**Abstract.** The cloud albedo at the subtropical marine subtropical stratocumulus regions has a key role in regulating the regional energy budget. Based on 12 years of monthly data from multiple satellite datasets, the long-term, monthly and seasonal cycle averaged cloud albedo at five stratocumulus regions were investigated to inter-compare the atmosphere-only simulations of Phase 5 and 6 of the Coupled Model Inter-comparison Project (AMIP5 and AMIP6). Statistical results showed that the long-term regressed cloud albedos were underestimated in most AMIP6 models compared with the satellite-driven cloud albedos, and the AMIP6 models produced a similar spread of AMIP5 at all regions. The monthly mean and seasonal cycle of cloud albedo of AMIP6 ensemble mean showed better correlation with the satellite-driven observation than that of AMIP5 ensemble mean, however, fail to reproduce the values and amplitude in some regions. By employing the Modern-Era Retrospective Analysis for Research and Applications Version 2 data, this study estimated the relative contributions of different aerosols and meteorological factors on the marine stratocumulus cloud albedo under different cloud liquid water path (LWP) conditions. The multiple regression models can explain ~60 % of the changes in the cloud albedo. Under the monthly mean  $LWP \leq 60 \text{ g m}^{-2}$ , dust and black carbon dominantly contributed to the changes in the cloud albedo, while sulfate aerosol contributed the most under the condition of  $60 \text{ g m}^{-2} < LWP \leq 120 \text{ g m}^{-2}$ . These results suggest that the parameterization of cloud-aerosol interactions is critical for accurately simulating the cloud albedo in models.

## 25 **1 Introduction**

One of the critical parameters in regulating the distribution of solar radiation in the atmosphere and surface is cloud albedo that is the proportion of incoming solar radiation reflected by clouds (Mueller et al., 2011; Wall et al., 2018). A change in the cloud albedo over low-level clouds can cause a significant alteration in the planetary albedo (Engström et al., 2014) and even could offset the warming caused by doubled carbon dioxide (Latham et al., 2008). Recent studies employing the cloud-system-resolving and plume models have shown that changes in the cloud albedo are largely dependent on aerosol and meteorological conditions (Wang et al., 2011; Stuart et al., 2013; Kravitz et al., 2014). However, there are still non-neglectable uncertainties in simulations (Bender et al., 2016).

This study specifically focused on the cloud albedo in the subtropical marine stratocumulus regions as it is particularly difficult to reproduce the cloud properties by numerical models (Eyring et al., 2016), which results in a larger uncertainty in energy budget simulations and climate predictions (Wood, 2012). The subtropical marine stratocumulus regions are mainly covered by low-level clouds that usually reflect most of the solar radiation and significantly contribute to the planetary albedo (Seethala et al., 2015). In addition, the contribution of the cloud albedo to planetary albedo over these dark oceans could be tremendous compared with those of snow/ice-covered regions with a high surface albedo (Mueller et al., 2011). However, it is a challenge to accurately estimate the cloud albedo in regions where there are different types of clouds for evaluating the cloud albedo resulted from the relationship between the planetary albedo and cloud fractions at a monthly scale (Bender et al., 2011; Bender et al., 2019).

To date, climate models have continuously advanced in main physical processes, model structures and initial conditions to improve the capability to reproduce numerous observed climate events (Van Weverberg et al., 2017). Many studies have paid attention to understand the cloud albedo and its controlling factors over the subtropical marine stratocumulus regions for reducing the uncertainty in models' outputs (Latham et al., 2008; Wood, 2012; Engström et al., 2014; Bender et al., 2019). The cloud albedos obtained from regressing satellite observations at five typical subtropical marine stratocumulus regions exhibited distinct characteristics, ranging from 0.32 to 0.39, and noticeable diurnal variations (Bender et al., 2011; Engström et al., 2014), which may be induced by respective aerosols and meteorological conditions at each region. For example, the southeast Atlantic stratocumulus region (Namibian) is a typical region with massive biomass burning aerosols loading (Wilcox, 2010) while a dominant aerosol loading type in the Canarian region is dust (Waquet et al., 2013). As the value of cloud albedo is usually determined by the cloud optical thickness (COT) and the solar zenith angle (Wood, 2012), the main factors (i.e., the cloud droplets number and sizes) controlling the COT may affect changes in the cloud albedo (George and Wood, 2010; Bender et al., 2016). Since the cloud droplets amount and the droplets sizes are affected by cloud condensation nuclei (CCN), it is crucial to understand the interactions in key dynamical and microphysical processes controlling CCN with regard to improving the model capacity to simulate the cloud albedo (Bender et al., 2016; Rosenfeld et al., 2019).

Regarding the microphysical processes, the aerosol-cloud-radiation interactions over the subtropical marine stratocumulus regions have been actively examined in previous studies (Twomey, 1974, 1977; Wang et al., 2011; Bender et al., 2016, 2019). Among them, some studies have demonstrated the effect of aerosols on the marine stratocumulus cloud albedo (Twomey effect). In other words, an increase in aerosols can result in smaller droplet sizes and more droplets, leading to a higher cloud albedo (Twomey, 1974, 1977). However, the cloud-aerosol interactions are complex and varying with aerosol types due to their different effects on clouds. Unfortunately, the Intergovernmental Panel on Climate Change currently lacks confidence in estimating the global aerosol indirect effects (Boucher et al., 2013). Furthermore, the semi-direct effects of absorbing aerosols (e.g., black carbon) are also difficult to be quantified by numerical models (Herbert et al., 2020). Given different model experiments from the Coupled Model Intercomparison Project phase 5 (CMIP5), Frey et al. (2017) estimated the impact of anthropogenic sulfate and non-sulfate aerosol forcing on changing the cloud albedo and concluded that

absorbing aerosols play a key role in offsetting the cloud brightening at a certain degree. Regarding the dynamical processes, previous studies found that the dynamical factors (e.g., vertical velocity or instability) can influence the vapor supersaturation, leading to the activation of CCN (Twomey, 1959; Lu et al., 2012; Rosenfeld et al., 2019). Besides, the free-  
70 troposphere relative humidity is also considered as a critical factor in regulating the cloud albedo, because it is closely related to the cloud-top entrainment/drying process that influences the cloud albedo effect (Betts and Ridgway, 1989).

However, most of these studies are based on rapid cloud adjustment to study the effects of specific meteorological factors, or aerosol-cloud interactions over the marine subtropical stratocumulus regions. Few systematic studies focus on the effects of meteorological factors and various aerosol types on the cloud albedo and changes at the monthly scale. Furthermore, it is  
75 also crucial to evaluate the performance of current climate models to accurately project the cloud albedo responses to climate change. By the intercomparison of outputs between CMIP3 and CMIP5, Engström et al. (2014) found that the regressed regional averaged cloud albedo and intermodal spread of CMIP5 in the subtropical marine stratocumulus regions are more comparable with the satellite observations compared with those of CMIP3. Given the release of up-to-date CMIP6, as in the previous study, it is necessary to systematically evaluate the performance of CMIP5 and CMIP6 in reproducing the cloud  
80 albedo for understanding advances in the skill of climate models to resolve long-standing problems in the marine stratocumulus regions. Based on multiple satellite datasets, this study evaluated the performance of ten CMIP5/AMIP and twenty-eight CMIP6/AMIP outputs. As an essential part of CMIP experiments, the AMIP outputs forced by observed sea surface temperatures and sea ice concentrations (Eyring et al., 2016) were used in the study. By employing the reanalysis data, this study quantitatively estimated the contributions of each factor to the marine stratocumulus cloud albedo to identify  
85 main factors dominating the long-term variations of the marine stratocumulus cloud albedo. This study will provide useful information for comprehensively understanding the impacts of different aerosol types and meteorological factors on cloud albedo changes.

The article is organized as follows. The datasets and methods are given in section 2. The comparison of performances between CMIP5 and CMIP6 is presented in Section 3.2. The impacts of different aerosol types and meteorological factors on  
90 the cloud albedo are described in Section 3.2. Lastly, section 4 addresses the conclusions and discussion.

