Abstract. The unintended consequences of reductions in regional anthropogenic sulfur dioxide (SO\textsubscript{2}) emissions implemented to protect human health are poorly understood. SO\textsubscript{2} decreases began in the 1970s in the US and Europe and are expected to continue into the future, while recent emissions decreases in China are also projected to continue. In addition to the well documented climate effects (warming) from reducing aerosols, tropospheric oxidation is impacted via aerosol modification of photolysis rates and radical sinks. Impacts on the hydroxyl radical and other trace constituents directly affect climate and air quality metrics such as surface ozone levels. We use the Geophysical Fluid Dynamics Laboratory Atmospheric Model version 3 nudged towards National Centers for Environmental Prediction (NCEP) reanalysis wind velocities to estimate the impact of SO\textsubscript{2} emissions from the United States, Europe, and China by differencing a control simulation with an otherwise identical simulation in which 2015 anthropogenic SO\textsubscript{2} emissions are set to zero over one of the regions. Springtime sulfate aerosol changes occur both locally to the emission region and also throughout the Northern Hemispheric troposphere, including remote oceanic regions and the Arctic. Hydroperoxy (HO\textsubscript{2}) radicals are directly removed via heterogeneous chemistry on aerosol surfaces, including sulfate, in the model, and we find that sulfate aerosol produced by SO\textsubscript{2} emissions from the three individual northern mid-latitude regions strongly reduces both HO\textsubscript{2} and hydroxyl (OH) by up to 10\% year-round throughout most of the troposphere north of 30 \textdegree N latitude. Regional SO\textsubscript{2} emissions significantly increase nitrogen oxides (NO\textsubscript{x}) by about 5-8\% throughout most of the free troposphere in the Northern hemisphere by increasing the NO\textsubscript{x} lifetime as the heterogeneous sink of HO\textsubscript{2} on sulfate aerosol declines. Despite the NO\textsubscript{x} increases, tropospheric ozone decreases at northern mid-latitudes by 1-4\% zonally averaged and by up to 5 ppbv in summertime surface air over China, where the decreases in HO\textsubscript{2} and OH suppress O\textsubscript{3} production. Since 2015 anthropogenic SO\textsubscript{2} emissions in China exceed those in the US or Europe, the oxidative response is greatest for the China perturbation simulation. Chemical effects of aerosols on oxidation (reactive uptake) dominate over radiative effects (photolysis rates), the latter of which are only statistically significant locally for the large perturbation over China. We find that the SO\textsubscript{2} emissions decrease in China, which has yet to be fully realized, will have the largest impact on oxidants and related species in the Northern Hemisphere free troposphere compared to future decreases in Europe or the USA. Our results bolster previous calls for a multipollutant strategy for air pollution mitigation, to avoid the unintended consequence
of aerosol removal leading to surface ozone increases that offset or mask surface ozone gains achieved by regulation of other pollutants, especially in countries where current usage of high-sulfur emitting fuels may be phased out in the future.

1 Introduction

Understanding and constraining tropospheric oxidants such as the hydroxyl radical (OH) remains a key challenge of direct relevance to understanding the oxidizing power of the atmosphere, radiative forcing, and surface air quality. Despite the critical role in atmospheric chemistry, OH abundances differ widely among chemistry-climate and chemical transport models (Stevenson et al., 2020; Zhao et al., 2019). In addition, global, annual mean OH response to historical anthropogenic emission changes (all species) between the preindustrial and the present-day ranged from a 12.7% decrease to a 14.6% increase across 17 global models (Naik et al., 2013b), with similar discrepancies across simulations of future composition and climate (Voulgarakis et al., 2013). These differences between model estimates of OH suggest major knowledge gaps in our understanding of the drivers of OH. One potential driver of tropospheric oxidant changes that has not received sufficient study is aerosols, which can uptake radical species (chemical effect) and scatter or absorb incoming solar radiation (radiative effect), thereby impacting OH and other important chemical species (Jacob, 2000; Wild et al., 2000).

