**Abstract:** China has made great efforts to monitor and control air pollution in the past decade. Comprehensive characterization and understanding of pollutants in three-dimension (3-D) are, however, still lacking. Here, we used data from an observation network consisting of 13 aerosol lidars and more than 1000 ground observation stations, combined with a data assimilation technique, to conduct a comprehensive analysis of an extreme heavy aerosol pollution (HAP) over the North China Plain (NCP) from November–December 2017. During the studied period, the maximum hourly mass concentration of surface PM<sub>2.5</sub> reached  $\sim 390 \mu\text{g}\cdot\text{m}^{-3}$ . After assimilation, the correlation between model results and the independent observation sub-dataset was  $\sim 50\%$  higher than the that without the assimilation, and the root mean square error was reduced by  $\sim 40\%$ . From pollution development to dissipation, we divided the HAP in the NCP (especially in Beijing) into four phases—an early phase (EP), a transport phase (TP), an accumulation phase (AP), and a removal phase (RP). We then analyzed the evolutionary characteristics of PM<sub>2.5</sub> concentration during different phases on the surface and in 3-D space. We found that the particles were mainly transported from south to north at a height of 1-2 km (during EP and RP) and near the surface (during TP and AP). The amounts of PM<sub>2.5</sub> advected into Beijing with the maximum transport flux intensity (TFI) were through the pathways in the relative order of the southwest > southeast > east pathways. The dissipation of PM<sub>2.5</sub> in the RP stage (with negative TFI) was mainly from north to south, with an average transport height of  $\sim 1$  km above the surface. Our results quantified the multi-dimensional distribution and evolution of PM<sub>2.5</sub> concentration over the NCP, which may help policymakers develop efficient air pollution control strategies.

# 1 **1 Introduction**

2 Frequent heavy air pollution has exerted significant impacts on air visibility, climate,  
3 human health, and other environmental concerns (Gao, Woodward, et al. 2017; Pokharel et al.  
4 2019; Su, Cheng, and Poschl 2020). As a developing country with the largest population in the  
5 world, China's air quality has exhibited an obvious improvement trend in recent years (Zhang  
6 and Cao 2015; Cao et al. 2017). Regional air pollution in China is still serious, however,  
7 especially the heavy aerosol pollution (HAP) caused by fine particulate matter (PM<sub>2.5</sub>) in winter,  
8 which has attracted attention worldwide (Zheng et al. 2019; Li, Zhang, et al. 2017; Zheng et al.  
9 2015; Cheng et al. 2016). Therefore, providing a reliable distribution of the PM<sub>2.5</sub> concentration  
10 of HAP, especially at any time and at any height in a given region, is particularly important in  
11 the quest of the public to avoid health problems and to provide government policy makers with  
12 help in designing effective controls (Hu et al. 2015).

13 Compared with other air pollutants (e.g., ozone and nitrogen dioxide), PM<sub>2.5</sub> has a longer  
14 atmospheric lifetime (3–5 days), during which it can be transported vertically to great heights  
15 and horizontally hundreds of kilometers (Wang et al. 2017; Zhang et al. 2014), depending on  
16 the meteorological conditions (e.g., relative humidity and precipitation) and chemical  
17 composition (Yang et al. 2017). Previous study demonstrated that regional transport plays an  
18 important role for pollution formation in major cities of China, e.g., transport contributes over  
19 50% of the PM<sub>2.5</sub> mass concentration in Beijing city, Shanghai city, Hangzhou city, Guangzhou  
20 city, Hong Kong and Chengdu city during the relatively polluted period (Sun et al. 2017). From  
21 2005–2010, annually, about 35.5% (32.8  $\mu\text{g}\cdot\text{m}^{-3}$ ) of the PM<sub>2.5</sub> in Beijing was attributed to  
22 regional transport from the North China Plain (NCP), within which up to 60.4% (64.3  $\mu\text{g}\cdot\text{m}^{-3}$ )  
23 from southerly and westerly air flows (Wang et al. 2015). Since the 2013 implementation of  
24 the most stringent clean air policy in China, the control of local pollution sources has led to the  
25 rapid reduction of total PM<sub>2.5</sub> concentration (Zhang, Zheng, et al. 2019). It should be noted,  
26 however, that the local contributions, intra-regional transport, and inter-regional transport  
27 accounted for 47% (12.7  $\mu\text{g}\cdot\text{m}^{-3}$ ), 25% (6.6  $\mu\text{g}\cdot\text{m}^{-3}$ ), and 28% (7.6  $\mu\text{g}\cdot\text{m}^{-3}$ ), respectively, of the  
28 total PM<sub>2.5</sub> for the Beijing-Tianjin-Hebei (BTH) region from 2014–2017, with the 2017  
29 contribution of regional transport to the BTH concentration rate ranging from 32.5–68.4%  
30 (Dong et al. 2020).

31 Previous studies have shown that it is difficult to use surface observations to characterize  
32 the impact of upper-level pollutants in the atmosphere (Huang, Wang, and Ding 2018), which  
33 is affected by local emissions, regional transport, meteorological conditions, geographical

1 factors etc. (Tao et al. 2020; Che, Gui, et al. 2019). Therefore, understanding the key processes  
2 that drive the dynamic temporal and spatial evolutionary characteristics of pollutants on the  
3 NCP is essential for revealing the source and transport of aerosols, which has different radiative  
4 forcing at different heights (Kumar et al. 2017; Che, Xia, et al. 2019). Actually, stereo-  
5 monitoring devices and technologies, such as lidar (Sheng et al. 2019; Fan et al. 2019; Chen,  
6 Schofield, et al. 2019), MAX-DOAS (Hong et al. 2018; Zhang et al. 2020), and satellite remote  
7 sensing (Pang et al. 2018; Schwartz et al. 2012; Zhang, Liu, et al. 2019), can reveal the vertical  
8 distribution of pollutants at different heights (Tian et al. 2017; Heese et al. 2017). Due to the  
9 limited spatial and temporal observations, however, it is impossible to provide physical and  
10 chemical properties in the atmosphere at any time period and on any path, which makes it  
11 difficult to directly reveal the formation and source of pollution.

12 On the other hand, although the distribution of pollutants can be simulated by air quality  
13 models (Huang et al. 2018; Zhang et al. 2008), large uncertainties remain, mainly from the  
14 influence of emission inventory, meteorological fields, and some hypothetical conditions (Xu  
15 et al. 2016; Chen et al. 2017; Huang et al. 2016). Fortunately, the above observed data and the  
16 results of the model can be fused using data assimilation techniques, which can correct the  
17 model simulation results via the observed data (Wang et al. 2013; Ma et al. 2019). Research  
18 has shown that mainstream data assimilation (DA) technologies, including 3DVAR (Jiang et  
19 al. 2013; Ma et al. 2018), 4DVAR (Yumimoto et al. 2008), and EnKF (Chen, Liu, et al. 2019),  
20 can be used to assimilate observation data from the surface, remote sensing data (such as AOD)  
21 from satellites, and vertical profile data from lidar, all of which can be used to improve the  
22 performance of the model, including the simulation of  $PM_{2.5}$  and  $PM_{10}$ .

