar to the results of Dupart et al., 2014 we observe a trend inversion in
437 [HONO] vs RH at higher RH, between 25-30 %. An increase in HONO as a function of RH
438 has also been observed on TiO₂ containing surfaces (Langridge et al., 2009;Gandolfo et al.,
439 2015;Gandolfo et al., 2017) with a similar profile for the observed RH dependence of HONO
440 being observed by Gandolfo et al., (2015) from photo-catalytic paint surfaces with a maximum
441 in HONO mixing ratio found at 30 % RH. In comparison, a study focusing on the products of
442 the uptake of NO₂ on TiO₂ surfaces showed a maximum in the gas-phase HONO yield at 5 %
443 RH with the yield of HONO plateauing off with further increase in humidity (Bedjanian and
444 El Zein, 2012).

445 **3.2 Dependence of reactive uptake coefficient on initial NO₂ mixing ratio**

446 The reactive uptake coefficient, $\gamma_{NO_2 \rightarrow HONO}$ for NO₂→HONO on TiO₂ aerosol particles was
447 determined experimentally for 18 different initial NO₂ mixing ratios, and is shown in Figure 8.
448 For each initial NO₂ mixing ratio, the gradient of the first order rate coefficient for HONO
449 production, k , as a function of aerosol surface area density (e.g. Figure 4) and in conjunction
450 with equation 8, was used to obtain $\gamma_{NO_2 \rightarrow HONO}$. The uptake coefficient initially increases with
451 NO₂, reaching a peak at $\gamma_{NO_2 \rightarrow HONO} = (1.26 \pm 0.17) \times 10^{-4}$ for an initial NO₂ mixing ratio of
452 51 ± 5 ppb, before sharply decreasing as the NO₂ mixing ratio continues to increase above this
453 value.

Figure 8 Experimental results showing the reactive uptake coefficients of NO_2 to form HONO, $\gamma_{\text{HONO} \rightarrow \text{NO}_2}$ onto TiO_2 aerosol surfaces as a function of the initial NO_2 mixing ratio. All experiments were conducted in N_2 at 295 K at 15 ± 1 % RH, a photon flux of $(1.63 \pm 0.09) \times 10^{16}$ photons $\text{cm}^{-2} \text{s}^{-1}$ and an illumination time of 52 ± 2 seconds. $\gamma_{\text{HONO} \rightarrow \text{NO}_2}$ was determined for each NO_2 mixing ratio from the gradient of the pseudo-first-order rate coefficient for HONO production, k , versus aerosol surface area density varied from 0 - $0.04 \text{ m}^2 \text{ m}^{-3}$ (e.g. as shown in Figure 4) and equation 8.

454 The increase in uptake coefficient with NO_2 at low NO_2 (< 51 ppb) has not been seen previously
 455 in studies of HONO production from TiO_2 containing aerosols with similar $[\text{NO}_2]$ ranges
 456 (Gustafsson et al., 2006;Ndour et al., 2008;Dupart et al., 2014) nor with other aerosol surfaces
 457 (Bröske et al., 2003;Stemmler et al., 2007) or TiO_2 surfaces (El Zein and Bedjanian, 2012b). It
 458 is worth noting that several of these studies reported the overall uptake of NO_2 onto aerosol
 459 surfaces and not specifically the uptake to form HONO, although HONO was indirectly
 460 measured in all studies noted here (Gustafsson et al., 2006;Ndour et al., 2008;Dupart et al.,
 461 2014). For single-component TiO_2 aerosols, Gustafsson et al., (2006) reported a uptake
 462 coefficient, γ_{NO_2} , of 9.6×10^{-4} at 15 % RH and 100 ppb NO_2 . Taking into account the HONO
 463 yield of 0.75 given by (Gustafsson et al., 2006), an estimated $\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = 7.2 \times 10^{-4}$ is
 464 determined and can be compared to the value observed in this work at 15 % RH and 100 ppb
 465 NO_2 , ($\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = (2.68 \pm 0.23) \times 10^{-5}$). The $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$ we determine is 27 times smaller
 466 than reported by Gustafsson et al., (2006). This difference is mostly due to the lower
 467 experimental photon flux in our setup, ~ 19 times less at $\lambda_{\text{max}} = 365$ nm owing to the use of

468 one 15 W UV lamp to irradiate the flow tube (Boustead, 2019) compared to Gustafsson et al.,
469 2006 which utilised four 18 W UV lamps.

470 The origins of the increase in $\gamma_{NO_2 \rightarrow HONO}$, together with reaching a maximum and the
471 subsequent decrease at larger NO_2 mixing ratios was investigated using the kinetic box model
472 and postulated mechanism for HONO production described in Section 2.5. The aim was to
473 compare the observed production of HONO and $\gamma_{NO_2 \rightarrow HONO}$ with the modelled values, as a
474 function of NO_2 mixing ratio. The skill of the model to reproduce the observed behaviour
475 enables a validation of the postulated mechanism for HONO production, and variation of the
476 kinetic parameters enables the controlling influence of different steps in the mechanism on
477 HONO production to be evaluated.

478 **3.3 Modelling the HONO production mechanism on illuminated TiO_2** 479 **aerosol surfaces**

480 The HONO production on illuminated TiO_2 aerosol surfaces was investigated for each of the
481 mechanisms outlined in Table 1.