Anthropogenic emissions of sulfur dioxide (SO₂), a precursor to sulfate aerosol, have significantly decreased in the United States and Europe for the last several decades and are projected to continue to decline (Riahi et al., 2011; Vuuren et al., 2011; Westervelt et al., 2015). In China, emissions of anthropogenic aerosols began to decline in about 2013 after increasing for decades (Fontes et al., 2017; Li et al., 2017; Samset et al., 2018). Previous research has indicated that these past and forthcoming emission changes have the potential to influence the tropospheric oxidation capacity on both a regional and global basis (Dentener and Crutzen, 1993; Dickerson et al., 1997; Martin et al., 2003). The aerosol decreases in China were associated with subsequent increases in summertime surface ozone (O₃) in China, attributed to a reduction in the sink of radical species such as the hydroperoxyl radical (HO₂) that promote O₃ production (Li et al., 2019b). Using a model and observations, the authors found that a 40% decrease in fine particulate matter (PM₂.₅) in China between 2013 and 2017 led to an increasing ozone trend of up to 3 ppb per year in eastern China and was a more important factor than NOₓ emissions reductions over the same time period (Li et al., 2019b, 2019a). These findings confirm earlier modelling work and point to an important role for aerosol impacts on tropospheric oxidation with implications for surface O₃ concentrations, especially over China (Li et al., 2018; Lou et al., 2014).

On a global scale, the impact of aerosols on tropospheric oxidants has received little attention. Often, aerosol impacts are assumed to be negligible in constraining present and future OH concentrations (Voulgarakis et al., 2013). Primary production of OH depends on the amount of water vapor and O(¹D) present (formed via O₃ photolysis), and is the dominant pathway of OH formation in most locations except for high latitudes (Spivakovsky et al., 2000). Secondary production involves reactions of HO₂ or RO₂ (organic peroxy) radicals generated from oxidation of volatile organic compounds (VOCs) or carbon
monoxide (CO) with nitric oxide (NO) which regenerates OH. Concentrations of these atmospheric constituents and certain meteorological factors such as absolute humidity, temperature, and ultraviolet radiation are thought to predominantly control OH abundance (Spivakovsky et al., 2000). However, by differencing a Goddard Earth Observing System Chemistry Transport Model (GEOS-Chem) control simulation of late 1990s atmospheric composition with a sensitivity simulation in which the offline global aerosols are excluded, Martin et al. (2003) find that the presence of all aerosols decreases OH by 9% globally and 5-35% in the northern hemisphere boundary layer. The authors also find 15-45 ppbv decreases in boundary layer O$_3$ over India in March associated with the presence of all aerosols compared to all aerosols removed. In a similar global study, (Tie et al., 2005) use the Model for Ozone and Related Chemical Tracers version 2 (MOZART-2) to show that the net effect of all aerosols (natural and anthropogenic) reduces HO$_x$ (defined as OH + HO$_2$) and O$_3$ by 30% and 20%, respectively, improving on past methodology (e.g., Martin et al., 2003) by calculating aerosol abundances interactively. Past studies only considered global distributions of aerosols and often focused on natural aerosols such as dust or sea salt (Bian and Zender, 2003; Liao et al., 2003). The impact of rapidly changing spatially heterogeneous anthropogenic aerosol abundances on tropospheric OH and O$_3$ in response to regional air pollution control programs is thus an open question.

We expand on past studies by considering sulfate aerosol decrease via SO$_2$ emissions reductions within individual regions (China, Europe, and the US), and quantify the local and remote impacts of changing these emissions on atmospheric HO$_x$, NO$_x$, and O$_3$ concentrations on a seasonal basis within a chemistry-climate model nudged to observed meteorology. We focus on anthropogenic SO$_2$ emissions which have decreased most dramatically in many regions compared to anthropogenically-sourced carbonaceous aerosols or natural aerosols such as dust and sea salt. We seek mechanistic understanding on the interactions between aerosols, oxidants and radical species, and photolysis rates over different regions and in different seasons. We consider two main pathways through which aerosols can affect oxidation: modification of photolysis rates via extinction of incoming solar radiation (radiative effect) and heterogeneous uptake of radical species onto aerosol surfaces (chemical effect). Finally, we consider the impact of anthropogenic SO$_2$ emissions reductions on boreal summertime surface O$_3$ concentrations in China, Europe, and the US.