## 2 Datasets and Method

This study compiled multiple satellite datasets, 10 CMIP5/AMIP outputs, 28 CMIP6/AMIP outputs and reanalysis data not only to evaluate the performance of CMIP5 and CMIP6 outputs but also to investigate the variations of the cloud albedo over the typical subtropical marine stratocumulus regions. Since spatial resolutions vary with climate models, all data were  
95 interpolated to a  $1.0^\circ \times 1.0^\circ$  spatial resolution and monthly temporal resolution for fairly evaluating and intercomparing the performance. The following sections address more details on the satellite datasets, CMIP5, CMIP6, and reanalysis data.

## 2.1 CERES and MODIS

Estimating the cloud albedo is required multiple atmospheric variables such as the top-of-atmosphere (TOA) downward, upward (all-sky) shortwave fluxes, cloud liquid water path (LWP) and cloud fractions. In this study, the TOA downward and upward shortwave fluxes were obtained from the Clouds and the Earth's Radiant Energy System (CERES, Wielicki et al., 1996) Single Scanner Footprint (SSF) monthly Ed4A datasets. The LWP and cloud fractions were also obtained from the Moderate Resolution Imaging Spectro-Radiometer (MODIS; Platnick et al., 2003) collection 6.1 level 3 monthly products during the period from 2003 to 2014, i.e., MODIS MYD08\_M3 (Aqua) and MOD08\_M3 (Terra) products, respectively. The spatial resolutions of these products are  $1.0^\circ \times 1.0^\circ$ . The CERES TOA shortwave fluxes were converted from broadband (0.2-5.0 $\mu\text{m}$ ) radiances by applying empirical angular distribution models to correct the instrument's incomplete spectral response (Loeb et al., 2001). Then, the real-time fluxes were aggregated to produce 24-hour mean fluxes from empirical diurnal albedo models that create meteorology conditions at the over-flight time (Loeb et al., 2018). In addition, the cloud fraction, a fraction of MODIS cloudy pixels to the total pixels at each grid box, is determined based on daytime scenes entirely and represents all cloud phases (Platnick et al., 2003). As the CERES and MODIS instruments are both carried onboard Aqua (cross the equator time: 1130) and Terra (pass the equator time: 1030) satellites in polar orbits, we averaged the Aqua and Terra products to obtain the observed combined all-sky albedo, cloud fraction, LWP and cloud albedo as in the works of the Engström et al. (2015) and Bender et al. (2017).

## 2.2 CMIP5/AMIP and CMIP6/AMIP

The outputs of 10 CMIP5/AMIP and 28 CMIP6/AMIP include all variables necessary to estimate the cloud albedo, i.e., monthly mean TOA downward, upward (all-sky) fluxes and total cloud fractions (Taylor et al., 2012; Eyring et al., 2016). This study identified ten climate models that provide both CMIP5 and CMIP6 outputs and implemented the intercomparison of performance for the regressed cloud albedo during the period from 2003 to 2008. Furthermore, this study evaluated the cloud albedo for twenty-eight CMIP6/AMIP outputs during the period from 2003 to 2014. Tables 1-2 show the characteristics of CMIP5 and CMIP6 models. Note that there is a considerable discrepancy in the total cloud fractions between the CMIP models and MODIS observations, which is caused by different definitions, cloud overlap algorithms and different threshold assumptions for cloud formation (Engström et al., 2015). Moreover, the total cloud fractions in the climate models are usually calculated based on daytime and nighttime cloud fractions while only daytime cloud fractions are considered to evaluate the observed cloud fractions. As used in Engström et al. (2015), this study also employed the total cloud fractions as there are no available MODIS simulator outputs for CMIP6.

## 2.3 MERRA-2

The study employed the Modern-Era Retrospective Analysis for Research and Applications Version 2 (MERRA-2) which provides a long-term aerosol and atmospheric reanalysis record (1980-present) at  $0.625^\circ \times 0.5^\circ$  resolution based on the

Goddard Earth Observing System Model, version 5.12.4 (Gelaro et al., 2017). The aerosol reanalysis has been produced by a global data assimilation system that combines satellite- and ground-based observed aerosols with meteorological conditions. Here, the mass mixing ratios of different aerosol types and air density at different levels from 3-hourly aerosol product (inst3\_3d\_aer\_Nv) and meteorological data from monthly atmosphere product (instM\_3d\_asm\_Np) are collected to represent the monthly regional aerosol and meteorological conditions. The outputs of MERRA-2 reanalysis were used during the common period from 2003 to 2014 with satellite observations record. As selected in McCoy et al. (2017) and Li et al. (2018), the impacts of different aerosol types on marine stratocumulus cloud albedo were evaluated based on the mass concentrations of hydrophilic black carbon (BC), hydrophilic organic carbon (OC), sulfate aerosol (SO<sub>4</sub>), sulfur dioxide (SO<sub>2</sub>), the smallest particles dust (DU, i.e., 0.1-1 μm size) and sea salt (SS, 0.03-0.1 μm size) at the 910hPa level. Furthermore, this study employed the relative humidity at 850hPa (RH850) and vertical velocity at 900hPa (omega900) factors to investigate the meteorological effects on the cloud albedo.

## 2.4 Methods

The planetary albedo ( $\alpha$ ) can be calculated mainly from the cloud fraction  $f$  (Bender et al., 2011) as expressed in Eq. (1):

$$\alpha = \alpha_{cloud}f + \alpha_{clear}(1-f) \quad (1)$$

where,  $\alpha_{cloud}$  and  $\alpha_{clear}$  denote the albedo under cloudy-sky and clear-sky conditions, respectively. For a given region where the cloud and surface type are homogeneous (i.e., constant  $\alpha_{cloud}$  and  $\alpha_{clear}$ ), namely, a change in  $\alpha$  should be driven by a change in the cloud fraction  $f$ . The cloud albedo can be estimated by the derivative of Eq. (1) as in Eq. (2):

$$\alpha_{cloud} = d\alpha / df + \alpha_{clear} \quad (2)$$

The invariable  $\alpha_{cloud}$  and  $\alpha_{clear}$  should be applied for the same cloud type and ocean region. In this light, as the works in Klein and Hartmann (1993), this study also analyzed for only five marine stratocumulus regions: Peruvian (10°S–20°S, 80°W–90°W; A1), Namibian (10°S–20°S, 0°E–10°E; A2), Californian (20°N–30°N, 120°W–130°W; A3), Australian (25°S–35°S, 95°E–105°E; A4) and Canarian (15°N–25°N, 25°W–35°W; A5). Previous study (Engström et al., 2014) has also demonstrated that there is a near-linear relationship between cloud cover and planetary albedo in these regions. Fig. 1 illustrates the locations of above stratocumulus regions and the near-global distribution of combined planetary albedo averaged from Aqua and Terra during the common period from 2003 to 2014.

In the study, the annual mean analyses are implemented with deseasonalized monthly mean data processed by removing a mean seasonal cycle and then adding the monthly mean value.

The selection of variables is a crucial step to build a multiple linear regression model for the monthly cloud albedo as a function of meteorological factors and aerosol types under two different LWP scenarios ( $LWP < 60 \text{ g m}^{-2}$  and  $60 \text{ g m}^{-2} < LWP < 120 \text{ g m}^{-2}$ ). This study selected suitable variables based on correlation analysis. If the correlation between the cloud albedo and a candidate is significant at a 90% confidence level, the variable was considered as a predictor factor.

Furthermore, the partial least squares were used to reduce the collinearity between the selected variables (McCoy et al.,  
160 2017). The regression model of cloud albedo  $\alpha_{cloud}$  as follow:

$$\alpha_{cloud} = \sum_{i=1}^I a_i M_i + \sum_{j=1}^J b_j \log_{10} A_j + c \quad (3)$$

where  $a$  and  $b$  are regression coefficients,  $c$  is a constant term,  $M_i$  represents the  $i$ th meteorological predictor,  $I$  is the number of meteorological predictor variables,  $A_j$  is the  $j$ th aerosols predictor, and  $J$  is the number of aerosol predictor variables.