482 **3.3.1 Model 1**

483 Model 1 (see Table 1 and Figure 5), which contains the simplest mechanism, was designed to
484 reproduce the decreasing value of the NO_2 uptake coefficient to form HONO, $\gamma_{NO_2 \rightarrow HONO}$, with
485 increasing NO_2 and also the plateauing at higher NO_2 mixing ratios caused by NO_2 reaching a
486 maximum surface coverage, as seen by Stemmler et al., (2007). A decrease in the uptake
487 coefficient of NO_2 , γ_{NO_2} , onto dust aerosol surfaces was also seen in studies where the
488 formation of HONO from NO_2 uptake was not directly studied (Ndour et al., 2008; Dupart et
489 al., 2014). The mechanism for Model 1 which is given in Table 1 describes the adsorption of
490 one NO_2 molecule to a surface site which then undergoes the reaction which forms HONO,
491 followed by desorption of HONO to the gas-phase, R9-R11. Any representation of the specific
492 chemical processes which convert NO_2 to HONO on the surface following the initial photo-
493 production of electron-hole pairs in the TiO_2 structure (R2) was not included here as the
494 primary focus was to produce the relationship between $\gamma_{NO_2 \rightarrow HONO}$ and the NO_2 mixing ratio.
495 Gustafsson et al., (2006) reported that the measured rate of photo-induced HONO production
496 is 75% that of the rate of NO_2 removal, whereas the dark disproportionation reaction (R28)
497 would predict a 50% yield, and hence that the HONO observed in their studies is not simply a
498 photo-enhancement of:

499 Gustafsson et al., (2006) suggests that an oxidant on the surface is produced following the
 500 creation of the electron-hole pair (OH is generated in (R2)), and suggests H₂O₂ as a possibility,
 501 which is consistent with the observation of OH and HO₂ radicals produced from the surface of
 502 illuminated TiO₂ aerosols (Moon et al., 2019). For Model 1, outputs for the predicted
 503 concentration of HONO and the reactive uptake coefficient, $\gamma_{NO_2 \rightarrow HONO}$, as a function of initial
 504 NO₂ mixing ratio are shown in Figure 9.

Figure 9 Model 1 calculations for (a) the concentration of HONO and (b) the reactive uptake coefficient to form HONO, $\gamma_{NO_2 \rightarrow HONO}$, as a function of NO₂ mixing ratio for a model run time of 52 s. The estimated rate coefficients used in this model are shown in Table 1.

505 For a run time of 52 s, equal to that of the experimental illumination time, Model 1 predicts an
 506 increase in HONO production with increasing NO₂ mixing ratio until the HONO concentration
 507 begins to plateau, reaching ~0.25 ppb at [NO₂] = 400 ppb, presumably owing to saturation on
 508 active aerosol surface sites by NO₂. This leads to the modelled reactive uptake coefficient,
 509 $\gamma_{NO_2 \rightarrow HONO}$, monotonically decreasing with increasing NO₂ mixing ratio; a variation in NO₂
 510 uptake coefficient similar to that seen in previous photo-enhanced NO₂ aerosol uptake studies
 511 (Bröske et al., 2003; Stemmler et al., 2007; Ndour et al., 2008; Dupart et al., 2014). However,

512 the model predictions for Model 1 do not reproduce the experimental variations shown in
513 Figure 6 and Figure 8, in which there is an observed initial rise and then a fall in both the
514 HONO concentration and $\gamma_{NO_2 \rightarrow HONO}$ with increasing NO_2 mixing ratio. Hence, additional
515 processes were considered in the model in order to try to reproduce this behaviour.

516 **3.3.2 Models 2 and 3. Investigating the role of NO_2 dimerisation for the surface** 517 **formation of HONO, and including additional surface losses of HONO**

518 As the experimental $\gamma_{NO_2 \rightarrow HONO}$ increases with NO_2 at low NO_2 (Figure 8), we postulate in
519 Models 2 and 3 that the production of HONO under illuminated conditions is not fully first
520 order in NO_2 and requires more than one NO_2 molecule to form HONO, consistent with the
521 formation of the symmetric NO_2 dimer (N_2O_4) followed by isomerisation on the surface to
522 form the asymmetric *trans*-ONO- NO_2 dimer, which has been suggested to be more reactive
523 with water than the symmetric N_2O_4 dimer (Finlayson-Pitts et al., 2003; Ramazan et al.,
524 2004; Ramazan et al., 2006; Liu and Goddard, 2012) due to the autoionisation to form
525 $(NO^+)(NO_3^-)$ which we propose is accelerated by the presence of light; the full mechanism for
526 which is shown in Figure 5. A recent rotational spectroscopy study found that the *trans*-ONO-
527 NO_2 was better described as the ion pair $(NO^+)(NO_3^-)$ (Seifert et al., 2017). Reaction of the
528 $(NO^+)(NO_3^-)$ ion pair with surface adsorbed water can then lead to the formation of HONO and
529 HNO_3 , the feasibility of which is supported by molecular dynamics simulation studies (Varner
530 et al., 2014). While the symmetric N_2O_4 dimer is favoured as it is the most stable conformer,
531 the asymmetric forms have been experimentally observed in several studies (Fateley et al.,
532 1959; Givan and Loewenschuss, 1989b, a, 1991; Pinnick et al., 1992; Forney et al., 1993; Wang
533 and Koel, 1998, 1999; Beckers et al., 2010). A more recent *ab initio* study of NO_2 adsorption
534 at the air-water interface suggested an orientational preference of NO_2 on the surface, with both
535 oxygen atoms facing away from the interface which may imply that the asymmetric dimer
536 ONO- NO_2 can form directly, meaning the high barrier between the symmetric and asymmetric
537 forms does not need to be overcome (Murdachew et al., 2013).