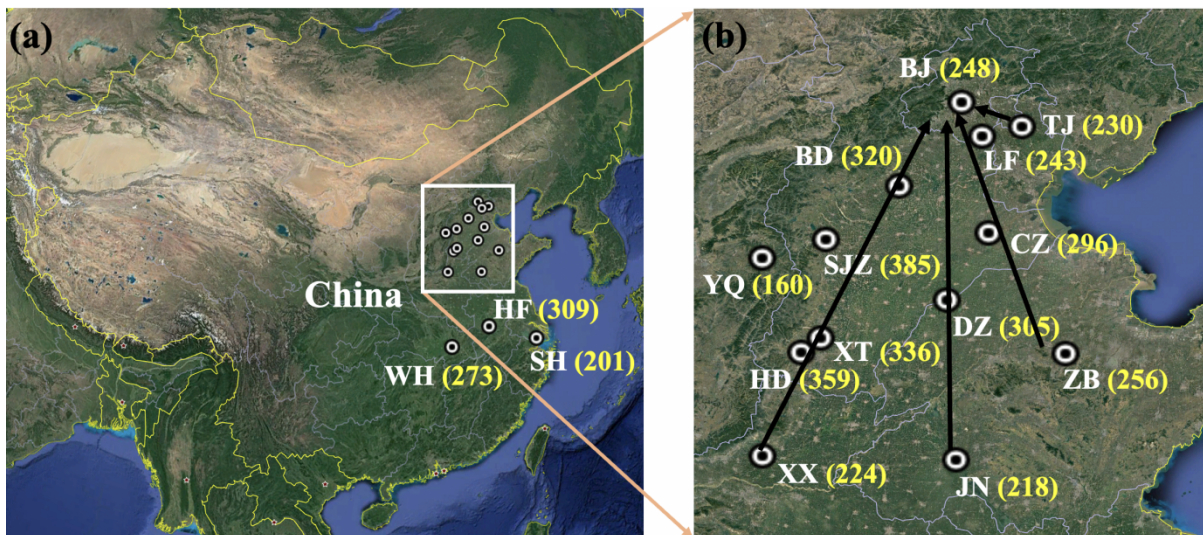

23 In this study, we analyzed the observation data from a vertical observation network  
24 consisting of 13 lidars and surface observation stations during an extreme pollution event in  
25 eastern China, especially in the NCP. Next, all of the data were utilized by the Gridpoint  
26 Statistical Interpolation (GSI) three-dimensional (3-D) variational (3DVAR) data assimilation  
27 system to revise the  $PM_{2.5}$  results from the WRF-Chem simulation (Pagowski et al. 2014).  
28 Finally, the multi-dimensional evolutionary characteristics of  $PM_{2.5}$  at the surface and in the  
29 vertical layer, as well as the 3-D distribution, were analyzed in detail. Although data  
30 assimilation has been applied in China using surface observation network data (Gao, Saide, et  
31 al. 2017), AOD (Saide et al. 2014; Saide et al. 2013; Schwartz et al. 2012; Liu et al. 2011), and  
32 lidar data (Cheng et al. 2019), to our knowledge, this is the first attempt in China to apply lidar  
33 network data to assimilation technology, from which the high-precision 3-D distribution of

1 pollutants can be provided, thus supplying effective data support for clarifying the formation  
2 mechanism of pollutants (Zheng et al. 2017).

## 3 2 Measurements and methods

### 4 2.1 Lidar observation network

5 The vertical aerosol observation network of the NCP was composed of 13 aerosol lidar  
6 monitoring stations (Fig. 1), covering four main transport channels of Beijing pollutants,  
7 including the southwestern transport path of Baoding City (BD), Shijiazhuang City (SJZ),  
8 Xingtai City (XT), Handan City (HD), Xinxiang City (XX), and Yangquan City (YQ); the  
9 southern transport path of Dezhou City (DZ) and Jining City (JN); the southeastern transport  
10 path of Langfang City (LF), Cangzhou City (CZ), and Zibo City (ZB); the eastern transport  
11 path of Tianjin City (TJ); and a lidar in the urban area of Beijing (BJ).

12  
13 **Figure 1.** © Google maps of (a) China with the studied cities and (b) the North China Plain with all the  
14 lidar stations. The data in brackets are the maximum PM<sub>2.5</sub> concentrations ( $\mu\text{g}\cdot\text{m}^{-3}$ ) at the surface during  
15 the observation period. The black arrows in (b, d) from left to right show that the main pollution  
16 pathways of Beijing come from the four directions of southwest, south, southeast, and east.

17 The lidar system was developed by the Anhui Institute of Optics and Fine Mechanics  
18 (AIOFM), Chinese Academy of Sciences (CAS), and was used for the long-term continuous  
19 observation of aerosol vertical distribution. The lidar system adopted the Nd: YAG laser, which  
20 emits a 532-nm wavelength, with 30-mJ single-pulse energy and 10–30-Hz pulse repetition  
21 frequency. The vertical resolution is 7.5 m, with the original time resolution of 3–10 min. The  
22 detection blind area is 0.1 km, and more specific technical details can be found in other  
23 literature (Xiang et al. 2019). The vertical distribution of the aerosol extinction coefficient was  
24 retrieved using the Fernald method (Fernald 1984), which is more suitable for vertical detection  
25 and more accurate than the Collis (Collis, Fernald, and Ligda 1964) and Klett (Klett 1981)

1 methods (Lu et al. 2015). Furthermore, combining the extinction coefficient with the PM<sub>2.5</sub> *in-*  
2 *situ* surface observations, the vertical distribution of the PM<sub>2.5</sub> mass concentration in the  
3 boundary layer was obtained using the empirical formula fitting method, which has proven to  
4 be reliable and highly accurate; the specific technical details can be found in other literature  
5 (Lv et al. 2017b; Tao et al. 2016; Lv et al. 2017a). In addition, an image recognition algorithm  
6 was used to evaluate the height of the atmospheric boundary layer (Xiang et al. 2019; Barrera  
7 et al. 2019).

## 8 **2.2 WRF-Chem model configurations**

9 The WRF-Chem chemical transport model (version 3.8.1) was used to investigate the  
10 particulate concentrations and meteorological parameters in the study area and was configured  
11 with nested domains consisting of 100 × 100 (36 km) and 103 × 103 (12 km) grids (Figs. S1).  
12 The domain had 41 vertical layers from the surface to 50 hPa. To better simulate the conditions  
13 within the boundary layer, the resolution of the boundary layer was increased, and 20 layers  
14 were set in the range of 0–2 km. The initial and boundary meteorological conditions were  
15 derived from the 6-h National Centers for Environmental Prediction Final Analysis data with  
16 1° × 1° spatial resolution. The inventory of anthropogenic emissions for 2016 was obtained  
17 from the Multi-resolution Emission Inventory for China (MEIC) data with 0.25° × 0.25°  
18 resolution (Zhou et al. 2017). Terrestrial biogenic emissions were estimated using the Model  
19 of Emissions of Gases and Aerosols from Nature (MEGAN) model (Chatani et al. 2011). The  
20 gas-phase chemistry module CBM-Z and the Model for Simulating Aerosol Interactions and  
21 Chemistry (MOSAIC) aerosol module were used in this simulation. Detailed information  
22 concerning the model configuration is provided in Table S1. The model runs from November  
23 20, 2017–December 9, 2017, and the results from November 25–December 9, 2017 were used  
24 for the analysis in Section 3.

## 25 **2.3 GSI 3DVAR DA system**

26 The GSI DA (Gridpoint Statistical Interpolation Data Assimilation) system provides  
27 3DVAR analysis by minimizing the cost function as shown below (Gao, Saide, et al. 2017):

$$28 \quad J(x) = (x - x_b)^T B^{-1} (x - x_b) + (y - H(x))^T R^{-1} (y - H(x)) \quad (1)$$