2 Model and simulations

We use the National Oceanic and Atmospheric Administration Geophysical Fluid Dynamics Laboratory Atmospheric Model version 3 (GFDL-AM3), which is the atmosphere-only component of the GFDL coupled climate model, CM3 (Donner et al., 2011). The model has been rigorously evaluated against observations in previous work, including against surface observations of O$_3$ over the US, Europe, and China (Donner et al., 2011; Naik et al., 2013a, Westervelt et al., 2019). Paulot et al. (2016) evaluate sulfate concentrations in GFDL-AM3 over the US (Interagency Monitoring of Protected Visual Environments, IMPROVE) and Europe (European Monitoring and Evaluation Programme, EMEP), and find a normalized mean bias of 0.07 in model surface concentrations compared against IMPROVE and a -0.43 mean normalized bias over Europe against EMEP. The model has 48 vertical layers from the surface up to about 0.01 hPa and a six-face cubed-sphere grid with
48 cells along each edge (C48), which is regridded to a 2 degree latitude by 2.5 degree longitude Cartesian grid. Emissions of anthropogenic trace gases and aerosols for year 2015 emissions are from the Representative Concentration Pathway 8.5 (RCP8.5) scenario (Riahi et al., 2011). The tropospheric chemical mechanism for aerosols and gas-phase species follows the work of Horowitz et al. (2003) and Horowitz et al. (2007) with updates to photolysis, radical uptake by aerosols, and convective wet scavenging of aerosols. The Fast-JX module (Bian et al., 2003; Wild et al., 2000) calculates the impact of online aerosols and clouds on photolysis rates and actinic fluxes, implemented into GFDL-AM3 according to Mao et al. (2013b). Heterogeneous uptake of radical species is simulated according to Mao et al. (2013b) and Mao et al. (2013a) using a first order reactive uptake rate constant \( k \) (Equation 1):

\[
k = - \left( \frac{r_e}{D_g} + \frac{4}{\nu v} \right)^{-1} A
\]

(Equation 1)

where \( r_e \) is the aerosol effective radius (m), \( D_g \) is the gas-phase molecular diffusion coefficient, \( \nu \) is the mean molecular speed of the gas, and \( A \) is the aerosol surface area per unit volume of air. Here we set the heterogeneous reactive uptake coefficient (\( \gamma \)) of HO\(_2\) to 0.2 instead of the value of 1.0 in Mao et al. (2013a). Though estimates of \( \gamma \) are uncertain, recent literature suggests such high values of 1.0 are not supported by observations and that the parameter is likely closer to 0.2 (Abbatt et al., 2012; Li et al., 2019a, 2019b; Taketani et al., 2012). Taketani et al. (2012) recommends a middle \( \gamma \) value of 0.24 based on measurements at two high altitude sites in China. Reactive uptake coefficients for all other reactions including N\(_2\)O\(_5\), NO\(_3\), and NO\(_2\) are shown in Table 1, taken from Jacob (2000). We allow uptake of HO\(_2\), N\(_2\)O\(_5\), NO\(_3\), and NO\(_2\) onto all aerosol types, including sulfate, black carbon, organic carbon, sea salt, and dust using the same coefficients for each composition. We also include updates to convective wet scavenging of aerosols in the form of finer vertical discretization of convective updraft plumes, resulting in improvements in aerosol budgets (Paulot et al., 2015). Horizontal wind velocities are nudged using a pressure-dependent technique towards reanalysis values from the National Centers for Environmental Prediction Global Forecast System (NCEP GFS; (Lin et al., 2012)). Further model description and model evaluation against observations can be found in Donner et al. (2011), Naik et al. (2013a), and Rasmussen et al. (2012).