538 The energy barrier to isomerisation of symmetric N_2O_4 in the gas-phase may be reduced due
539 to the interaction with water adsorbed on surfaces. We therefore rule out the dimer in the gas-
540 phase adsorbing onto the surface first, and then reacting to form HONO (Varner et al., 2014).
541 An interesting question is whether the first NO_2 molecule adsorbed to the surface dimerises via
542 the addition of a gaseous NO_2 via an Eley-Rideal (ER) type process, or whether a Langmuir-
543 Hinshelwood (LH) type mechanism is operating in which both NO_2 molecules are first

544 adsorbed and then diffuse together on the surface forming N_2O_4 . Both ER and LH mechanisms
 545 to form the NO_2 dimer have been included in the model, denoted as Model 2 and Model 3,
 546 respectively. The outputs for Models 2 and 3 (see Table 1 for details of the processes included)
 547 for the HONO concentration and $\gamma_{NO_2 \rightarrow HONO}$ as a function of NO_2 are shown in Figure 10
 548 together with the experimental data. The stoichiometric relationship of the requirement of two
 549 NO_2 molecules forming HONO on the surface was key to reproducing the experimental trend
 550 of first an increase and then a decrease in both the HONO concentration and the reactive uptake
 551 coefficient with the initial NO_2 mixing ratio.

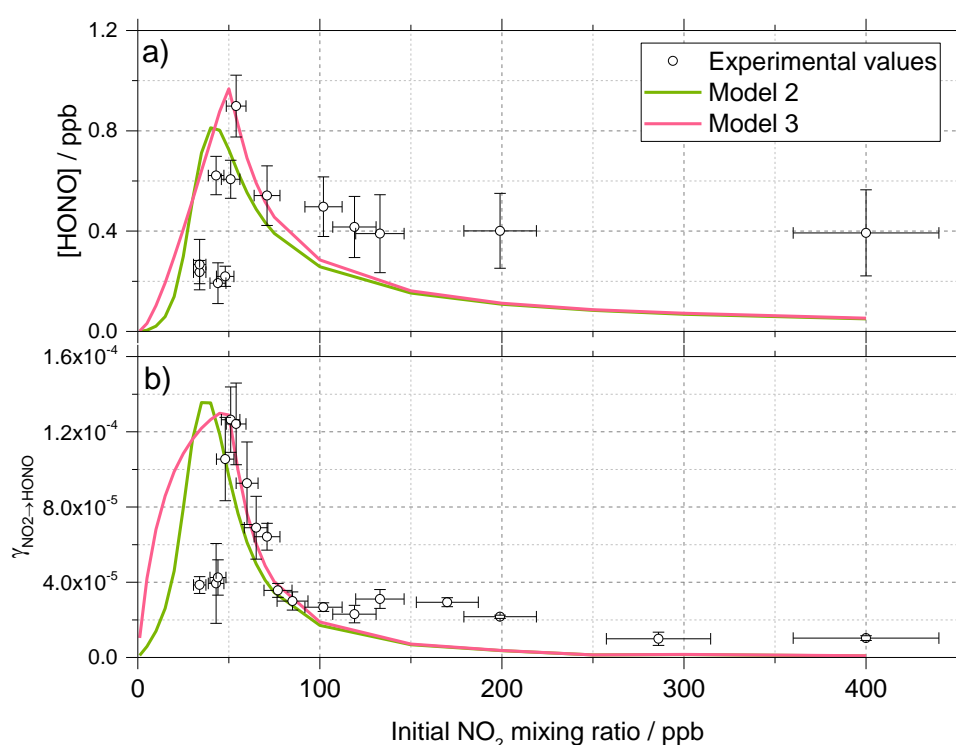

Figure 10. Experimental values (open circles with 1σ error bars), Model 2 (green line) and Model 3 (pink line) calculations for (a) HONO concentration after 52 s illumination and (b) NO_2 reactive uptake coefficient, $\gamma_{NO_2 \rightarrow HONO}$, as a function of the initial NO_2 mixing ratio. The mechanisms used for these model runs included a 2:1 stoichiometric relationship between the NO_2 adsorbed on the TiO_2 aerosol surface and the HONO produced, as well as additional HONO loss reactions which are dependent on NO_2 , see Table 1 for details. Models 2 and 3 use an Eley-Rideal and Langmuir-Hinshelwood mechanisms, respectively, for the formation of the NO_2 dimer on the aerosol surface. Modelled $\gamma_{NO_2 \rightarrow HONO}$ was calculated using Eq. 6 and Eq. 7 with a constant surface area of $1.6 \times 10^{-2} m^2 m^{-3}$ chosen to match the aerosol surface area density of $(1.6 \pm 0.8) \times 10^{-2} m^2 m^{-3}$ shown in the experimental [HONO] values in (a).

552 In previous work that investigated HONO production from humic acid aerosols, a saturation
 553 effect was seen with HONO production plateauing with increasing NO₂ mixing ratio (Stemmler
 554 et al., 2007), with the decreasing uptake coefficient, $\gamma_{NO_2 \rightarrow HONO}$, with increasing NO₂ being
 555 attributed to NO₂ fully saturating available surface sites. However, the observed decrease of
 556 [HONO] at the high NO₂ mixing ratios shown in Figure 8 and Figure 10a suggests that
 557 additional reactions on the surface may remove HONO and result in the reduction of [HONO]
 558 that is measured. As [HONO] decreases with the increase in the NO₂ mixing ratio, the removal
 559 process should either involve NO₂ directly:

560 or involve species made rapidly from NO₂ on the surface, such as NO₂⁺:

561 which may be present at high enough concentrations of HNO₃ on the surface (Syomin and
 562 Finlayson-Pitts, 2003) or following reaction with h^+_{VB} , or a product of the reaction of
 563 O_2^- (or e^-_{CB}) with NO₂ (R4) i.e. NO₂⁻. Similar results were observed in a study by El Zein and
 564 Bedjanian (2012a) where NO₂ and NO were found to be formed from the heterogeneous
 565 reaction of HONO with TiO₂ surfaces in both dark and illuminated conditions suggesting the
 566 loss of HONO via an auto-ionisation reaction between the gas phase and adsorbed HONO to
 567 generate NO⁺ and NO₂⁻ (El Zein and Bedjanian, 2012a). Additional HONO surface loss
 568 pathways were assumed to occur under illuminated conditions due to the presence of e^- and h^+
 569 leading to the oxidation of HONO to NO₂ and the reduction of HONO to NO (El Zein et al.,
 570 2013). Transition state theory (TST) studies of the gas-phase reaction of HONO with NO₂ to
 571 form HNO₃ calculated a large activation energy which varied depending on whether the
 572 reaction occurs via O abstraction by HONO (159 kJ mol⁻¹) or via OH abstraction via NO₂
 573 (~133-246 kJ mol⁻¹)(Lu et al., 2000). In the gas-phase these reactions are too slow to be
 574 important but they could be enhanced on the surface, potentially more so on a photoactive
 575 surface such as TiO₂. For models 2 and 3 the shape of the trend in HONO concentration and
 576 uptake coefficient, γ , versus NO₂ concentration depended strongly on the value of k_{R19} reaction,
 577 R19, and the choice of a 2:1 stoichiometric ratio of the NO₂ molecules adsorbed to the HONO
 578 molecules produced. Without these two key processes being included, a maximum in either the
 579 HONO concentration or γ as the NO₂ concentration is increased could not be obtained in the
 580 model. A third key condition was the requirement that the desorption rate coefficient, k_{R16} , be

581 larger than the rate coefficient for the loss of HONO, k_{R17} and $k_{R18}=1 \times 10^{-3} \text{ s}^{-1}$, but slower than
 582 the adsorption rate coefficient, k_{R9} . Changing the values of all other kinetic parameters in the
 583 model had an effect on the absolute concentration of HONO, but crucially not on the shape of
 584 the trends in HONO or the uptake coefficient versus NO_2 concentration. Changing the values
 585 of the rate coefficients for the gas phase loss reactions, R23-27, only had a very small impact
 586 on the HONO concentration. The NO_2 -dependent loss reaction, k_{R19} in Table 1, was necessary
 587 in the model to reproduce the sharp decrease in [HONO] versus NO_2 seen experimentally after
 588 ~ 54 ppb NO_2 . Without k_{R19} the modelled [HONO] continued to increase to a plateau, as seen
 589 in Model 1 (see Figure 9). In order to observe the model output seen in Figure 10 for model 2
 590 and 3, k_{R19} also had to be slower than the desorption of HONO from the surface, k_{R16} .

591 The addition of an NO_2 dependent loss reaction to both Model 2 and 3 had the most significant
 592 effect on the trend in modelled HONO concentration. Though it is also possible that a
 593 secondary product could remain adsorbed and therefore block active sites on the TiO_2 surface,
 594 effectively poisoning the photo-catalyst, NO_2 independent loss reactions in the model, k_{R17} and
 595 k_{R18} had little effect on the trend in [HONO] vs NO_2 , only having an effect on the overall
 596 [HONO]. HNO_3 has however been shown to remain adsorbed to surfaces once formed
 597 (Sakamaki et al., 1983;Pitts et al., 1984;Finlayson-Pitts et al., 2003;Ramazan et al., 2004) and
 598 may also react with adsorbed HONO, further reducing the product yield (Finlayson-Pitts et al.,
 599 2003): these NO_2 independent loss reactions may therefore become more important at higher
 600 NO_2 concentrations and hence surface concentrations of HONO and HNO_3 :

601 The photolysis of particulate nitrate was not considered in Models 2 or 3, due to the lack of
 602 particulate nitrate in the system at $t=0$. The gas-to-particle conversion of any HNO_3 formed
 603 was not considered to be important due to the assumption that most HNO_3 formed would
 604 remain adsorbed to the aerosol surface (Sakamaki et al., 1983;Pitts et al., 1984;Finlayson-Pitts
 605 et al., 2003;Ramazan et al., 2004).

606 For Model 2, which includes the production of HONO via the Eley-Rideal mechanism, in order
 607 to reproduce the experimentally observed sharp increase followed by a decrease in both
 608 [HONO] and $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$ as a function of increasing NO_2 mixing ratio, the modelled rate
 609 coefficient for the adsorption of a gas-phase NO_2 molecule to another the surface adsorbed
 610 NO_2 to initially form the symmetric N_2O_4 dimer, k_{R12} , had to be larger than for the isomerisation
 611 step to form HONO and HNO_3 via *trans*-ONO- NO_2 , k_{R13} . Interestingly, for HONO production

612 via the Langmuir-Hinshelwood mechanism, Model 3, the modelled rate coefficient for the
613 diffusion of one NO₂ molecule across the surface to form the dimer with another NO₂ molecule,
614 k_{R14} , had to be smaller than for the isomerisation step, k_{R15} , to more closely represent the
615 experimental results for the uptake coefficient. Additionally, in order to reproduce the
616 experimental trend in HONO formation as a function of NO₂ mixing ratio, the rate coefficient
617 for the NO₂ dependent loss reaction, k_{R19} , had to be larger than the NO₂ independent reactions,
618 k_{R17} and k_{R18} , leading to $k_{R19} = 5 \times 10^{-3} \text{ s}^{-1}$. The modelled HONO concentration also sensitive
619 to the active site surface concentration: Model 3 required an active site surface concentration
620 2.5 times that of Model 2 to reproduce the peak in [HONO] at ~ 51 ppb NO₂ observed in the
621 experimental results. The reason for this is due to the difference in active site occupation in the
622 2 models: one active site is being occupied by two NO₂ molecules per HONO formed in Model
623 2 as opposed to Model 3 where two active sites are occupied per HONO formed. Regardless
624 of the choice of an Eley Rideal or Langmuir Hinshelwood mechanism, both models reproduce
625 the general shape of [HONO] and $\gamma_{NO_2 \rightarrow HONO}$ with NO₂, providing evidence that two NO₂
626 molecules are required to form HONO.