The relative contributions of each predictor to the change in the cloud albedo (Huang and Yi, 1991) were evaluated using Eq.  
165 (4):

$$R_j = \frac{1}{m} \sum_{i=1}^m [T_{ij}^2 / (\sum_{j=1}^a T_{ij}^2)] \quad (4)$$

where  $m$  is the number of the monthly samples,  $a$  is the number of predictors, and  $T_{ij}$  is the product of the regression coefficients of each term ( $b_j$ ) and predictor variables ( $x_{ij}$ ).

After removing the effect of meteorological factors, we further investigated the pure relationship between aerosols and the  
170 cloud albedo using the partial correlations between  $\alpha_{cloud}$  and  $\log_{10} A$ , as expressed in Eq. (5):

$$r_{\alpha_{cloud} \log_{10} A \cdot M} = \frac{r_{\alpha_{cloud} \cdot \log_{10} A} - r_{\alpha_{cloud} \cdot M} r_{\log_{10} A \cdot M}}{\sqrt{1 - r_{\alpha_{cloud} \cdot M}^2} \sqrt{1 - r_{\log_{10} A \cdot M}^2}} \quad (5)$$

where  $r_{\alpha_{cloud} \cdot \log_{10} A}$ ,  $r_{\alpha_{cloud} \cdot M}$  and  $r_{\log_{10} A \cdot M}$  is the total correlation between each variable pair and  $r_{\alpha_{cloud} \log_{10} A \cdot M}$  is the correlation between  $\alpha_{cloud}$  and  $\log_{10} A$  which eliminates the effects of meteorological factors  $M$ . More details on the partial correlation are described in Jiang et al. (2018) and Engström and Ekman (2010).

## 175 3 Results

### 3.1 Satellite observations and CMIP5/6 simulations

The first two columns in Fig. 2 (from a to e) show the estimated long-term mean cloud albedo corresponding to the correlation between planetary albedo and cloud fraction over the five regions from the observation and 22 AMIP5/6 models, including 10 individual models and an ensemble mean for AMIP5 and AMIP6 (represented by AMIP5-MEM and AMIP6-MEM), during the period from 2003 to 2008. For the combined satellite observations, the correlation coefficient values are  
180 above 0.85 in all regions. The correlation over the Peruvian region was the largest (~0.95), while a relatively weak correlation (~0.88) appeared in the Canarian region. Such a high correlation between planetary albedo and cloud fraction further indicates the homogeneity of cloud and surface types over these regions. The regressed cloud albedo from the satellite ranged from 0.30 to 0.42 for the five stratocumulus regions, which is consistent with previous studies (Bender et al.,  
185 2011; Engström et al., 2014). As the values averaged over Aqua and Terra albedos and cloud fractions were used as the observation in this study, the regressed cloud albedo values need to be within the range of the Aqua and Terra (Engström et al., 2014). Regarding the AMIP5 and AMIP6 models, a higher correlation (> 0.8) appeared for most models at the five regions, especially higher at the Australian and Canarian regions. At the Peruvian, Namibian and Californian regions, the

190 correlations of the observation were relatively higher than those of most climate models while the observed correlation was approximately close to the median value of model simulations at the Australian and Canarian regions.

The correlation coefficients of the AMIP6 models between planetary albedo and cloud fraction showed a lower value than those of the AMIP5, indicating that the linear relationship between cloud fraction and planetary albedo in the AMIP6 models' simulations is not superior to that of AMIP5. While the AMIP6 simulations displayed a similar spread in the estimated cloud albedo for all regions, some AMIP6 models produced a lower correlation coefficient than those of the

195 AMIP5 models (e.g., AMIP6/INM-CM4-8). Notably, the AMIP5-MEM and AMIP6-MEM always produced a worse correlation relationship and more irrational cloud albedo values, indicating that the AMIP5/AMIP6 models have a lack of skill in simulating cloud properties over the marine stratocumulus regions. Note that the performance of NorESM2-LM is superior to that of the previous version of the model (NorESM1-M) by improving the cloud physical parameterization, e.g., the stratiform cloud parameterization that causes underestimation of the cloud fraction and overestimation of the cloud liquid

200 water in NorESM1-M (Seland et al., 2020). This advance in NorESM2-LM may induce the more reasonable representation of the cloud albedo in the stratocumulus regions. Kawai et al. (2020) also concluded that the MRI-ESM2 employed a new stratocumulus scheme to improve the representation of low clouds from the previous version of the model (MRI-CGCM3). However, the cloud albedo simulated from MRI-ESM2 showed a significant improvement only in the Canarian region compared with that of the MRI-CGCM3 simulation.

205 The third and fourth columns in Fig. 2 (from f to j) also shows the estimated long-term mean cloud albedo and the correlation between planetary albedo and cloud fraction over the five regions for the observation and 29 AMIP6 models during 2003 to 2014. The simulated correlation exhibited a larger spread at the Peruvian and Namibian regions than those at other regions, indicating that the AMIP6 models have a lack of capacity to capture the linear relationship between planetary albedo and cloud fraction. The cloud albedos were underestimated in most CMIP6/AMIP models compared with the

210 satellite-based cloud albedos. The Australian (0.30-0.43) and Canarian (0.24-0.42) regions displayed a larger inter-model variability in the cloud albedo than other regions due to a poor skill in simulating the cloud properties (e.g., LWP and COT). Over the Canarian regions, the correlation and cloud albedo of AMIP6-MEM showed good agreement with those of the satellite observation compared with those of the individual AMIP6 models, resulting from the offsetting effect between models.

215 The ACCESS-ESM1-5 and CAMS-CSM1-0 models produce a higher correlation coefficient and more accurate cloud albedo at the Peruvian region. The MPI-ESM1-2-HR, NorESM2-LM, CESM2-FV2 and IPSL-CM6A-LR models simulated the correlation and the cloud albedo comparable to the observations at the Namibian, Californian, Australian and Canarian regions, respectively. In contrast, the EC-Earth3, FGOALS-f3-L, FGOALS-f3-L, INM-CM5-0 and CESM2 models simulated the worst results at the Peruvian, Namibian, Californian, Australian and Canarian regions, respectively. Overall,

220 the AMIP6 models reproduced the cloud albedo and correlation well at the Australian region while a higher uncertainty in model's simulations, i.e., a larger intermodal spread, at the Peruvian region (Engström et al., 2014).

Engström et al. (2014) also found that CMIP5 models simulating a higher cloud cover have a tendency to produce a smaller cloud albedo value. Darker clouds can offset the contribution of the higher cloud cover to the planetary albedo, resulting in relatively a consistent model-driven planetary albedo. This is a presentation of the "too few, too bright" problem that persists in GCMs (Nam et al., 2012). To validate whether or not this problem has been improved in the AMIP6 models, we compared the relationship between regressed cloud albedo and cloud fraction (See Fig. S1). The correlations driven by the 28 AMIP6 models were -0.28, 0.19, -0.11, -0.71 and 0.43 for the Peruvian, Namibian, Californian, Australian and Canarian regions, respectively. Compared with the results from the CMIP5 models (Engström et al., 2014), noticeable progress was found at the Namibian and Californian regions while a high negative correlation was simulated at the Australian region, indicating that the new generation models need to be further improved to resolve the longstanding problem.