We conduct a two-year (2014-2015) nudged control simulation in which emissions of aerosols and their precursors follow RCP8.5 and contrast it with three perturbations: one in which all anthropogenic SO\(_2\) emissions are set to zero over the United States (30°N - 50°N, 70°W – 125°W), all anthropogenic SO\(_2\) emissions are set to zero over Europe (35°N – 70°N, 15°W – 55°E), and all anthropogenic SO\(_2\) emissions are set to zero over China (15°N – 50°N, 95°E – 130°E). SO\(_2\) is oxidized by the hydroxyl radical in the gas phase and by ozone and hydrogen peroxide in clouds to form sulfate aerosol, which is a dominant component of total aerosol in GFDL-AM3 (Westervelt et al., 2015, 2017). We separately subtract each regional SO\(_2\) perturbation simulation from the control simulation, thereby isolating the impact of regional SO\(_2\) emissions (and subsequent sulfate formation) on tropospheric oxidants and related species. We test for statistical significance using a Student’s t-test on seasonal mean responses with the null hypothesis being that the difference between the control and the perturbation simulation is zero. Only the full year of 2015 is used for analysis to allow for a full year of initialization. SO\(_2\) perturbations from our simulations are 10.8, 12.4, and 16.2 Tg SO\(_2\) y\(^{-1}\) for US, Europe, and China, respectively.
The global annual mean OH for the 2015 control simulation is $7.0 \times 10^5$ molecules cm$^{-3}$, which is within the range of the 14 Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) for year 2000 and 14 Chemistry Climate Model Initiative (CCMI) models (Voulgarakis et al., 2013b; Zhao et al., 2019) for years 2000-2010. The global annual tropospheric burden of O$_3$ in the 2015 control simulation is 356 Tg, which compares well to the year 2000 O$_3$ burden mean across the ACCMIP models of $337 \pm 23$ Tg (Young et al., 2013).

3 Results

Figure 1 shows the percent increase in seasonal (March-April-May, MAM) sulfate concentrations at the surface (right column) and at altitude (left column) due to the presence of all anthropogenic US SO$_2$ (first row), all European SO$_2$ (second row), and all Chinese SO$_2$ (third row) based on year 2015 anthropogenic emissions. Additional seasons are shown in the supplement (Figs. S1-3). The zeroing of 2015 SO$_2$ emissions in each location results in the largest relative perturbation in China, where emissions are highest, followed by Europe and the US. Sulfate increases are largest closest to the source region, but all three regional simulations show statistically significant remote impacts both horizontally and vertically in the atmosphere, as evidenced by the spatial and zonal plots in Fig. 1. Emissions from US, Europe, and China perturbations all significantly increase sulfate throughout the troposphere up to 200 hPa and higher towards the North Pole, with the largest increases of up to 30-40% resulting from the China SO$_2$ perturbation. Transport to the Arctic is a common feature in all three perturbations, and is consistent with previous studies on aerosol transport to the Arctic (Shindell et al., 2008; Stohl, 2006, Yang et al. 2017; Yang et al. 2018; Ren et al. 2020). The US perturbation impacts sulfate concentrations significantly at the surface and at altitude over the North Atlantic Ocean, while emissions from China exert a heavy influence over the Pacific reaching all of the way to the Western US. European SO$_2$ emissions have widespread influence on the Northern Hemisphere, but especially in the Arctic and the Mediterranean and northern Africa. In all cases, sulfate changes are nearly entirely confined to the Northern Hemisphere.

We analyze the impact of sulfate changes on atmospheric oxidation capacity, starting in Fig. 2 with OH (left column) and HO$_2$ (right column) for each of the three regional perturbations (rows of Fig. 2). Sulfate aerosol surfaces directly uptake HO$_2$ radicals as described in Sect. 2, resulting in significant decreases of HO$_2$ and OH (via their rapid cycling). For each perturbation, decreases in both OH and HO$_2$ occur throughout most of the Northern Hemisphere up to about 200 hPa vertically during the boreal spring (MAM). The largest decreases in OH and HO$_2$ occur in spring for each of the perturbations, followed by winter (December-January-February, DJF), autumn (September-October-November, SON), and summer (June-July-August, JJA). These additional seasons are plotted in Figs. S4-S6. In MAM, SO$_2$ emissions over the US decrease OH and HO$_2$ by about 5% within the US planetary boundary layer. In the mid-troposphere (400 – 600 hPa), OH decreases are 5% or greater and are located spatially above the Arctic. For the Europe SO$_2$ and China SO$_2$ cases during MAM, the Arctic middle troposphere OH decreases are larger in percent change (>10%) than the local changes near the surface (~8%). The presence of 2015 China SO$_2$ emissions also decreases OH and HO$_2$ by about 10% over the north Pacific Ocean middle troposphere (about
400-600 hPa) in the model. By comparing the first row of Fig. 2 with the second and third rows, we find that the zonal structure of the OH and HO$_2$ response to anthropogenic SO$_2$ emissions is very similar across the three regional perturbations, while the magnitude is largest in response to China SO$_2$ emissions, followed by Europe SO$_2$, and US SO$_2$. We conclude that regional SO$_2$ emissions may have stronger impacts remotely than locally, and OH may be relatively more sensitive to aerosol changes in the Arctic and remote oceans at higher altitudes where its production is more limited.