627 **3.4 HONO production from illumination of a mixed NH₄NO₃/TiO₂ aerosol** 628 **in the absence of NO₂**

629 The photolysis of particulate nitrate has been postulated as a source of HONO under ambient
630 sunlit conditions during several field campaigns, from both aircraft and ground based
631 measurements (Reed et al., 2017;Ye et al., 2017a;Ye et al., 2017b). Here, experiments were
632 carried out to investigate the formation of HONO from particulate nitrate photolysis, with and
633 without the addition of a photo-catalyst. This is of significant interest for marine environments
634 downwind of arid desert regions due to the availability of TiO₂ or other photocatalytic materials
635 within aerosols in dust plumes that are transported from these regions (Hanisch and Crowley,
636 2003).

637 Using the aerosol flow tube setup described in Sections 2.1-2.4, an aqueous solution of
638 ammonium nitrate (5 g NH₄NO₃ in 500 ml milli-Q water) was used to generate nitrate aerosols.
639 At the RH used in this experiment, ~ 50 %, the aerosols were still deliquesced. For these
640 experiments the residence time of the aerosols in the illuminated region of the flow tube was
641 30 seconds (flow rate ~ 6 lpm), with the production of HONO following illumination measured
642 as a function of aerosol surface area density. The number of lamps was increased from 1 to 4,
643 increasing the photon flux from $(1.63 \pm 0.09) \times 10^{16}$ to $(8.21 \pm 2.39) \times 10^{16}$ photons cm⁻² s⁻¹

644 and $j(\text{NO}_2)$ from $(6.43 \pm 0.30) \times 10^{-3}$ to $(3.23 \pm 0.92) \times 10^{-2} \text{ s}^{-1}$. The $j(\text{NO}_2)$, $j(\text{HONO})$ and flux
 645 values for 4 lamps were more than 4 times that of 1 lamp only due to the lamp casings being
 646 mirrored, and so with 4 lamps, with 2 lamps on either side of the flow tube, the casings reflected
 647 the light back into the flow tube, increasing the effective light intensity. For these experiments,
 648 no gaseous NO_2 was added to the gas entering the flow tube. As shown in Figure 11, for the
 649 illumination of pure nitrate aerosols, although a small amount of HONO was observed at higher
 650 aerosol loadings, no statistically significant production of HONO was seen.

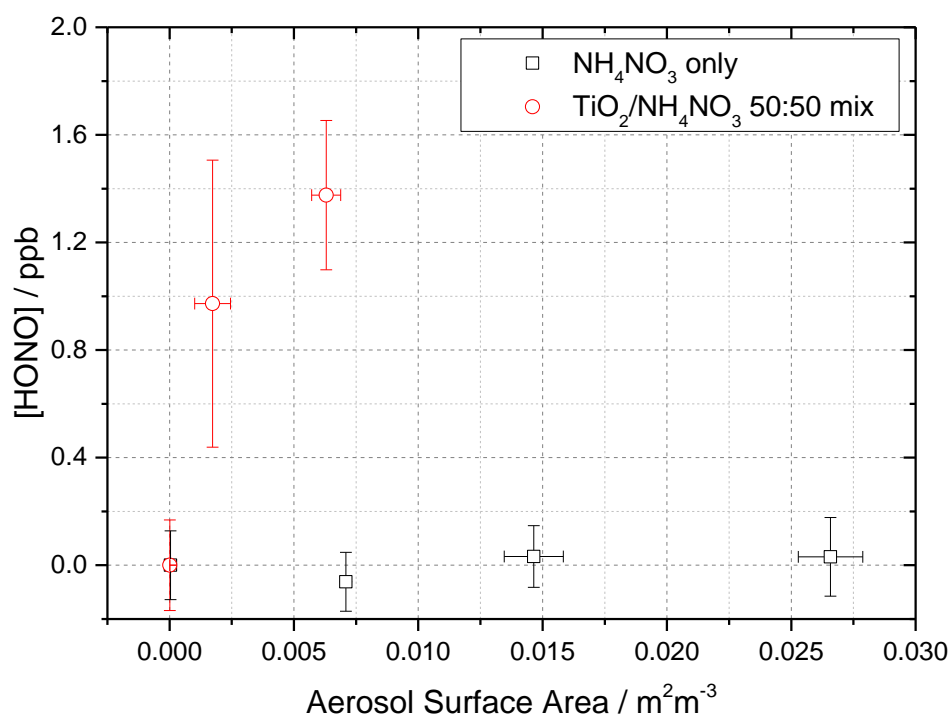

Figure 11. Dependence of the HONO concentration generated as a function of aerosol surface area density for pure NH_4NO_3 aerosol (black open squares, error bars represent 1σ) and 1:1 $\text{TiO}_2/\text{NH}_4\text{NO}_3$ mixed aerosol (red open circles, error bars represent 1σ). Both experiments were performed in N_2 at 295 K, an illuminated residence time of 30 s, and a lamp photon flux of $(8.29 \pm 2.39) \times 10^{16} \text{ photons cm}^{-2} \text{ s}^{-1}$. The NH_4NO_3 only experiment was performed at $\sim 50 \pm 5\%$ RH while the $\text{TiO}_2/\text{NH}_4\text{NO}_3$ mix experiment was performed at $20 \pm 2\%$ RH. For all points, the background HONO seen observed without illumination has been subtracted. At zero aerosol surface area density there is no HONO generated from the walls of the flow tube.