The monthly cloud albedo time series regressed from the satellite, MEM and AMIP6-MEM for the six-year period from 2003 to 2008 over the five regions are shown in Fig. 3(a-e). The temporal correlations (R5/R6) and corresponding confidence value (P5/P6) between simulated (AMIP5-MEM/AMIP6-MEM) and satellite regressed monthly cloud albedo time series are also given in Fig. 3(a-e). Note that the smoothed time series were produced by 12-month smoothing. The statistical results showed that the R5/R6 values were 0.62/0.78, 0.44/0.55, 0.38/0.45, 0.75/0.74 and 0.00/0.05 for the Peruvian, Namibian, Californian, Australian and Canarian regions, respectively. Among them, the correlations only at the Canarian region were insignificant (i.e., P5/P6=1.00/0.70). A high positive correlation appeared at the Australian region (>0.70), indicating that the changes in the cloud albedo are well captured by the models. Compared with AMIP5-MEM, the regressed monthly cloud albedo of AMIP6-MEM showed a better correlation with the satellite regressed values, while poor performance in reproducing the monthly cloud albedo values and amplitude (the difference between the maximum and minimum values of cloud albedo) at the Peruvian and Namibian regions. Furthermore, the monthly cloud albedos obtained from the satellite and models displayed obvious seasonal cycle at all regions except for the Canarian region. This may be related to the fact that a weaker linear relationship between monthly cloud cover and planetary albedo may exist at the Canarian region, resulting in a significant change in the estimated cloud albedo (see Fig. S2). Overall, the performance of AMIP5-MEM in reproducing monthly cloud albedo and amplitude was better than that of AMIP6-MEM.

The monthly cloud albedo time series for the satellite and AMIP6-MEM for the period from 2003 to 2014 in the five regions are shown in Fig. 3(f-j). The cloud albedos driven by the satellite and model at the Peruvian region ranged from 0.35 to 0.45 and from 0.25 to 0.38, respectively (Fig. 3f). The monthly cloud albedo values of AMIP6-MEM were significantly underestimated compared with those at other regions. In contrast, the monthly cloud albedos of the models showed good agreement with the satellite-based observation at the Namibian and Australian regions, which means that AMIP6-MEM captures the observed seasonal cycle of the cloud albedo well. However, the amplitudes of the cloud albedo simulated from the model were larger than that of the satellite at the Peruvian, Namibian and Californian regions while smaller at the Australian and Canarian regions. Note that at the Australian region, the monthly cloud albedo exhibited a large variation than that at other regions based on the satellite-based observation, which means that the cloud optical properties (e.g., COT and cloud effective radius) have been considerably changed within the Australian region.

This study further assessed the performance of the AMIP6 models in reproducing the cloud albedo time series. Figs. 4a-e provide the Taylor diagrams (Taylor, 2001) for the five regions, which include the correlation coefficients, the centered root mean square error (RMSE, the green circle), and the standard deviation value between individual AMIP6 models and the satellite-based observations. The centered RMSE and the standard deviation values represent the model's ability to reproduce the phase and amplitude of the variable, respectively. Correlation coefficients greatly varied with regions, ranging from negative (Peruvian, Namibian and Canarian) and positive values. Compared with other regions, most of the models showed a high positive correlation ( $>0.6$ ) at the Peruvian region while the monthly cloud albedos simulated from the six GCMs (FGOALS-g3, FGOALS-f3-L, INM-CM-4-8, INM-CM5-0, MIROC6 and GISS-E2-1-G) showed a negative correlation with the observation. The model-driven cloud albedo was most poorly correlated with the observation at the Canarian region, e.g.,  $< 0.4$  or negative values. On the contrary, at the Australia region, all models showed a significant positive correlation ( $> 0.4$ ). The standard deviation values of the models at the Peruvian, Namibian and California ranged 0.02-0.09, 0.02-0.11 and 0.03-0.10, respectively while 0.03 for the satellite-based observation. This result indicates that most of the models overestimate the amplitude of the cloud albedo time series at the regions. Some models produced the standard deviation values of cloud albedos three times larger than the observation. It is evident that the standard deviation values of the cloud albedo at the Australian regions are a narrower spread than that of other regions, indicating that the AMIP6 models also perform well in simulating the amplitude of the monthly cloud albedo time series at this region. Overall, the intermodal variability in the correlation coefficient, RMSE and standard deviation values was smallest at the Australian region while the largest at the Peruvian region. Among all the models, the ACCESS-ESM1-5 model outperformed other models at all regions. In contrast, the FGOALS-g3-L and INM-CM5-0 models performed poorly in reproducing the monthly cloud albedo in most regions. These results may be induced by models' capacity in reproducing the linear relationship between cloud cover and planetary albedo for these regions (See Fig. S3).

Further, Figure 5 shows the annual cycles of the cloud albedo estimated by the satellite and AMIP5/AMIP6 models for the five regions. The seasonal variation in the cloud albedo at each region takes a shape of single peak distribution. In terms of similarity among regions, the cloud albedo at all regions reached the maximum value during the boreal winter season, i.e., December to January in the Northern Hemisphere while June to July in the Southern Hemisphere. Many previous studies (Lin et al., 2009; Wood, 2012; Dong et al., 2014) have demonstrated that the seasonal variations of marine cloud properties (e.g., cloud fraction, LWP and cloud thickness) are strongly affected by meteorological conditions. Employing a 19-month record of ground-based lidar/radar observations from the Atmospheric Radiation Measurement Program Azores site, for example, Dong et al. (2014) found that the seasonal variations of cloud thickness and LWP are closely related to the seasonal synoptic patterns (e.g., transport of water vapor, relative humidity, high/low pressure system). Furthermore, the influence of aerosols loading is non-neglectable. While the aerosols act as CCN, the concentration of CCN can significantly influence the cloud albedo of low clouds (Twomey, 1974). On the other hand, absorbing aerosols near stratocumulus may enhance absorbing solar energy, resulting in an influence on the dynamical evolution of stratocumulus causing a change in the cloud albedo (Wilcox, 2010). The seasonal cycle of the cloud albedo at the Australia region showed the largest amplitude among

290 the five regions (ranging from 0.37 to 0.52) while the amplitudes at other regions were less than 0.10. Such a result means that the meteorological conditions and aerosol loadings of the cloud system at the Australian region have a relatively larger seasonal variation compared with those at other regions.

The COT usually increases with an increase in cloud LWP, resulting in an increase in the cloud albedo (Wood, 2012). Gryspeerd et al. (2019) also concluded that LWP is the main factor controlling liquid cloud albedo. Thus, this study  
295 investigated the seasonal variation of LWP and found that the change in LWP is strongly correlated with the change in cloud albedo at the Peruvian, Australian and Canarian regions (see Fig. S4). For the Namibian region, however, many studies have shown that the continuous transportation of absorbing biomass burning aerosols from Africa to the region during the African biomass burning season from August to October (Das et al., 2017) can reside above the clouds, resulting in an increase in the cloud albedo by thickening the stratocumulus (Wilcox, 2010, 2012). Zuidema et al. (2018) also found that the biomass  
300 burning aerosols generally exist in the boundary layer at the earlier time of the biomass burning seasons and are mainly located at above the clouds in September to October, which is caused by the northwestward transportation of the biomass burning aerosols from the African continent. However, Fig. 5b shows that the peak of the cloud albedo occurred in July and then continuously decreased from August to October at the Namibian, indicating that the changes in the cloud albedo are difficult to be explained by the negative semi-direct effect of the biomass burning aerosols. This result is consistent with the  
305 work of Bender et al. (2016) which concluded that the direct effect and positive semi-direct effect are the main aerosol effects (Wilcox, 2012). That is, clouds become darker under a polluted environment. Regarding the seasonal cycles of cloud droplet number concentration ( $N_d$ , Li et al., 2018), we found that the seasonal cycles of the cloud albedo at the Namibian region were highly correlated with those of  $N_d$  obtained from The Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO), whereas the seasonal cycles of  $N_d$  and the cloud albedo showed opposite seasonal changes to each  
310 other at the California region. The relationship between the  $N_d$  and the cloud albedo varies with different regions, which may be caused by excluding the effect of meteorological conditions. These results indicate that it is a challenge to study the variability in the cloud albedo over the marine stratocumulus regions under various meteorological and aerosol conditions.