In Fig. 3 we plot spring (MAM) changes in NO$_x$ (defined as NO + NO$_2$) concentrations in response to anthropogenic SO$_2$ emissions in the US, Europe, and China. While HO$_2$ and OH strongly decreased in response to SO$_2$ emissions, NO$_x$ significantly increases throughout most of the Northern Hemisphere. In the model, aerosols can take up NO$_2$ directly but with a very low reaction probability (0.0001, Table 1), such that little uptake actually occurs and is easily offset by feedbacks onto other chemical reactions involving NO$_x$. Instead, reduction in the sinks of NO$_x$ via OH (nitric acid formation) during the day and uptake of NO$_3$ at night dominates the response to SO$_2$ emission changes, increasing NO$_x$ in the model as OH decreases. At night, NO$_3$ is removed by reaction with the nitrate radical (NO$_3$), which forms dinitrogen pentoxide (N$_2$O$_5$) (Chang et al., 2011; Jacob, 2000). Sulfate aerosols are effective at removing NO$_x$ via reactive uptake (reaction probability of 0.1), slowing down this night-time NO$_x$ sink and thus increasing NO$_x$ abundance. This hindering of day and night NO$_x$ sinks is most effective during MAM and DJF in the Northern Hemisphere mid-troposphere (Fig. 3a-c for MAM, additional seasons shown in Figs. S7-S9). Mid-tropospheric northern hemisphere NO$_x$ increases reach about 7-8% in response to Chinese SO$_2$ emissions specifically, with smaller effects for both US and Europe SO$_2$ perturbations. NO$_x$ at the surface increases slightly less at about 5-7% depending on the regional emissions perturbation, though these changes still are statistically significant. N$_2$O$_5$ is removed by aerosols also with a reaction probably of 0.1, although several previous studies have used smaller reactive uptake coefficients for N$_2$O$_5$ (Evans and Jacob, 2005; Holmes et al., 2019; Macintyre and Evans, 2010; McDuffie et al., 2019) based on more recent laboratory experiments, but only find impacts on mean tropospheric O$_3$ burden of 2-4%. Using a box modelling approach, McDuffie et al. (2019) find a median $\gamma$ for N$_2$O$_5$, of 0.076, reasonably close to our assumed value of 0.1.

In most of the Northern Hemisphere troposphere, O$_3$ decreases in MAM by up to 4% in response to US, European, or Chinese SO$_2$ emissions increases in the model (Fig. 4), mostly coinciding with regions of large HO$_x$ decreases (Fig. 2), despite the increase in NO$_x$ (Fig. 3). O$_3$ decreases are the largest in response to Chinese anthropogenic SO$_2$ emissions, owing to the larger SO$_2$ perturbation compared to the US and Europe emissions perturbations. The O$_3$ increases in the upper troposphere are mostly not significant. We examine model diagnostics of gross ozone production (the sum of HO$_2$+NO and all RO$_2$+NO reaction pathways) and O$_3$ loss (which includes reaction of O$_3$ with HO$_x$ and with alkenes, plus O$_3$ photolysis followed by O$^1$D+H$_2$O) to interpret further the O$_3$ decrease. While both O$_3$ production ($P_{O_3}$) and loss ($L_{O_3}$) rates decline (Fig. S10 and Fig. S11), production decreases more strongly than loss, lowering O$_3$ concentrations. We confirm that transport of O$_3$ from other latitudes is unlikely to contribute much to the modelled O$_3$ response as the change in zonal mean advective or convective tendency in O$_3$ (Fig. S12) is far smaller than the chemical production and loss terms (Fig. S10). The O$_3$ production and loss rates decrease most strongly in the lower troposphere over the source regions (Fig. S10 and Fig. S11) while the O$_3$
decreases (Fig. 4) propagate more widely through the free troposphere, indicating reduced export from these source regions. Additional seasons for O₃ change are shown in Figs. S13-S15.