651 A second set of experiments were performed with an aqueous solution of titanium dioxide and
 652 ammonium nitrate combined in a 1:1 mass ratio to give a $\text{TiO}_2/\text{NH}_4\text{NO}_3$ aerosol mixture (5 g
 653 NH_4NO_3 and 5 g TiO_2 in 500 ml milli-Q water) to investigate if the photo-catalytic properties
 654 of TiO_2 facilitate the production of HONO in the presence of nitrate. The RH was decreased to
 655 ensure the maximum TiO_2 photocatalytic activity (Jeong et al., 2013). A recent study using
 656 Raman micro spectroscopy to observe phase changes in salt particles reported an efflorescence

657 point of pure ammonium nitrate to be between 13.7-23.9 % RH (Wu et al., 2019). It is possible
658 therefore that at the RH used in this experiment, ~ 20 %, the aerosols were still deliquesced.
659 As shown in Figure 11, the presence of TiO₂ in the aerosol mixture showed a significant
660 production of HONO without the presence of NO₂, a potentially significant result for the
661 production of HONO in low NO_x environments in the presence of mixed dust/nitrate aerosols,
662 for example in oceanic regions off the coast of West Africa, or in continental regions impacted
663 by outflow from the Gobi desert. Using the Aerosol Inorganic Model (AIM) (Clegg et al.,
664 1998; Wexler and Clegg, 2002), the nitrate content of the aerosol at both 20 and 50 % RH was
665 calculated, in accordance with the experimental RH conditions. From this and the aerosol
666 volume distribution given by the SMPS, the [NO₃⁻] within the aerosols could be calculated.
667 The formation of HONO by photolysis of particulate nitrate is given by:

$$\frac{d[\text{HONO}]}{dt} = j(\text{pNO}_3)[\text{NO}_3^-] \quad (10)$$

668 and hence:

$$[\text{HONO}] = j(\text{pNO}_3)[\text{NO}_3^-]t \quad (11)$$

669 where $j(\text{pNO}_3)$ is the photolysis frequency of nitrate for the lamps used in these experiments
670 and t is the illumination time of the experiment. With knowledge of [HONO], [NO₃⁻] and $t =$
671 30 s, $j(\text{pNO}_3)$ can be calculated from a measurement of [HONO] as a function of [NO₃⁻], as
672 shown in Figure 12, for the mixed nitrate/ TiO₂ experiment.

Figure 12. Dependence of [HONO] on the calculated nitrate concentration in the aerosol (using the AIM model) for the mixed TiO₂/ammonium nitrate aerosol experiment. Using equation 10 and for $t = 30$ s, the gradient gives $j(\text{pNO}_3) = (3.29 \pm 0.89) \times 10^{-4} \text{ s}^{-1}$. Experiment performed at 15 ± 1 % RH, in N₂ at 295 K with a lamp photon flux of $(8.29 \pm 2.39) \times 10^{16} \text{ photons cm}^{-2} \text{ s}^{-1}$. For all points, the background HONO seen observed without illumination has been subtracted.

673 When using the 4 lamps together, the experimental particulate nitrate photolysis rate, $j(\text{pNO}_3)$,
674 was determined to be $(3.29 \pm 0.89) \times 10^{-4} \text{ s}^{-1}$ for the mixed nitrate/TiO₂ aerosol. From this, it
675 is possible to estimate $j(\text{pNO}_3)$ for ambient conditions typical of the tropical marine boundary
676 layer. Taking the ratio of the experimental $j(\text{HONO})$ for 4 lamps $((8.35 \pm 0.18) \times 10^{-3} \text{ s}^{-1})$ and
677 the measured $j(\text{HONO})$ from the RHaMBLe campaign held at the Cape Verde Atmospheric
678 Observatory [May-June,2007] $(1.2 \times 10^{-3} \text{ s}^{-1})$ (Carpenter et al., 2010;Whalley et al., 2010;Reed
679 et al., 2017) and assuming that $j(\text{pNO}_3)$ and $j(\text{HONO})$ scale in the same way, ambient $j(\text{pNO}_3)$
680 can be determined from:

$$j(\text{pNO}_3)_N = j(\text{pNO}_3) \times \frac{1.2 \times 10^{-3}}{j(\text{HONO})} \quad (12)$$

681 where $j(\text{pNO}_3)_N$ is the photolysis rate coefficient of particulate nitrate at Cape Verde, $j(\text{pNO}_3)$
682 is the experimentally determined photolysis rate coefficient of particulate nitrate to form

683 HONO and $j(\text{HONO})$ is the HONO photolysis rate coefficient calculated from the
684 experimentally determined $j(\text{NO}_2)$.

685 Using $j(\text{pNO}_3) = (3.29 \pm 0.89) \times 10^{-4} \text{ s}^{-1}$, the rate of HONO production from nitrate photolysis
686 at Cape Verde was calculated to be $j(\text{pNO}_3)_N = (4.73 \pm 1.01) \times 10^{-5} \text{ s}^{-1}$ from the mixed
687 nitrate/ TiO_2 aerosol experiment. Although for pure nitrate aerosol in the absence of TiO_2 the
688 data were scattered and the HONO production small (Figure 11), an upper limit estimate of
689 $j(\text{pNO}_3)_N = (1.06 \pm 1.15) \times 10^{-6} \text{ s}^{-1}$ under conditions at Cape Verde could be made using
690 equation 11, as done for rate of HONO production from mixed nitrate/ TiO_2 aerosols. The
691 atmospheric implications of this will be considered below.