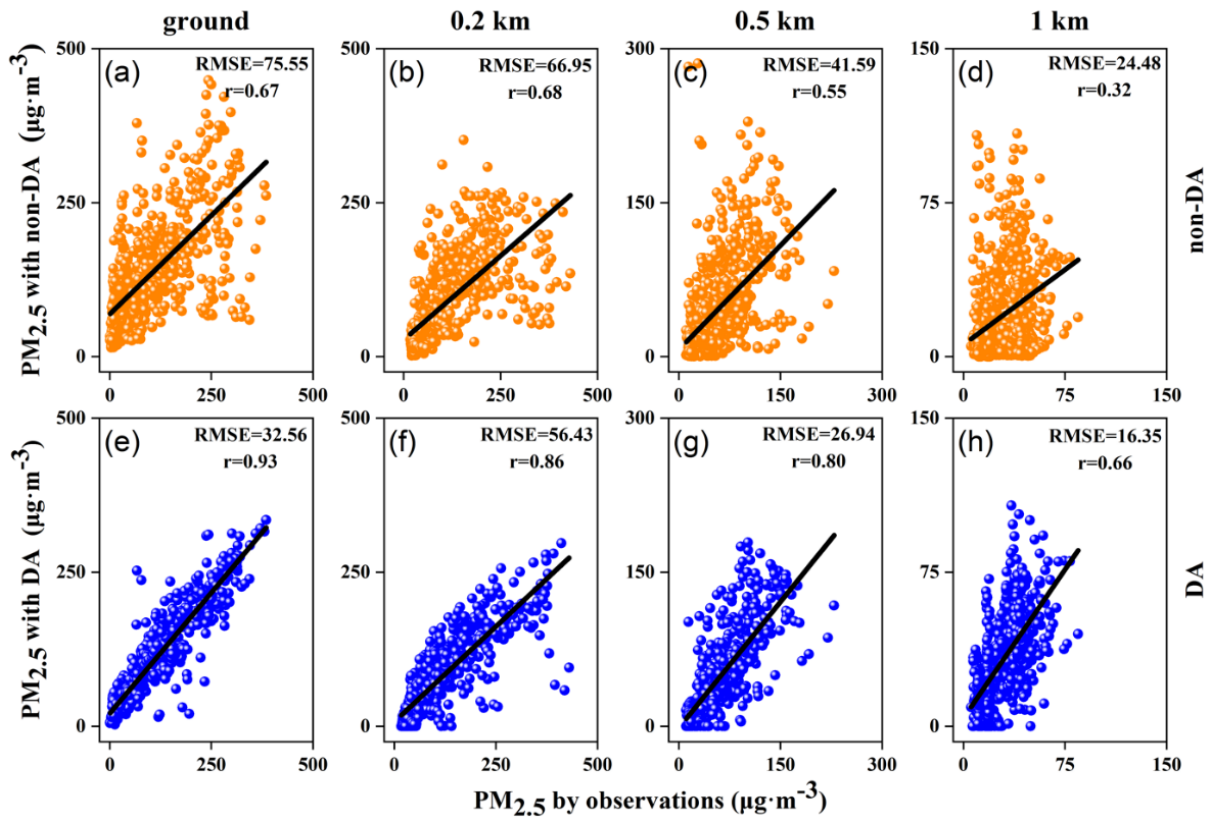

29 In this equation,  $x$  is the analysis vector,  $x_b$  denotes the background vector,  $y$  is an observation  
30 vector,  $B$  represents the background error covariance matrix,  $R$  represents the observation error  
31 covariance matrix, and  $H$  is the observation operator used to transform model grid point values  
32 to observed variables, which was performed via interpolation in our research. The background  
33 error covariance matrix was calculated using the National Meteorological Center (NMC)

1 method (Parrish and Derber 1992; Saide et al. 2013), which simulated the difference of results  
2 at the same time (November 25, 2017) with two different starting times (November 20, 2017  
3 and November 21, 2017, respectively). The 1-hour assimilated window data included 13  
4 groups (see Fig. 1 for site distribution) of PM<sub>2.5</sub> vertical profiles retrieved from lidar, and the  
5 surface PM<sub>2.5</sub> data from hundreds of surface monitoring stations (see Fig. 5 for site distribution)  
6 from the China Environmental Monitoring Center. The observation errors of PM<sub>2.5</sub> ground and  
7 its vertical distribution (through the ground PM<sub>2.5</sub> fitting method in Section 2.1) originated  
8 from measurement errors and representative errors. The measurement error was computed  
9 using  $\varepsilon_0 = 1.5 + 0.0075 * obs$  (Pagowski et al. 2014), where *obs* indicates observed values.  
10 The representative error was computed using  $\varepsilon_r = \gamma \varepsilon_0 \sqrt{\Delta x / L}$  (Elbern et al. 2007), where  $\gamma$  is  
11 the adjustable scale factor (we used the value of 0.5 recommended by the GSI system),  $\Delta x$  is  
12 the model grid resolution (we selected 12 km of domain 2), and  $L$  is the influencing radius (we  
13 used 60 km).

### 14 **3 Results and discussion**

#### 15 **3.1 Evaluation of assimilation performance using vertical PM<sub>2.5</sub> data**

16 In order to evaluate the improvement of model simulation performance from data  
17 assimilation using lidar vertical profile data and surface station data, considering the sharp  
18 decline of PM<sub>2.5</sub> value at 1 km height (Fig. 6), only the non-assimilation and assimilation results  
19 at the surface, 0.2 km, 0.5 km, and 1 km were compared, as shown in Fig. 2. These data were  
20 selected from five of the most polluted stations, including the cities of TJ, LF, BD, SJZ, and  
21 XT. It should be noted that these observation data were not assimilated, which means that the  
22 following comparisons are independent (Bocquet et al. 2015). Obviously, the data assimilation  
23 used can greatly improve the simulation accuracy. Compared with the observation data at  
24 different heights (ground, 0.2, 0.5 and 1 km), the simulation results of PM<sub>2.5</sub> levels under the  
25 condition of non-assimilation were higher (Figs. 2 a–d), the root-mean-square error (RMSE)  
26 was  $52.14 \pm 20.27 \mu\text{g}\cdot\text{m}^{-3}$ , and the correlation coefficient was only  $0.56 \pm 0.15$ .  
27 Correspondingly, the results of PM<sub>2.5</sub> simulated with assimilation were closer to the observed  
28 values (Figs. 2 e–h), the RMSE was  $33.07 \pm 14.69 \mu\text{g}\cdot\text{m}^{-3}$ , which represents a reduction of  
29 about 40% in simulation error after assimilation. The correlation coefficient was  $0.81 \pm 0.10$ ,  
30 demonstrating that the simulation accuracy was improved by about 50% after assimilation.