Fig. 5(a-e) shows the seasonal cycles of cloud albedo at the five regions during a period from 2003 to 2008 for the AMIP5/AMIP6 and the satellite-based observation. Shading areas in Fig. 5 represent the range of the cloud albedo simulated  
315 by the 22 models. The R5/R6 and P5/P6 values for the seasonal cycles of the cloud albedo obtained from the models and the satellite-based observation are also given in Fig. 5. For the AMIP5-MEM and AMIP6-MEM, the correlations of the cloud albedo seasonal cycles between the models and the observation are highly positive at all regions ( $R5/R6 > 0.6$ ), except for the Canarian region ( $R5/R6 = 0.22/0.53$ ). The R values were the largest at the Namibian ( $R5/R6 = 0.82/0.92$ ) and Australian regions ( $R5/R6 = 0.93/0.92$ ). Overall, the results of AMIP6 were slightly superior to those of AMIP5, especially at the  
320 Canarian region. However, the seasonal cycles of cloud albedo estimated from the AMIP6-MEM at the Canarian region for 12 years from 2003 to 2014 (Fig. 5j) exhibited a significant negative correlation with that of the satellite-based observation, indicating AMIP6-MEM has a lack of skill to capture the seasonal cycle of the cloud albedo at this region. On the contrary, AMIP6-MEM showed a good agreement with the satellite-based observation at the Australian region (Fig. 5i,  $R = 0.93$ ),

indicating a good skill to reproduce the seasonal cloud albedo at this region. Although the correlation coefficient value at the  
325 Peruvian region was the highest ( $R=0.95$ ), AMIP6-MEM systematically underestimated the monthly cloud albedo values.

### 3.2 The impacts of different aerosol types and meteorological factors on cloud albedo changes

Cloud liquid water may affect the COT, which is subsequently influencing the cloud albedo (Wood, 2012). Bender et al.  
(2016) found that for constant cloud fraction, the LWP dominates the change in the cloud albedo. Furthermore, the change of  
330 LWP also may influence the relationship between aerosols and cloud properties (Robert et al., 2008; Gryspeerd et al., 2019;  
Douglas and L'Ecuyer, 2019). For example, the effect of aerosols on the cloud albedo may be weakened by a change in the  
LWP (Han et al., 2002; Twohy, 2005). Given various LWP ranges, this study evaluated the impact of meteorological  
parameters and aerosol types on the cloud albedo to evaluate the influence of LWP on the cloud albedo. Firstly, the 720  
monthly sample data obtained from the five regions were divided into two groups based on the range of monthly mean LWP  
335 values:  $LWP \leq 60 \text{ g m}^{-2}$  and  $60 \text{ g m}^{-2} < LWP \leq 120 \text{ g m}^{-2}$ .

Figure 6a-b shows the regression coefficients in the partial correlation calculation and the relative contributions for  
individual variables related to cloud albedo changes under different LWP conditions. The units of vertical velocity and  
aerosol mass concentrations are  $\text{Pa s}^{-1}$  and  $\text{kg m}^{-3}$ , respectively. Normalized variables were incorporated into the regression  
models. There is a considerable discrepancy in the results between the two groups. For the lower LWP bin (i.e.,  $LWP \leq 60 \text{ g}$   
340  $\text{m}^{-2}$ ), the results showed that the regression coefficient related BC to the cloud albedo was positive while DU and OC-related  
coefficients were negative, which indicates that the cloud albedo increase with increasing BC and decrease with increasing  
DU/OC. Fig. 6b also clearly shows that DU and BC have a larger contribution to the change in the cloud albedo compared  
with other predictors, e.g.,  $\omega_{900}$  and RH850. Under  $LWP > 60 \text{ g m}^{-2}$ , the contribution of  $\text{SO}_4$  to the cloud albedo was  
the largest. In addition, DU,  $\text{SO}_2$ , BC and RH850 also considerably contributed to the cloud albedo.

345 In addition to the effects of LWP, the difference in the relative contribution may be induced by the regional variability in  
aerosol types. A smaller LWP mainly appeared at the Namibian and Canarian where the main aerosol types are DU and BC,  
while lower BC loadings were found at the regions with a larger LWP (Fig. S5). While the positive coefficient for BC  
reflects the indirect effect of aerosols on the cloud albedo, the negative dependency of BC may represent the direct and semi-  
direct effects of absorbing aerosols (Johnson et al., 2004; Bender et al., 2016). For example, Johnson et al. (2004) found that  
350 absorbing aerosols in clouds can make the clouds warmer and thinner, resulting in a decrease in cloud albedo. Besides,  
McCoy et al. (2018) found a negative dependence of  $N_d$  on BC at regions with low BC loadings. This means that a decrease  
in the cloud albedo may be associated with a decrease in  $N_d$ . The dependence of  $N_d$  on OC has been also investigated in  
previous studies (McCoy et al., 2018; Li et al., 2018) and a negative dependence of  $N_d$  on OC has been found in some marine  
regions. The negative sensitivities of OC to the cloud albedo may attribute to a decrease of  $N_d$  with an increase of OC.

355 Dust is a crucial predictor of the cloud albedo and the coefficient of DU was negative for the two datasets divided in this  
study, which may be induced by the semi-direct effects of absorbing aerosols. In literature, many studies have examined the  
impacts of dust aerosols on stratocumulus (Doherty and Evan, 2014; Amiri-Farahani et al., 2017). For example, Karydis et al.  
(2011) showed that aged dust reduces  $N_d$  by consuming the supersaturation of clouds. Pradelle et al. (2002) employing  
satellite observations also investigated the effect of Saharan dust on marine stratocumulus clouds and found that minimum  
360 cloud albedo values appeared in regions with the most dust particles. They also found that the dust in a stratiform cloud may  
decrease the initial CCN and increase the effective droplet radius, which causes reducing the cloud albedo (Pradelle and  
Cautenet 2002). McCoy et al. (2017) estimated the indirect effect of aerosol from satellite observations and reanalysis data  
and found that the dust has a limited impact on  $N_d$  in different stratocumulus regions. A significant influence of dust on the  
cloud albedo in this study may be driven by the collected samples at the five regions where the cloud albedo and dust highly  
365 vary with the regions.

Under  $LWP \leq 60 \text{ g m}^{-2}$ , the coefficient of SS was a small positive value while the correlation coefficient of sea salt was  
insignificant under  $LWP > 60 \text{ g m}^{-2}$ , which means that these variables are not suitable as a predictor for estimating the cloud  
albedo. This is consistent with the results of McCoy et al. (2017; 2018) showing that  $N_d$  is weakly dependent on the SS  
although sea salt is an effective CCN. McCoy et al. (2018) have also validated the influence of SS on  $N_d$  with up-to-date  
370 observations. As submicron SS in the MERRA-2 reanalysis data can be simply predicted from wind speed and SST by a  
parameterization (Jaeglé et al., 2011; McCoy et al., 2018; Li et al., 2018), the effect of SS on the cloud albedo may be  
dependent on the relationship between the cloud albedo and near-surface wind speed, which may explain the limited effect  
of SS on the cloud albedo.

The previous studies (e.g., McCoy et al., 2017; Li et al., 2018) showed that  $SO_4$  plays a key role in modulating  $N_d$ . Although  
375 their results showed significant positive coefficients of  $SO_4$  with  $N_d$ , this study found an unexpected negative correlation of  
 $SO_4$  with the cloud albedo. Such a result may be driven by the fact that the sulfate aerosol particles and dust are externally  
mixed. The previous studies showed that sulfate-covered dust can act as CCN, which may induce a decrease in the cloud  
albedo by enhancing the collision-coalescence progress of droplets (Levin et al., 1996; Rosenfeld et al., 2001).