We find here that the decline in HOₓ and its impact on Pₒ₃ outweighs the aerosol-induced increases in NOₓ and decreases in O₃-HOₓ sinks, even during summer in all three source regions. We show the response of summertime surface 8-hour maximum daily average (MDA) O₃ to increasing anthropogenic SO₂ emissions in the US, Europe, and China in Fig. 5. Increasing sulfate aerosol increases the sink of HO₂ radicals and thus slows down O₃ production (Fig. S11), resulting in surface O₃ concentration decreases, which are largest and mostly confined to the emissions source region. Sulfate aerosol can also reduce NO₂ and O₃ photolysis rates. The combined effect of sulfate aerosol on changes in photolysis rates and heterogeneous chemistry is a statistically significant decrease of about 5 ppbv over most of eastern China, Korea, and Japan when Chinese SO₂ emissions are introduced, a decrease of about 3 ppbv over the eastern US for US SO₂ emissions, and a decrease of about 3 ppbv over Eurasia for the Europe SO₂ emissions perturbation. Changes in similar magnitude have been reported over China using both a chemistry-transport model and observations (Li et al., 2019). Large sulfate decreases have occurred since the 1970s in both Europe and the US. The SO₂ perturbation in our study (zero-out 2015 level emissions) is 10.8, 12.4, and 16.2 Tg SO₂ y⁻¹ in the US, Europe, and China, respectively. These results imply that the sulfate decreases from clean air regulations and technologies have had the unintended consequence of driving O₃ up by a few ppb during the summertime in the US and Europe. While this may be a small amount of the total surface O₃ concentration and not entirely outside the range of typical variability, our study only considers the impact of sulfate aerosol and not carbonaceous aerosols, which make up greater than 50% of the total aerosol mass in many environments (Jiminez et al., 2009). Additionally, even O₃ changes on the order of 3-5 ppbv may be important for holistically meeting tightening air quality standards. NOₓ emissions have also decreased dramatically over roughly the same time period and have likely more than offset any O₃ increase from decreasing sulfate. However, the full potential of possible O₃ improvement via NOₓ and anthropogenic volatile organic carbon (VOC) decreases may have been partially masked by sulfate decreases. These findings highlight the importance of a multi-pollutant strategy for effective clean air regulation.

Finally, in Fig. 6 we plot the relative change in MAM O₃→O(¹D) and NO₂ photolysis rates, denoted jₒ₁D and jₒ₂ in response to SO₂ emissions in each region. Photolysis of both species is slightly influenced by changing SO₂ emissions, especially over China in response to China SO₂ emissions, where decreases in both photolysis rates are about 7%. For each of the perturbations, especially the US and Europe cases, changes in photolysis rates rarely rise above the noise, which is likely caused by meteorological factors such as slight changes in cloud cover. We conclude that while radiative effects via photolysis are non-negligible, they are significantly less important than chemical effects for aerosol impacts on oxidation, consistent with previous findings (Li et al., 2019).
4 Summary and conclusions

Using the updated GFDL-AM3 nudged chemistry-climate model with online aerosol heterogeneous chemistry and interactions with radiation, we estimate the impact of northern hemisphere mid-latitude regional anthropogenic SO$_2$ emissions on tropospheric OH, HO$_2$, O$_3$, and NO$_x$. Regional SO$_2$ emissions perturbations lead to significant changes to sulfate aerosol in far-reaching regions of the world, particularly in the Arctic and the mid and upper troposphere. OH and HO$_2$ decrease throughout the northern hemisphere mid-troposphere by up to 10%, which in turn increase NO$_x$ concentrations by at least 5%.