1

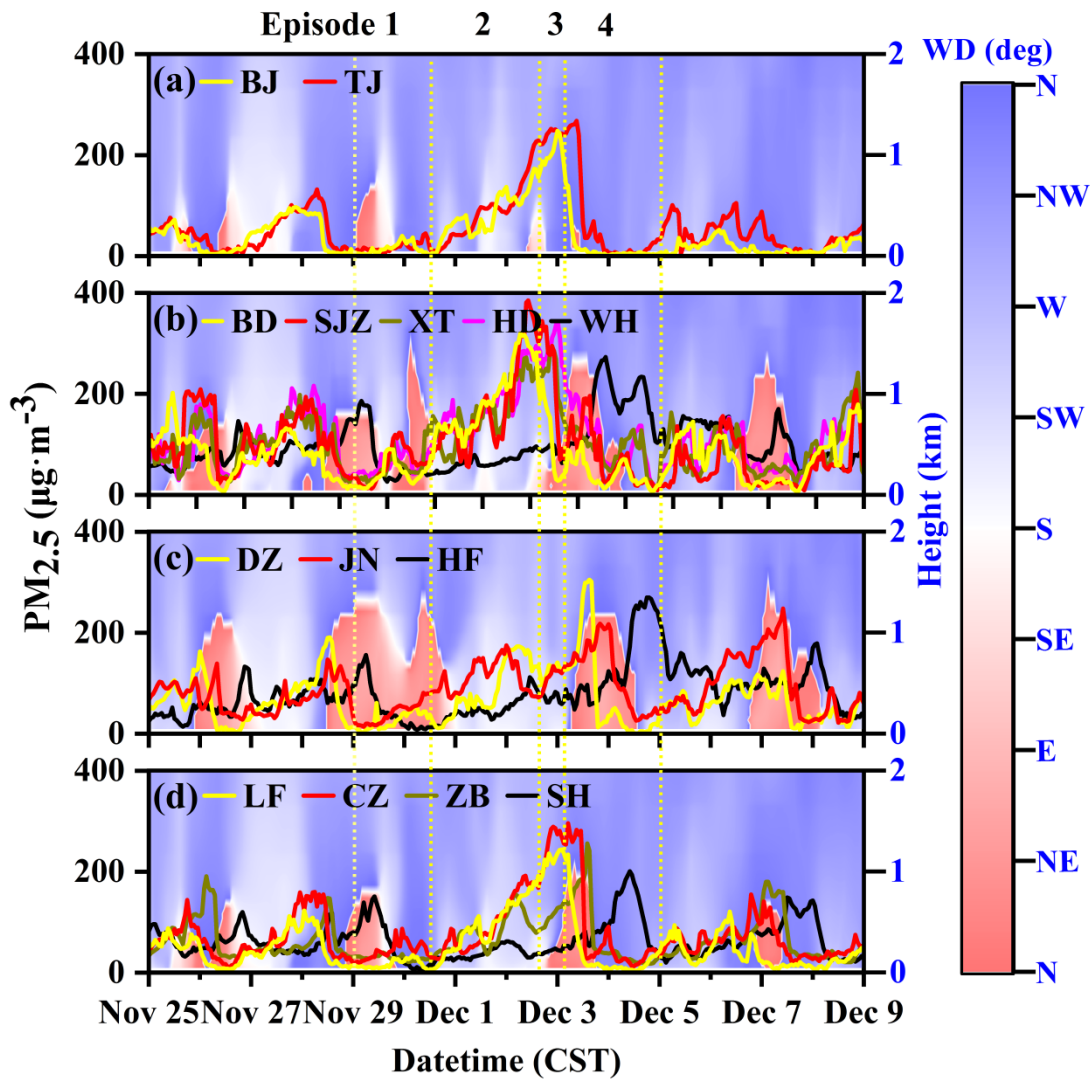

2 **Figure 2.**  $\text{PM}_{2.5}$  mass concentration comparison results from lidar at different heights (b–d, f–h) and  
 3 surface observations (a, e) with non-assimilation simulations (a–d) and assimilation simulations (e–h).

4 In addition, compared with the simulation with assimilation (Fig. 5 in Section 3.3), the  
 5 results without assimilation were significantly higher than the observed values (Fig. S2),  
 6 especially during the pollution period (Figs. S2d, S2e), which may be due to the simulation  
 7 error caused by the model (Zhang et al. 2016). Meanwhile, the comparison of the three-  
 8 dimensional results (Fig. 7 in Section 3.5 and Fig S3) further reveals that the simulation results  
 9 of upper air  $\text{PM}_{2.5}$  may also overestimate the actual values, which demonstrates the importance  
 10 of data assimilation in capturing the three-dimensional structure of pollution.

### 11 3.2 The four phases from aerosol pollution development to dissipation

12 Joint observations and analyses have been widely performed in an effort to reveal the  
 13 heavy aerosol pollution (HAP) in the NCP region (Li et al. 2016; Zhang et al. 2018). The key  
 14 processes of a HAP event, from aerosol pollution development to dissipation, usually include  
 15 an early phase (EP), a transport phase (TP), an accumulation phase (AP), and a removal phase  
 16 (RP) (Yuan et al. 2019; Zhong et al. 2017), classifications that are based on the increase and  
 17 decrease of  $\text{PM}_{2.5}$  mass concentration in Beijing (BJ) caused by changes in meteorological  
 18 conditions. Here, the curves in Fig. 3 shows the temporal evolution of  $\text{PM}_{2.5}$  mass concentration  
 19 monitored at the surface in different cities on the NCP from November 25–December 9, 2017,

1 while the superimposed colors represent the time-varying profiles of the simulated wind fields  
 2 in BJ, Baoding (BD), Dezhou (DZ), and Langfang (LF), respectively. Overall, PM<sub>2.5</sub> with high  
 3 concentrations was usually associated with pronounced southerly winds (S in Fig. 3) or  
 4 southwesterly winds (SW in Fig. 3), while the PM<sub>2.5</sub> concentrations decreased significantly  
 5 under the prevailing northerly winds (including the wind directions of N, NW, and NE in Fig.  
 6 3).

7  
 8 **Figure 3.** Surface PM<sub>2.5</sub> observations from different cities: (a) Beijing (including Tianjin) and its (b)  
 9 southwest cities, (c) southeast cities, and (d) east cities for the period November 25–December 9, 2017.  
 10 Superimposed colors represent the time-varying profiles of the simulated wind fields in Beijing,  
 11 Baoding, Dezhou, and Langfang, respectively.

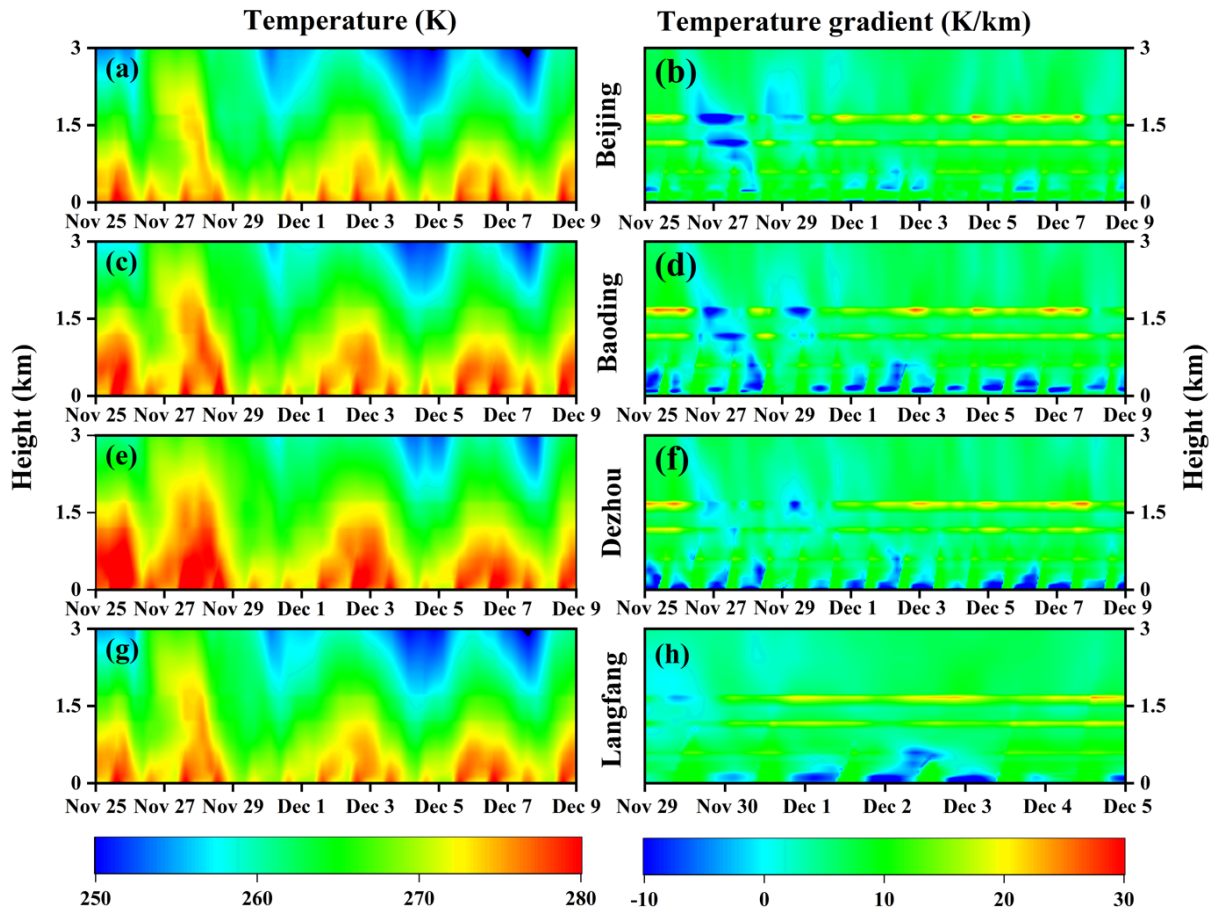

12 Furthermore, in order to characterize the evolution of PM<sub>2.5</sub> during different pollution  
 13 phases, the period from November 29–December 5 was selected as a typical extreme HAP  
 14 event covering the four pollution phases. This extreme pollution event lasted more than 4 days  
 15 and featured a regional transport process. During the EP (November 29–noon November 30;

1 episode 1 in Fig. 3), the air quality in BJ and its surrounding areas such as Tianjin (TJ) was  
2 relatively good, with an average  $\text{PM}_{2.5}$  value of  $\sim 15 \mu\text{g}\cdot\text{m}^{-3}$ , while slight pollution occurred to  
3 the southwest of BJ, including BD, Shijiazhuang (SJZ), Xingtai (XT), and Handan (HD), with  
4 an average value of  $\sim 50 \mu\text{g}\cdot\text{m}^{-3}$ .