692 **4 Implications of HONO production from TiO_2 for tropospheric chemistry**

693 **4.1 Production of HONO from sunlight aerosols containing TiO_2 in the** 694 **presence of NO_2**

695 For the reactive uptake of NO_2 onto illuminated TiO_2 particles as a function of the initial NO_2
696 mixing ratio, as shown in Figure 8, a maximum value of $\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = (1.26 \pm 0.17) \times 10^{-4}$
697 was determined at 51 ± 5 ppb NO_2 for a photon flux from the lamp of $(1.63 \pm 0.09) \times 10^{16}$
698 photons $\text{cm}^{-2} \text{ s}^{-1}$. These experiments were for single-component TiO_2 particles, and so for dust
699 aerosols a value of $\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = (1.26 \pm 0.17) \times 10^{-5}$ is appropriate assuming a 10 % fraction
700 of TiO_2 and/or other photoactive materials (which behave similarly for HONO production) in
701 mineral dust (Hanisch and Crowley, 2003). Dust aerosols are transported from the Gobi desert
702 to urban areas of China where high NO_x and nitrate aerosol concentrations have been observed
703 and in these areas HONO production facilitated by photo-catalysts may be important (Saliba
704 et al., 2014).

705 Using an average daytime maximum for $[\text{NO}_2]$, $j(\text{NO}_2)$ and aerosol surface area measurements
706 for a non-haze period in May-June in 2018 in Beijing, of 50 ppb, $1 \times 10^{-2} \text{ s}^{-1}$ and $2.5 \times 10^{-3} \text{ m}^2$
707 m^{-3} (of which a maximum of 0.3 % was assumed to be TiO_2 , though this could be higher in
708 dust impacted events (Schleicher et al., 2010)) respectively, a production rate of HONO of 1.70
709 $\times 10^5$ molecules $\text{cm}^{-3} \text{ s}^{-1}$ (~ 24.8 ppt h^{-1}) has been estimated using the maximum reactive uptake
710 coefficient measured in this work, $\gamma_{\text{NO}_2 \rightarrow \text{HONO}} = (1.26 \pm 0.17) \times 10^{-4}$. The average RH in
711 Beijing during summertime is significantly higher than the range of RH used in the TiO_2
712 aerosol experiments. In previous work (Gustafsson et al., 2006), the NO_2 reactive uptake
713 coefficient decreased for relative humidities above those studied here, and hence the HONO

714 production calculated under the conditions in Beijing may represent an upper limit. The lamp
 715 used to illuminate the TiO₂ aerosols in these experiments gives rise to $j(\text{NO}_2) = (6.43 \pm 0.3) \times$
 716 10^{-3} s^{-1} , and so $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$ has been scaled by a factor of 1.55 to match the noon $j(\text{NO}_2)$
 717 measured in May-June 2018 in Beijing (10^{-2} s^{-1}), to take into account the relatively small
 718 difference in experimental and atmospheric photon flux for Beijing. The HONO production
 719 rate estimated here for noontime summer [May-June 2018] in Beijing ($\sim 25 \text{ ppt hr}^{-1}$) is similar
 720 to the value for the maximum production of HONO from urban humic acid aerosol surfaces in
 721 Europe, 17 ppt h^{-1} at 20 ppb NO_2 reported by Stemmler et al., 2007. For comparison, the net
 722 gaseous production rate of HONO at noon in May-June 2018 Beijing was determined from the
 723 measured rate of gas-phase production and losses:

$$P_{\text{HONO}} = k_{\text{OH}+\text{NO}}[\text{OH}][\text{NO}] - (j(\text{HONO}) \times [\text{HONO}] + k_{\text{OH}+\text{HONO}}[\text{OH}][\text{HONO}]) \quad (13)$$

724 where $k_{\text{OH}+\text{NO}} = 3.3 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Atkinson et al., 2004), $k_{\text{OH}+\text{HONO}} = 6 \times 10^{-12}$
 725 $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Atkinson et al., 2004) and $j(\text{HONO}) = 1 \times 10^{-2} \text{ s}^{-1}$ for an average maximum
 726 noontime OH concentration of $8 \times 10^6 \text{ molecules cm}^{-3}$ (Whalley et al., 2020), NO
 727 concentration of 1.45 ppb (Whalley et al., 2020) and HONO concentration of 0.8 ppb (Whalley
 728 et al., 2020).

729 The net gas-phase production of HONO from equation 13 was calculated to be -3.8 ppb hr^{-1} (a
 730 net loss) as expected due to HONO loss by photolysis peaking at solar noon, suggesting the
 731 production of HONO heterogeneously from TiO₂ and NO₂ ($\sim 25 \text{ ppt hr}^{-1}$) would have little
 732 effect on the overall HONO budget for Beijing summertime at noon.

733 **4.2 Production of HONO from photolysis of mixed dust/nitrate aerosols**

734 Oceanic environments, for example the Atlantic Ocean which is impacted by both dust aerosols
 735 from the Sahara and high concentrations of mixed nitrate aerosols from sea spray, and despite
 736 low NO₂ concentrations could be important for particulate nitrate photolysis as a source of
 737 HONO (Hanisch and Crowley, 2003; Ye et al., 2017b). From the particulate nitrate photolysis
 738 experiments in the absence of NO₂ conducted here, a $j(\text{pNO}_3)_N = (4.73 \pm 1.01) \times 10^{-5} \text{ s}^{-1}$ was
 739 determined in the presence of the TiO₂ photo-catalysts (Section 3.4). Using the experimental
 740 $j(\text{pNO}_3)$, scaled to typical ambient light levels, and a mean noon concentration of nitrate
 741 aerosols of 400 ppt measured at Cape Verde (Reed et al., 2017), taken as an example marine
 742 boundary layer environment with a high concentration of mineral dust aerosols, a rate of
 743 HONO production from particulate nitrate at Cape Verde was calculated as 4.65×10^5

744 molecule $\text{cm}^{-3} \text{s}^{-1}$ (68 ppt hr^{-1}). We note that this value would be ~ 50 times smaller for pure
 745 nitrate aerosols. The missing rate of HONO production i.e. not taken into account by the gas
 746 phase production and loss, P_{other} , from the Cape Verde RHaMBLe campaign, can be calculated
 747 using the observed HONO concentration, $[\text{HONO}]$ and the known gas-phase routes for HONO
 748 production and loss:

$$P_{other} = ([\text{HONO}](j(\text{HONO}) + k_{\text{OH}+\text{HONO}}[\text{OH}])) - (k_{\text{OH}+\text{NO}}[\text{OH}][\text{NO}]) \quad (14)$$