The results of this study showed a weak dependency of the cloud albedo with  $\omega_{900}$ . Under  $LWP \leq 60 \text{ g m}^{-2}$ , the upward  
380 vertical velocity has a positive but weak effect on the cloud albedo by enhanced vapor supersaturations, which activates  
aerosol particles more and subsequently increasing  $N_d$  (Twomey, 1959; Reutter et al., 2009). Under  $LWP > 60 \text{ g m}^{-2}$ , no  
significant correlation between the cloud albedo and  $\omega_{900}$  was found. Note that the analysis of this study employed the  
average data at the monthly scale rather than raw satellite measurements at a pixel scale, which may make the cloud albedo  
less sensitive to  $\omega_{900}$ . In the study, the unexpected negative dependency of the cloud albedo with RH850 was found for  
385 the two datasets divided in this study. Drier free-troposphere humidity usually drives stronger entrainment of dry air, which  
induces evaporating and raising lifted condensation level, resulting in a reduced cloud thickness (Wood, 2012; Eastman and  
Wood, 2018). However, Ackerman et al. (2004) showed that the sedimentation of cloud droplets reduces the entrainment

rate simulated by a dynamics model. If overlying air is in drier and warmer environments, the reduced entrainment will result in a thicker cloud (Bretherton et al., 2007).

390 The analysis of the relative contribution of each predictor variable was similar to the results of the coefficients. Under  $LWP \leq 60 \text{ g m}^{-2}$ , DU and BC contributed approximately 70 % variations of the cloud albedo in the regression model. Under  $LWP > 60 \text{ g m}^{-2}$ ,  $\text{SO}_4$  has the largest relative contribution to the cloud albedo changes ( $\sim 30 \%$ ) while the contribution of  $\text{SO}_4$  and DU to the change of cloud albedo was about 50 %. Note that the contribution of RH850 was non-negligible, accounting for 20 %.

395 The normalized satellite-based and model-driven cloud albedos under different cloud water conditions are shown in Figure 6c-d, where the correlation (R) between the two cloud albedos is given in parentheses. A larger R value indicates a better model. Both of the correlation coefficients are greater than 0.6, indicating the regression model properly captures the changes in the cloud albedo for the two datasets. A considerable part of the variation in cloud albedo can be explained by the change in meteorological parameters and mass concentrations of different aerosol types.

400 It is also found from Figure 6 that changes in LWP can also cause an alteration of the relationship between aerosol and the cloud albedo. To further investigate the influence of meteorological factors on the relationship, the partial correlations were calculated to eliminate the influence of meteorological parameters individually or simultaneously. If the partial correlation is similar to the total correlation, it means that the influence of meteorological factors on the relationship is limited. In contrast, the influence of meteorological factors on the relationship may be significant if the partial correlation and the total

405 correlation are the opposite sign. Given three meteorological parameters ( $\omega_{900}$ , RH850 and LWP) considered in this study, the total correlation and partial correlation between the cloud albedo and different aerosols for two sample groups are given in Table 3. The total and partial correlations are similar for BC, OC,  $\text{SO}_4$  under  $LWP \leq 60 \text{ g m}^{-2}$ , indicating that meteorological factors have little influence on the interactions between the aerosols and the cloud albedo. The correlation of SS was weak when eliminating the effects of meteorological factors. When the influence of LWP was eliminated, the

410 correlation of DU becomes much weaker, indicating that the correlation of DU is sensitive to LWP. On the contrary, the correlation of  $\text{SO}_2$  was stronger when the influence of LWP was eliminated. Under  $LWP > 60 \text{ g m}^{-2}$ , the correlation of  $\text{SO}_2$  ranged from -0.11 to 0.25 by eliminating the influence of meteorological parameters, indicating the relationship between  $\text{SO}_2$  and the cloud albedo is extremely sensitive to the influences of meteorological factors. However, the impacts of meteorological factors on the aerosol-cloud interactions were insignificant for the other aerosol types.

#### 415 **4 Conclusions and discussion**

The cloud albedo at the subtropical marine subtropical stratocumulus regions has a key role in regulating the regional energy budget. However, climate models have a lack of skill to properly capture the cloud properties for the regions. Therefore, the CMIP6 has more attention to improving some long-standing model biases, e.g., the low cloud simulation over tropical oceans and surface processes (Stouffer et al., 2016). Accordingly, considerable improvements in reproducing the observed

420 seasonal planetary albedo over the subtropical stratocumulus have been found in CMIP6 (Jian et al., 2020). To enhance the confidence in climate predictions, it is necessary to systematically evaluate and compare the performance of CMIP5 and CMIP6 models and to further study the processes that contribute to the cloud albedo using the satellite-driven and reanalysis data. This study investigated the performances of CMIP6 models in reproducing the cloud albedo at the five marine subtropical stratocumulus regions during 2003 to 2014.

425 For the long-term regressed values, the cloud albedos were underestimated in most AMIP6 models compared with the satellite-driven cloud albedos. The AMIP6 models produced a similar spread of AMIP5 at all regions, even some AMIP6 models performed worse than AMIP5. The correlation between cloud fraction and planetary albedo for AMIP6 exhibited a larger spread at the Peruvian and Namibian regions while a larger intermodel variability in the cloud albedo at the Australian and Canarian regions compared with other regions. The monthly cloud albedo of AMIP6-MEM showed better correlation

430 with the satellite-driven observation than that of AMIP5-MEM. However, this study found a lack of skill in reproducing the values and amplitude at the Peruvian and Namibian, indicating that the cloud parameterization between two generations of AMIP models needs to be further improved to produce more accurate predictions. This study also found that most AMIP6 models overestimated the amplitude of the cloud albedo at all regions except for the Australian region, i.e., simulating higher seasonal variations. Overall, the AMIP6 models performed the best at the Australian region and the worst at the Canarian

435 region. In addition, both the AMIP5-MEM and AMIP6-MEM reproduced the seasonal cycle of the cloud albedo at all regions except for the Canarian region. The seasonal cycle of cloud albedo of AMIP6-MEM correlated better with satellite-driven observations than that of AMIP5-MEM. For the Australian region, the model-driven seasonal cycle of the cloud albedo was almost consistent with that of the satellite-driven observation, which indicates the superiority of model performance at this region.

440 Employing the satellite and reanalysis data, we further evaluated the impacts of different aerosol types and meteorological factors on the cloud albedo. Changes in aerosol types and meteorological factors explained ~60 % of the changes in the cloud albedo. However, the controlling factors and their contribution rates varied with LWP conditions. Under the monthly mean  $LWP \leq 60 \text{ g m}^{-2}$ , DU and BC dominantly contributed to the changes in the cloud albedo, while SO<sub>4</sub> contributed the most under the condition of  $60 \text{ g m}^{-2} < LWP \leq 120 \text{ g m}^{-2}$ .

445 Due to the limitations of polar-orbiting satellite observations, this study did not obtain a complete diurnal cycle of cloud properties and radiation flux, which may induce a bias in the results of this study. The diurnal cycle of marine subtropical stratocumulus cloud albedo is usually significant due to the diurnal cycle of solar energy (Wood, 2012). The maximum cloud thickness usually occurs in the morning and gradually decreasing over the afternoon due to absorbing solar radiation in the cloud layer (Wood et al., 2002; Christensen et al., 2013). It is a challenge to evaluate how much of the cloud albedo bias

450 contributes to the diurnal cycle of cloud albedo. Therefore, it is necessary to evaluate the diurnal cycle of cloud albedo in the marine subtropical stratocumulus regions for reducing the uncertainties in cloud radiation interactions in GCMs. Note that the “too bright, too few” problem was improved at the Namibian and Californian regions in AMIP6. However, even if some models can simulate the cloud albedo more reasonably, it is questionable if other cloud properties can be captured (e.g., total

cloud fraction), consequently resulting in significant biases in radiation (see Fig. S3). Therefore, we need to pay more  
455 attention to improving the calculation of total cloud fraction in the GCMs. Recently, some studies are devoted to improving  
cloud overlap parameterization for accurately simulate the cloud fractions in GCMs (Li et al., 2018, 2019). Accordingly, it is  
also necessary to evaluate the improvement of cloud overlap scheme on cloud radiation interaction using long-term satellite-  
driven observations and reanalysis data.