5 During the TP (approximately the morning of December 2; episode 2 in Fig. 3), the  
6 variation of  $\text{PM}_{2.5}$  concentration was more sensitive and responded rapidly to the wind shift  
7 from northerly to southerly, causing the  $\text{PM}_{2.5}$  concentration in Beijing to increase quickly from  
8  $\sim 30 \mu\text{g}\cdot\text{m}^{-3}$  to  $\sim 150 \mu\text{g}\cdot\text{m}^{-3}$ , while southwest of Beijing (e.g., BD, SJZ, XT, and HD) the  $\text{PM}_{2.5}$   
9 concentration increased rapidly to  $\sim 200 \mu\text{g}\cdot\text{m}^{-3}$ . Research has revealed that the pollutant  
10 transport south of Beijing, especially in the southwest areas (the Taihang Mountains), is the  
11 most important contribution source of Beijing pollutants (Zhao et al. 2020). During the AP  
12 (approximately December 3; episode 3 in Fig. 3), diffusion of the pollutants was difficult due  
13 to the occurrence of a surface temperature inversion in Beijing (Fig. 4) (Wang et al. 2019),  
14 which caused the maximum concentration of  $\text{PM}_{2.5}$  in Beijing to reach  $\sim 250 \mu\text{g}\cdot\text{m}^{-3}$ .  
15 Meanwhile, the  $\text{PM}_{2.5}$  concentrations in TJ, LF, BD, and SJZ reached maximum values of  $\sim 270$ ,  
16 250, 320, and  $390 \mu\text{g}\cdot\text{m}^{-3}$ , respectively. Conversely, the pollution levels in Shanghai (SH),  
17 Hefei (HF), and Wuhan (WH) in the southernmost section of the NCP were relatively low,  
18 with average values  $< \sim 60 \mu\text{g}\cdot\text{m}^{-3}$ .

19 During the RP (approximately December 5; episode 4 in Fig. 3), the wind direction  
20 shifted from southwest to north, transporting the relatively clean air in the north to the south,  
21 and thereby causing the pollutant concentrations in Beijing to decrease rapidly. In just 9 hours,  
22 the air quality improved from heavy pollution to excellent, and the  $\text{PM}_{2.5}$  concentrations in the  
23 NCP also decreased significantly. Finally, by noon on December 4, the pollutant concentrations  
24 in the NCP had reached a low level, with an average value of  $\sim 40 \mu\text{g}\cdot\text{m}^{-3}$ . In contrast, due to  
25 the continuous southward advection of pollutants, serious pollution occurred in SH, HF, and  
26 WH, where the  $\text{PM}_{2.5}$  concentrations reached maximum values of  $\sim 210$ , 310, and  $280 \mu\text{g}\cdot\text{m}^{-3}$ ,  
27 respectively. These findings are also consistent with the results of previous studies on the  
28 regional transport of regional pollutants to the Yangtze River Delta (Hua et al. 2015), which  
29 showed them to be due to the continuous southward flow of northwest and northeast winds.

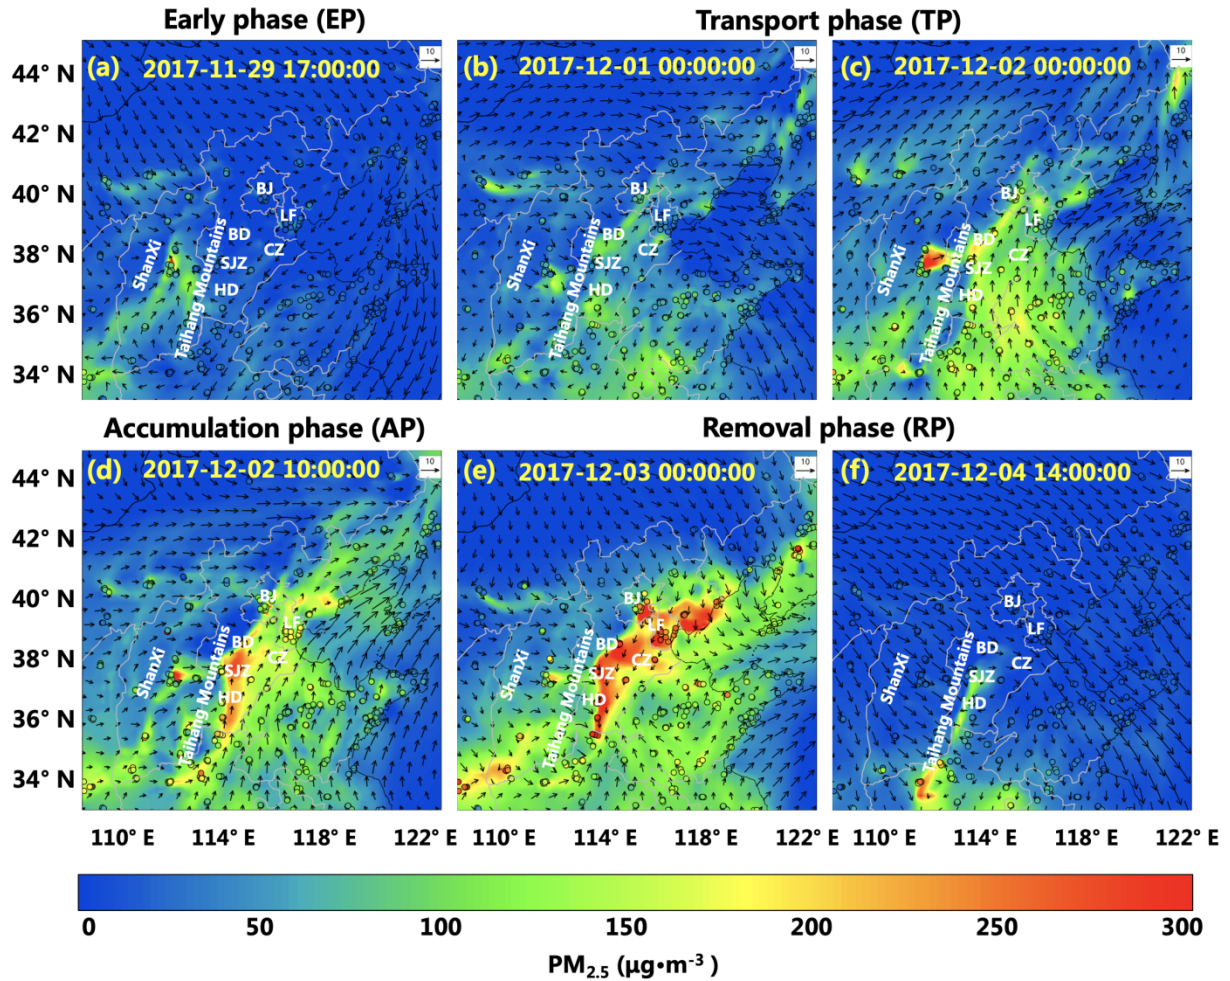

1  
2 **Figure 4.** Time series of vertical temperatures (a, c, e, g) and temperature gradients (b, d, f, h) from  
3 Beijing (a, b), Baoding (c, d), Dezhou (e, f), and Langfang (g, h) simulated by the WRF-Chem model.