749 where $k_{\text{OH}+\text{NO}} = 3.3 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Atkinson et al., 2004), $k_{\text{OH}+\text{HONO}} = 6 \times 10^{-12}$
 750 $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ (Atkinson et al., 2004) and $j(\text{HONO}) = 2 \times 10^{-3} \text{ s}^{-1}$ for average maximum
 751 measured concentrations of $1 \times 10^7 \text{ molecules cm}^{-3}$ for OH (Whalley et al., 2010), 5.41×10^7
 752 molecule cm^{-3} for NO (Whalley et al., 2010) and $1.23 \times 10^8 \text{ molecule cm}^{-3}$ for HONO (Whalley
 753 et al., 2010).

754 Using equation 14 this missing HONO production rate for Cape Verde was 34.6 ppt hr^{-1} , which
 755 is within a factor of two of the rate of HONO production (68 ppt hr^{-1}) calculated from nitrate
 756 photolysis using our experimental HONO production data for mixed nitrate/ TiO_2 aerosols.
 757 These results provide further evidence that particulate nitrate photolysis in the presence of
 758 photocatalytic compounds such as TiO_2 found in dust could be significant in closing the HONO
 759 budget for this environment (Whalley et al., 2010; Reed et al., 2017; Ye et al., 2017a).

760 **5 Conclusions.**

761 The experimental production of HONO from both illuminated TiO_2 aerosols in the presence of
 762 NO_2 and from mixed nitrate/ TiO_2 aerosols in the absence of NO_2 was observed, with the
 763 HONO concentrations measured using photo-fragmentation laser-induced fluorescence
 764 spectroscopy. Using experimental data, the reactive uptake of NO_2 onto the TiO_2 aerosol
 765 surface to produce HONO, $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$, was determined for NO_2 mixing ratios ranging from
 766 34 to 400 ppb, with a maximum $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$ value of $(1.26 \pm 0.17) \times 10^{-4}$ for single-component
 767 TiO_2 aerosols observed at 51 ppb NO_2 , and for a lamp photon flux of $(1.65 \pm 0.02) \times 10^{16}$
 768 $\text{photons cm}^{-2} \text{ s}^{-1}$ (integrated between 290 and 400 nm). The measured reactive uptake
 769 coefficient, $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$, showed an increase then subsequent decrease as a function of NO_2
 770 mixing ratio, peaking at 51 ± 5 ppb. Box modelling studies supported a mechanism involving
 771 two NO_2 molecules on the aerosol surface per HONO molecule generated, providing evidence
 772 for the formation of a surface-bound NO_2 dimer intermediate. The exact mechanism for HONO
 773 formation, for examples the step(s) which are accelerated in the presence of light, remains
 774 unclear, although previous studies would suggest the process occurs via the isomerisation of

775 the symmetric N_2O_4 dimer to give *trans*-ONO- NO_2 , either via *cis*-ONO- NO_2 or directly,
776 suggested to be more reactive with water than the symmetric dimer (Finlayson-Pitts et al.,
777 2003;Ramazan et al., 2004;Ramazan et al., 2006;de Jesus Madeiros and Pimentel, 2011;Liu
778 and Goddard, 2012;Murdachaw et al., 2013;Varner et al., 2014). Investigations into the RH
779 dependence of the HONO production mechanism on TiO_2 aerosols showed a peak in
780 production between ~25-30 % RH, with lower HONO production at higher NO_2 mixing ratios
781 observed for all RHs tested. The increase in HONO production with increasing RH can be
782 attributed to a higher concentration of H_2O on the surface increasing its availability for the
783 hydrolysis reaction to give HONO, whereas a decrease in HONO production after RH ~ 30 %
784 could be due to the increased water surface concentration inhibiting the adsorption of NO_2 .
785 Using the laboratory reactive uptake coefficient for HONO production, $\gamma_{NO_2 \rightarrow HONO}$, the rate of
786 production of HONO from illuminated aerosols in Beijing in summer for typical NO_2 mixing
787 ratios and aerosol surface areas was found to be similar to that estimated previously for the
788 production of HONO from urban humic acid aerosol surfaces in Europe.

789 In the absence of NO_2 , significant HONO production from 50:50 mixed nitrate/ TiO_2 aerosols
790 was measured. Using the experimental HONO concentrations observed, a rate of HONO
791 production from nitrate photolysis was calculated, which was then scaled to the ambient
792 conditions encountered at the Cape Verde Atmospheric Observatory in the tropical marine
793 boundary layer. A HONO production rate of 68 ppt hr^{-1} for the mixed nitrate/ TiO_2 aerosol was
794 found for CVAO conditions, similar in magnitude to the missing HONO production rate that
795 had been calculated previously in order to bring modelled HONO concentrations into line with
796 field-measured values at CVAO. These results provide further evidence that aerosol particulate
797 nitrate photolysis may be significant as a source of HONO, and hence NO_x , in the remote
798 marine boundary layer, where mixed aerosols containing nitrate and a photo-catalytic species
799 such as TiO_2 , as found in dust, are present.

800 However, the production of HONO from pure, deliquesced ammonium nitrate aerosols alone
801 could not be definitively confirmed over the range of conditions used in our experiments,
802 suggesting that another component within the aerosol is necessary for HONO production.
803 Future work should be directed towards studying pure nitrate aerosols over a wider range of
804 conditions, for example varying the aerosol pH, and also adding other chemical species into
805 the aerosol which may promote HONO production.