NO$_x$ is not efficiently removed by heterogeneous reactions on aerosols, while species that contribute to NO$_x$ sinks such as OH (via HO$_2$ uptake) and NO$_3$ are efficiently removed, slowing down the NO$_x$ sink and increasing NO$_x$ concentrations. However, any influence of NO$_x$ increases on tropospheric O$_3$ are overwhelmed by HO$_2$ decreases, and the resulting decrease in O$_3$ production offsets decreases in O$_3$ sinks, resulting in up to 4% decrease in O$_3$ in the free troposphere and at the surface. Aerosols impact oxidation primarily through heterogeneous reactive uptake pathways over photolysis pathways.

Surface ozone decreases by 3 to 5 ppbv in response to the introduction of regional SO$_2$ emissions. If SO$_2$ emissions decline in developing regions of the world such as South Asia and sub-Saharan Africa, a goal attained through air quality improvements to protect human health, there could be an unintended increase in surface O$_3$ concentrations. Decreasing surface O$_3$ in these regions will require a multipollutant approach in which NO$_x$ and VOCs are simultaneously decreased with aerosols in order to offset the effect of decrease in aerosols and their precursors. While SO$_2$ and NO$_x$ emissions decreases coincided to some extent in the US, end-of-pipe technologies at power plants allow for control of SO$_2$ and NO$_x$ individually, and other sources of fine particulate matter (PM$_{2.5}$) such as waste burning and vehicle emissions will have a similar effect on ozone as sulfate aerosols. PM$_{2.5}$ and SO$_2$ have decreased dramatically in recent years in the US and Europe, such that O$_3$ improvements may have been partially masked by the aerosol impact. SO$_2$ perturbations from our simulations are 10.8, 12.4, and 16.2 Tg y$^{-1}$ for US, Europe, and China, respectively, which result in a 3 ppbv surface ozone response over the US and Europe, and a 5 ppbv surface ozone response over China, where SO$_2$ emissions are the largest in 2015. Model overprediction of surface O$_3$ over urban areas in China (Westervelt et al., 2019) likely make this 5 ppbv change an upper estimate of the surface O$_3$ response to China SO$_2$ emissions.

Future work is needed to improve estimates of reactive uptake of HO$_2$ and other radical species by aerosols, as great uncertainty still exists surrounding this parameter as well as the dependence of aerosol composition on reactive uptake parameters (George et al., 2013). We focus here on anthropogenic aerosols as they are changing rapidly and expected to continue to change. Previous work finds a large influence of Saharan dust aerosols on oxidation (Tie et al., 2005). Regions of biomass burning such as Africa and South America are also potential contributors to aerosol-driven oxidation changes. In order to avoid “trading one problem for another” in areas of the world that are experiencing both rapid emissions changes and high exposures to air pollutants, we must better understand the impact of aerosols on atmospheric photochemistry.
Author Contributions

DMW wrote the manuscript, created all figures, and conducted all simulations. AMF and DMW originally conceived the project. CBB assisted with model setup and analysis of output. GC developed the model for use at LDEO. All authors contributed to editing the manuscript.

Figure 3: Boreal springtime (MAM) mean percent change in NOx between a control simulation and a perturbation simulation in which anthropogenic SO\textsubscript{2} emissions are removed over a certain region: (a) US, (b) Europe, and (c) China. Hatching denotes statistical significance according to a Student’s t-test at the 95% confidence level.
Figure 4: Boreal springtime (MAM) mean percent change in O3 between a control simulation and a perturbation simulation in which anthropogenic SO$_2$ emissions are removed over a certain region: (a) US, (b) Europe, and (c) China. Hatching denotes statistical significance according to a Student’s t-test at the 95% confidence level.
Figure 5: Summertime (JJA) surface O3 change (in ppbv) between a control simulation and a perturbation simulation in which anthropogenic SO2 emissions are removed over a certain region: (a) US, (b) Europe, and (c) China. Hatching denotes statistical significance according to a Student’s t-test at the 95% confidence level.
Figure 6: Boreal springtime (MAM) mean percent change in photolysis rates ($j_{O1D}$, left column and $j_{NO2}$, right column) between a control simulation and a perturbation simulation in which anthropogenic $SO_2$ emissions are removed over a certain region: (a,b) US, (c,d) Europe, and (e,f) China. Hatching denotes statistical significance according to a Student’s t-test at the 95% confidence level.