### 4 **3.3 Spatial distribution of PM<sub>2.5</sub> concentration in the surface layer**

5 Additionally, in order to analyze the pollution characteristics of the NCP, the spatial  
6 distribution results of PM<sub>2.5</sub> after data assimilation were plotted in Fig. 5 for all phases. The  
7 high concentrations of PM<sub>2.5</sub> in BJ were recorded during the TP, AP, and beginning of the RP,  
8 while the PM<sub>2.5</sub> concentrations at other times were lower. Moreover, during the EP, only the  
9 eastern cities of Shanxi (SX) Province experienced moderate pollution levels (Fig. 5a). During  
10 the TP, the pollutants in the south-central NCP were transported to the north of the NCP (Figs.  
11 5b and c) as a result of the southwesterly wind field, and under the superposition of the local  
12 pollutant emissions from each city (Li, Du, et al. 2017), the cities on the windward side of the  
13 Taihang Mountains (e.g., HD, SJZ, and BD) quickly developed varying levels of heavy  
14 pollution. In addition, during the AP, due to the large-scale inversion (Figs. 4b, d, f, h) caused  
15 by the rapid temperature rise (Figs. 4a, c, e, g) of the NCP region at upper levels, the  
16 atmospheric stratification was stable, causing the pollutant loading on the NCP (including BJ,  
17 BD, SJZ, HD, LF, CZ, and elsewhere) to increase (Fig. 5d), nearly reaching their pollution  
18 maxima (Fig. 3). Meanwhile, during the RP, affected by the cold air at upper levels (Figs. 4a,

1 c, e, g) from the northwest and the shift in wind direction over the NCP from southwest to  
 2 north, the pollution severity gradually eased from north to south (Fig. 5e), with the air quality  
 3 in the northern part of the region improving significantly (Fig. 5f).

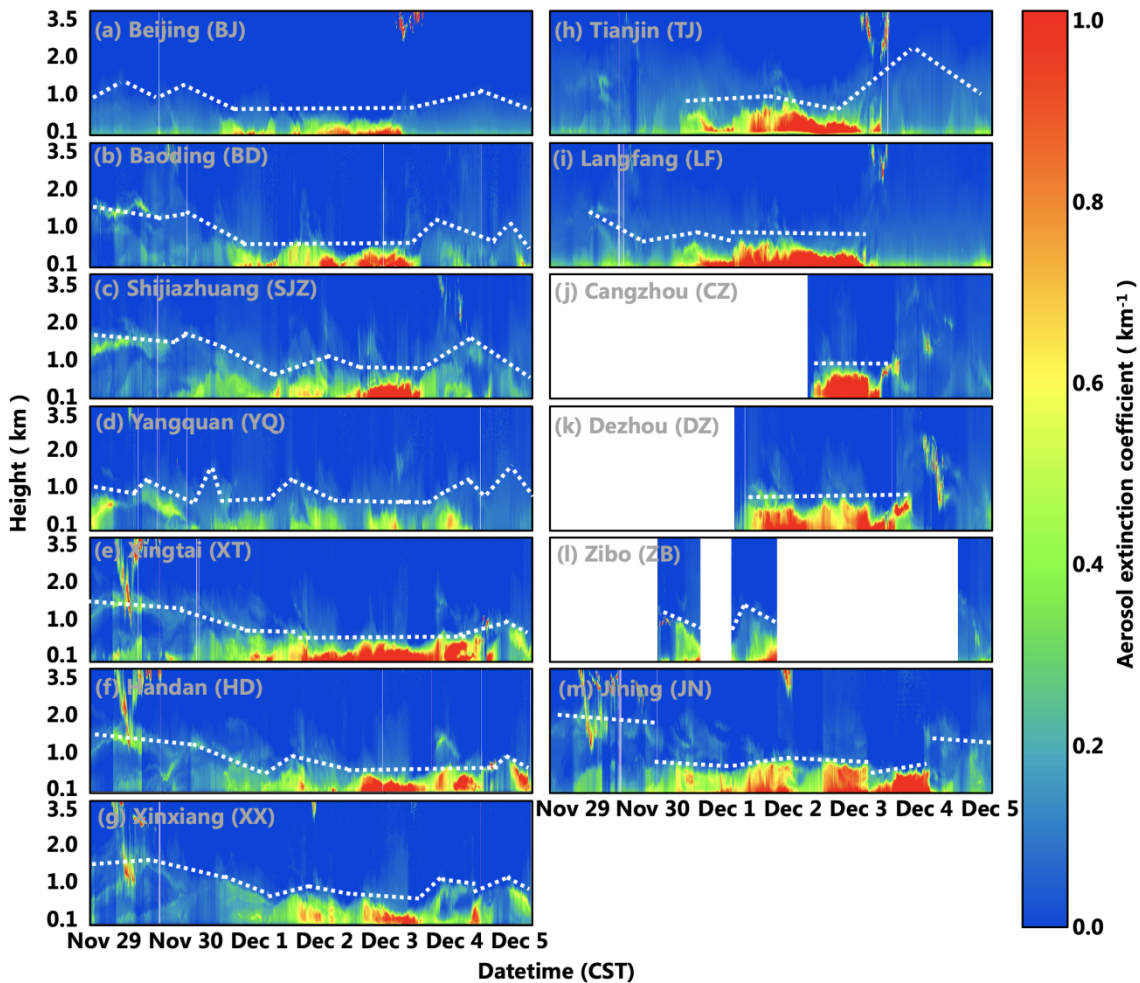

4  
 5 **Figure 5.** Spatial distribution of PM<sub>2.5</sub> in the surface layer during different phases after assimilation.  
 6 The black arrows indicate the wind direction. The circles represent the *in-situ* surface observations.

### 7 3.4 Vertical distribution of aerosols observed by the lidar network

8 In order to quantify the characteristic vertical distribution of aerosols, the observed  
 9 aerosol extinction coefficients from the 13 lidar stations in the NCP were plotted, as shown in  
 10 Fig. 6. These results revealed that on November 29, the aerosol concentration at the surface  
 11 was relatively low, although pollutant transport at heights of 1–2 km (see Figs. 8a, e) occurred  
 12 at six stations (BD, SJZ, YQ, XT, HD, and XX) on the windward side of the Taihang Mountains.  
 13 Figure S4 demonstrates that these pollutants in the upper air come from the local emissions on  
 14 the ground, which is due to the updraft lifting to 1-2 km above the ground on the night of  
 15 November 28. The upper air transport of pollutants continued until December 1, at which it  
 16 merged with the surface flow. Contrary to this, the pollutant transport from north to south  
 17 occurred at a height of 1 km during the RP (e.g., Figs. 6b, d–g). In addition, the atmospheric

1 boundary layer height (ABLH) reached its highest value of the observation period from  
 2 November 29 to 30, averaging more than 1.5 km. The ABLH began to decrease on December  
 3 1, averaging approximately 1 km on that day. The lowest value of the ABLH occurred on  
 4 December 2–3, when its average dropped to less than 0.5 km, making it difficult for pollutants  
 5 to diffuse and causing heavy pollution in the NCP (Li, Guo, et al. 2017). Fortunately, on  
 6 December 4, the atmospheric boundary layer gradually lifted, which was conducive to the  
 7 diffusion of pollutants.