#### 460 **Data availability**

The CERES datasets are available from the CERES website: <https://ceres.larc.nasa.gov/data/#single-scanner-footprint-ssf>.  
The MODIS datasets are available from the Level-1 and Atmosphere Archive & Distribution System (LAADS) Distributed  
Active Archive Center (DAAC) website: <https://ladsweb.modaps.eosdis.nasa.gov/archive/allData/61>. The MERRA-2  
reanalysis products are downloaded from the MERRA-2 website: <https://disc.gsfc.nasa.gov/datasets?keywords=MERRA-2>.  
465 The CMIP5 and CMIP6 products are downloaded from the Earth System Grid Federation (ESGF) website: [https://esgf-  
node.llnl.gov/projects/esgf-llnl/](https://esgf-<br/>node.llnl.gov/projects/esgf-llnl/).

#### **Competing interests**

The authors declare that they have no conflict of interest.

#### **Author contribution**

470 BJ and JL organized the paper and carried them out. BJ prepared the manuscript with contributions from all co-authors. JL  
conceptualized the paper and revised the whole manuscript. GW provided the computing resources. YL downloaded the data  
and maintain research data. YZ, JW and MZ processed the raw model output data into consistent gridded format for  
comparison with the satellite dataset. JH provided consultations and acquired the financial support for this study. All authors  
contributed to the discussion of the results and reviewed the manuscript.

#### 475 **Acknowledgments**

This research was jointly supported by the Strategic Priority Research Program of the Chinese Academy of Sciences (XDA2006010301), the National Science Fund for Excellent Young Scholars (42022037). The authors declare that they have no conflict of interest. We would like to thank the CERES, MODIS, CMIP5, CMIP6 and MERRA-2 science teams for providing excellent and accessible data products that made this study possible.

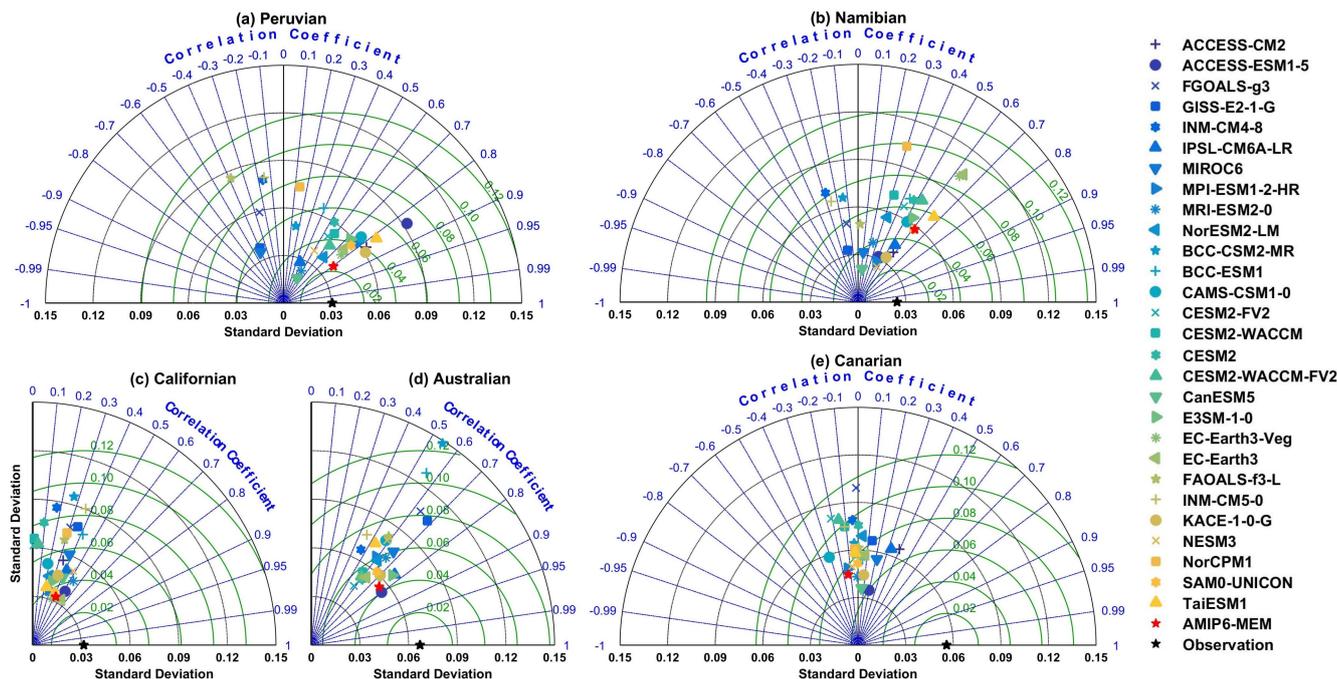

**Figure 1: Near-global distribution of combined planetary albedo averaged from Aqua and Terra during 2003-2014. Red rectangular boxes indicate the five regions used chosen for the analysis: (A1) Peruvian, (A2) Namibian (A3) Californian, (A4) Australian and (A5) Canarian.**