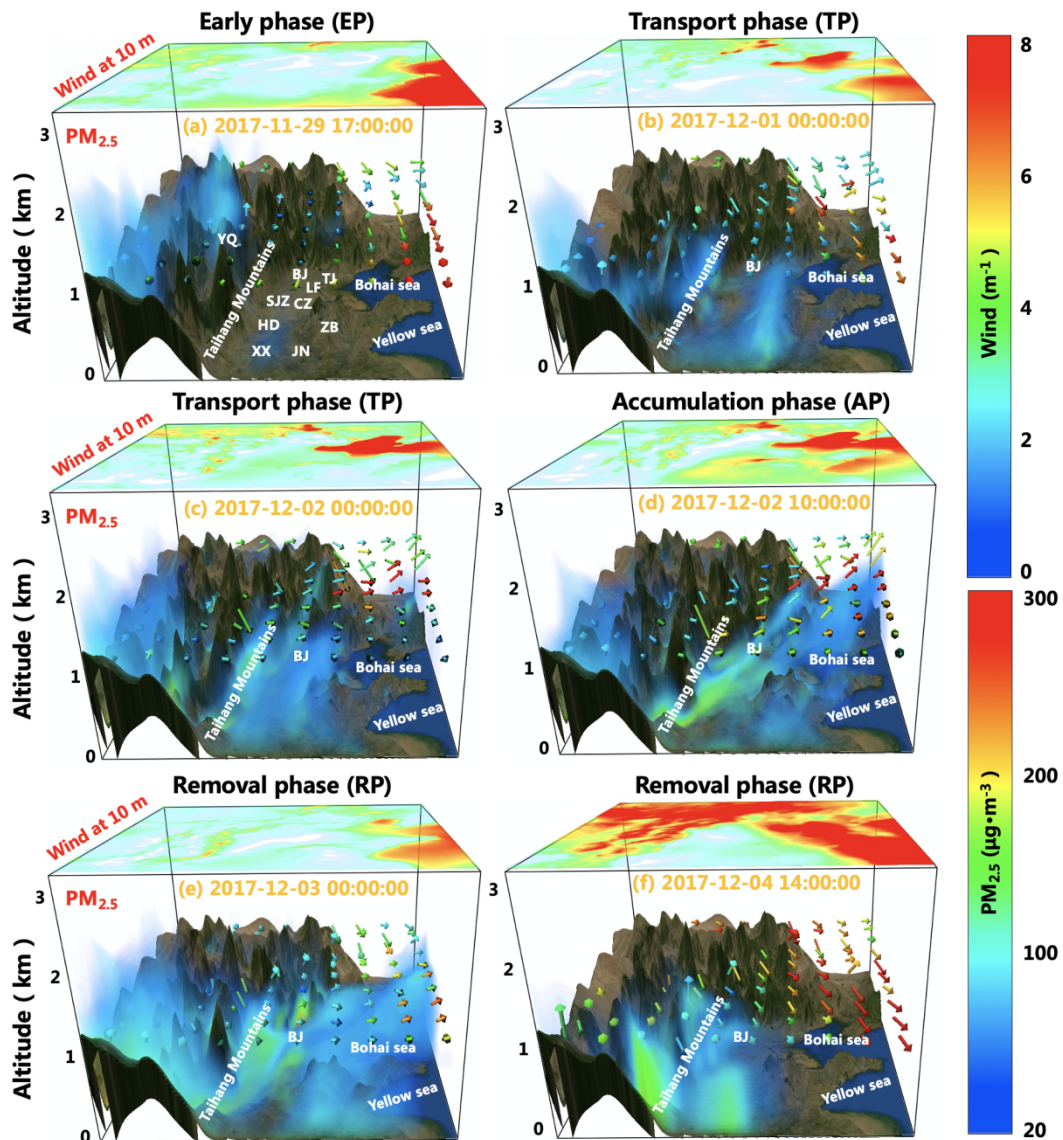

8  
 9 **Figure 6.** Time series of vertical distributions of the aerosol extinction coefficient observed on the  
 10 North China Plain from November 29–December 5, 2017. The white dashed lines represent the  
 11 approximate atmospheric boundary layer height. Missing datasets are plotted in white.

### 12 3.5 Dynamic 3-D evolution of the PM<sub>2.5</sub> concentrations

13 Figure 7 presents the 3-D distribution of PM<sub>2.5</sub> after assimilation, which clearly shows  
 14 the generation, dissipation, transport, and diffusion characteristics of pollutants in the  
 15 atmosphere. The tops of the boxes in the figure depict the wind speeds 10 m above the surface.  
 16 During the EP, the high-concentration pollutants only occurred in the upper air within ~1 km  
 17 of the surface in SX Province (e.g., YQ). During the TP, the high-concentration pollutants were

1 mainly found on the windward side of the Taihang Mountains (southwest pathway), and the  
 2 loading height of  $PM_{2.5}$  was  $< 1$  km, which is illustrated in Fig. 8. During the AP, the average  
 3 concentration of pollutants  $> 200 \mu\text{g}\cdot\text{m}^{-3}$  mainly occurred near the surface. Meanwhile, the  
 4 pollutants with low concentrations at upper levels could be transported to the Bohai Sea.  
 5 During the RP, high-concentration pollutants  $> 100 \mu\text{g}\cdot\text{m}^{-3}$  simultaneously occurred over the  
 6 Bohai Sea and the Yellow Sea.

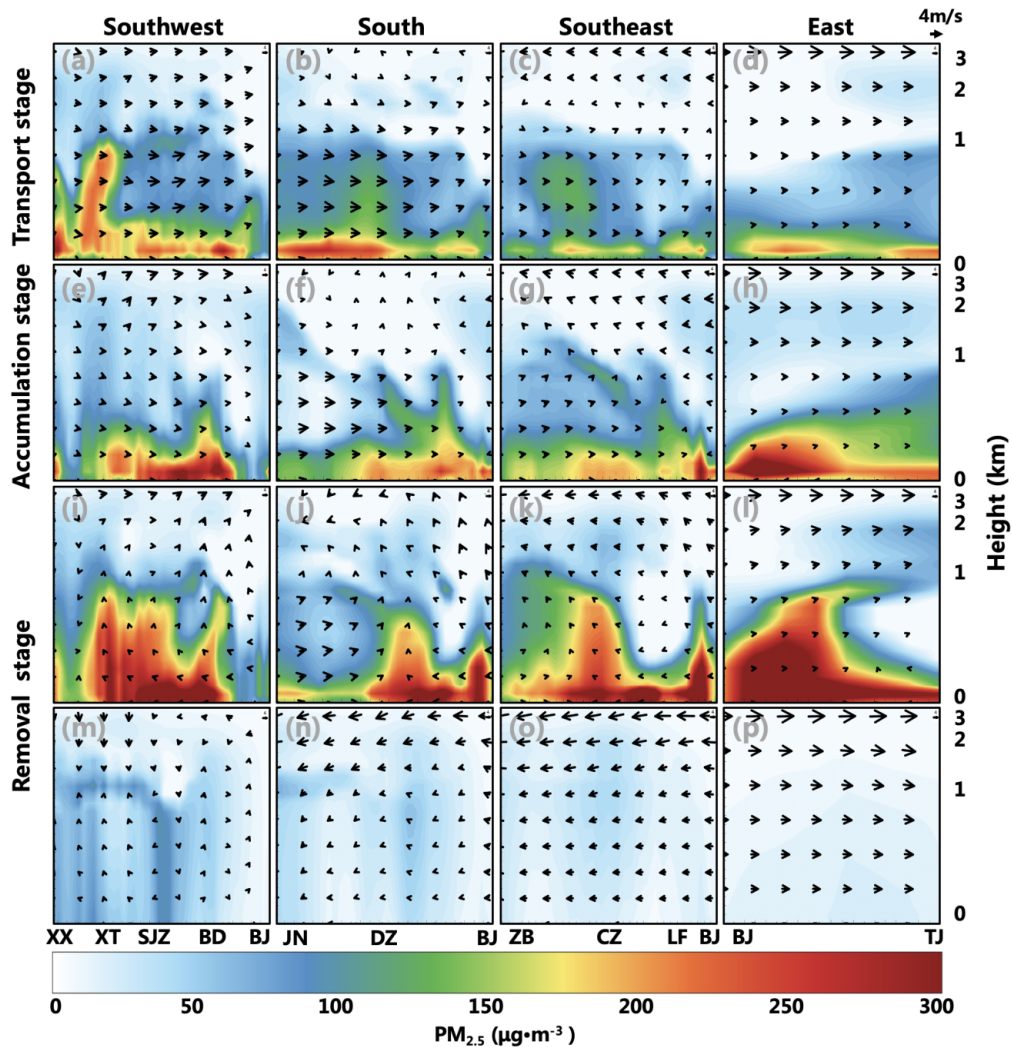

7  
 8 **Figure 7.** Three-dimensional distribution of  $PM_{2.5}$  during different phases after assimilation. Colors  
 9 within the boxes depict the  $PM_{2.5}$  concentrations. The color-coded arrows represent the wind direction  
 10 and speed at 1 km. On the tops of the boxes, the spatial distributions of wind speed at 10 m are plotted.