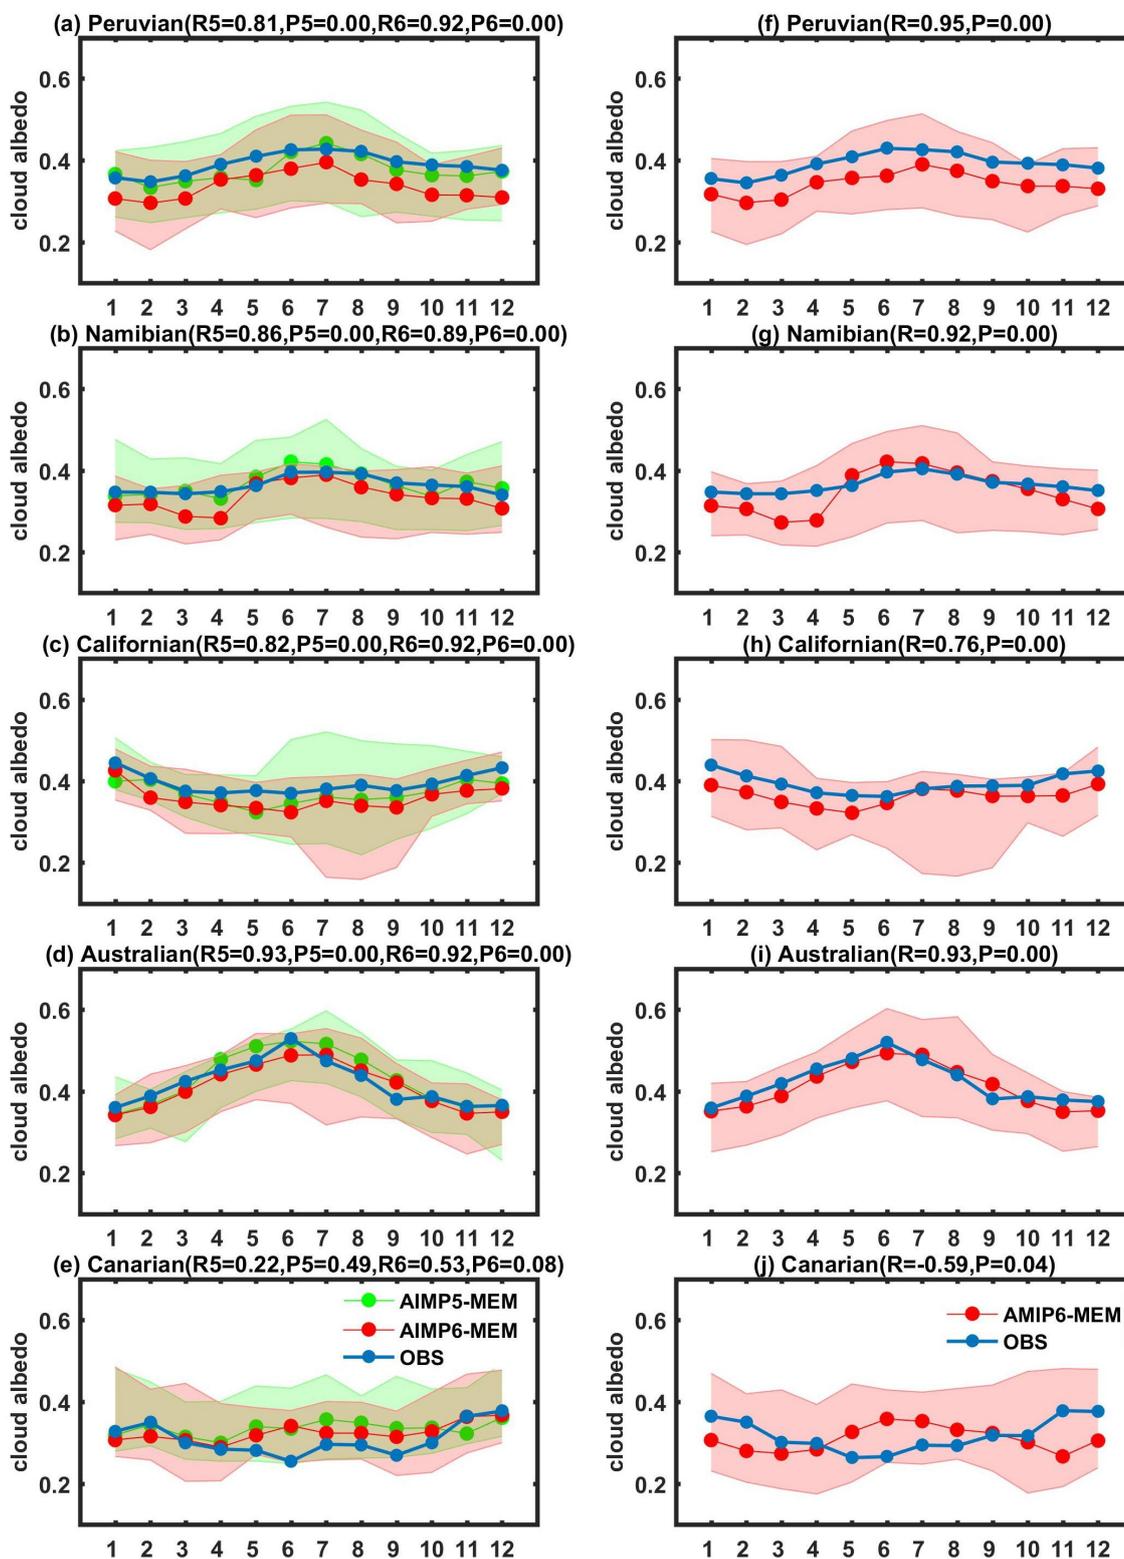

695 **Figure 3: Monthly mean time series of estimated cloud albedo (a-e) from AMIP5 and AMIP6 multimodel ensemble mean during 2003-2008, and (f-j) from AMIP6 multimodel ensemble mean during 2003-2014 compared with satellite observations, over the (a, f) Peruvian, (b, g) Namibian (c, h) Californian, (d, i) Australian and (e, j) Canarian regions.**

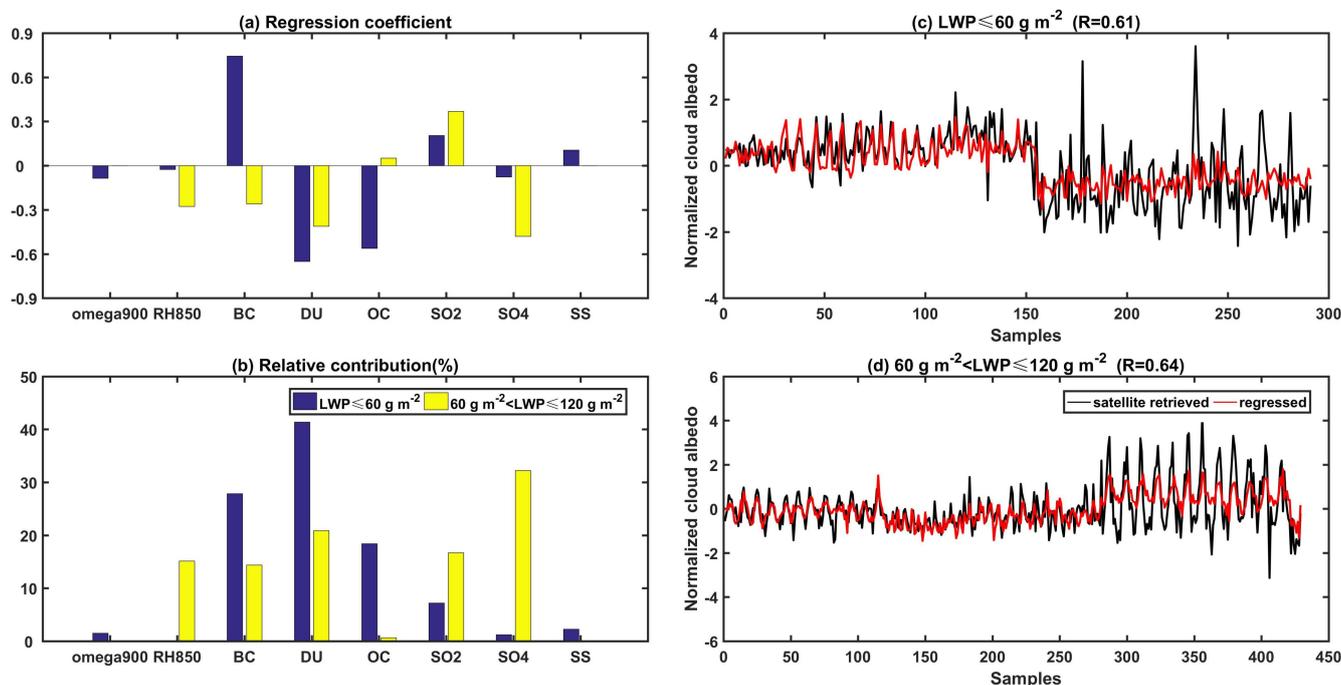

700 **Figure 4: Taylor diagram for monthly estimated cloud albedo between individual AMIP6 model and satellite observations during 2003-2014 over the (a) Peruvian, (b) Namibian (c) Californian, (d) Australian and (e) Canarian regions. The green circles indicate the centered root mean square error.**

705 **Figure 5:** Annual cycles of the cloud albedo estimated by (a-e) AMIP5 and AMIP6 multimodel ensemble mean during 2003–2008, and (f-j) AMIP6 multimodel ensemble mean during 2003–2014 compared with satellite observations, over the (a, f) Peruvian, (b, g) Namibian (c, h) Californian, (d, i) Australian and (e, j) Canarian regions. The green and red shading areas indicate the range of the cloud albedo simulated by AMIP5 and AMIP6 models, respectively. The temporal correlations (R5/R6/R value) and P5/P6/P value (if P5/P6/P < 0.10, indicating the correlation R5/R6/R is significant) for the seasonal cycles of the cloud albedo obtained from satellite-based observations and models are given in parentheses.

710 **Figure 6:** The (a) regression coefficients and corresponding (b) relative contribution of each predictor variables relating to cloud albedo from the multilinear regression models under two LWP conditions:  $LWP \leq 60 \text{ g m}^{-2}$  (blue) and  $60 \text{ g m}^{-2} < LWP \leq 120 \text{ g m}^{-2}$  (yellow). Note that for ease of comparison, eight variables are given in the figure, variables without values are not predictive variables of the sample group. And the satellite- and model-driven normalized cloud albedo trained in two sample groups: (c)  $LWP \leq 60 \text{ g m}^{-2}$  and (d)  $60 \text{ g m}^{-2} < LWP \leq 120 \text{ g m}^{-2}$ . The correlations (R value) between satellite- and model-driven normalized cloud albedo are given in parentheses.