### 11 3.6 Quantification of regional transport of $PM_{2.5}$

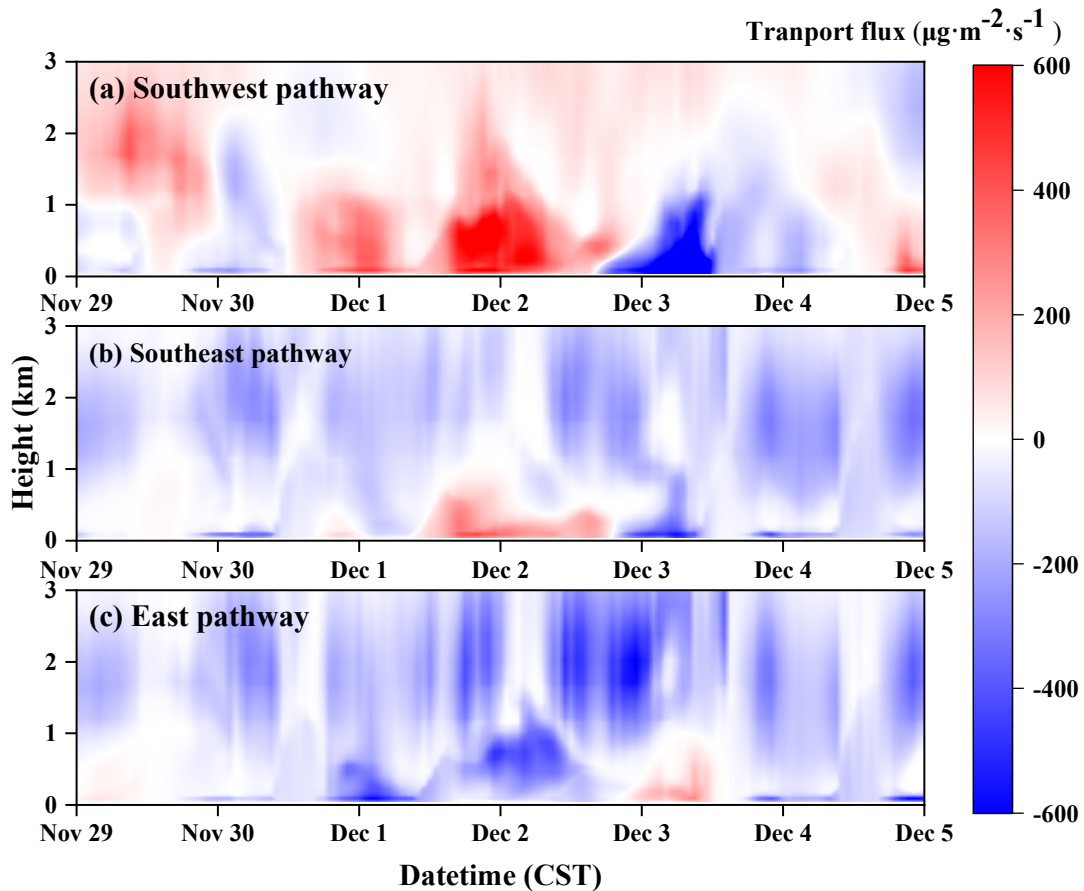

12 To evaluate the variation of pollutants along different transport pathways at different  
 13 stages, we plotted the vertical profile of the  $PM_{2.5}$  cross-section along the main pollution  
 14 pathways of Beijing coming from the four directions of southwest, south, southeast, and east

1 (see Figs. 1b, d). As shown in Fig.8, at XX and XT (located at the start of the southwest  
 2 transport pathway, Fig. 8a), the PM<sub>2.5</sub> concentration is more than 200  $\mu\text{g}\cdot\text{m}^{-3}$  at a height of 1  
 3 km (Fig. 8a), and the surface PM<sub>2.5</sub> concentration at JN (located in the south pathway) also  
 4 exceeds 200  $\mu\text{g}\cdot\text{m}^{-3}$  (Fig. 8b). These high concentrations of pollutants were transported to SJZ,  
 5 BD, LF, BJ, and other cities via southwest winds (Figs. 8e, f, g). At the same time, vertical  
 6 downdrafts reduced the height of loading of aerosol layer to  $\sim 0.6$  km (Fig. 8e). Different from  
 7 the southern (including southwest, south, and southeast) transport pathways, the pollutants in  
 8 TJ were mainly from BJ outflow in all stages of the eastern transport pathways (Figs. 8d, h, l,  
 9 p). In addition, wind direction inconsistencies at the origin (XX, JN, and ZB) and target location  
 10 (Beijing) of the transport pathways occurred at the beginning of the removal phase (Figs. 8i–  
 11 k), which may have been due to the southward delay of the northerly air flow.

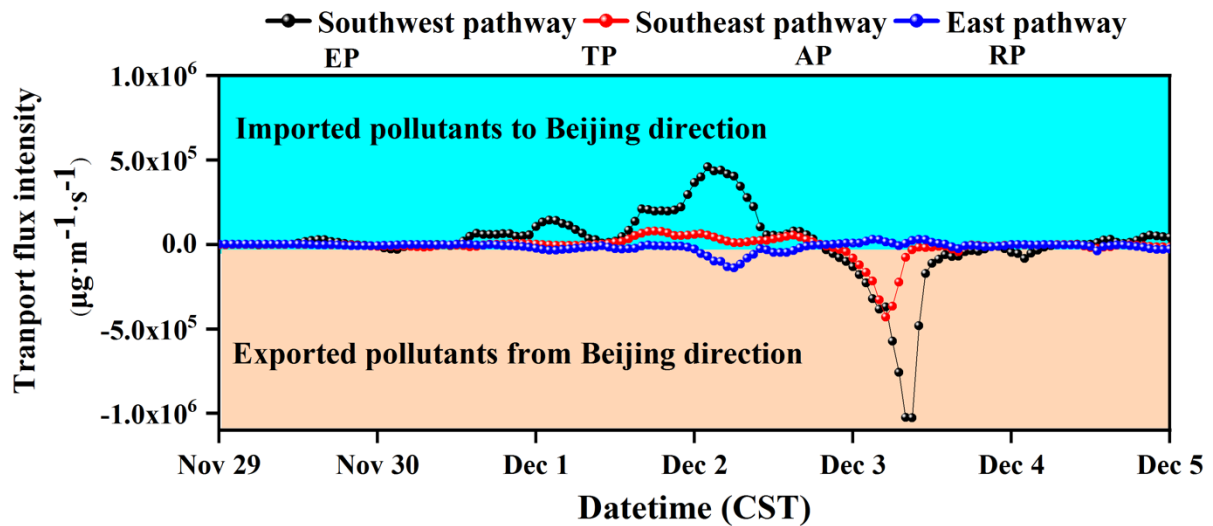

12  
 13 **Figure 8.** Vertical profiles of PM<sub>2.5</sub> cross-sections with wind vectors along the transport pathways,  
 14 including southwest (first column), south (second column), southeast (third column), and east (fourth  
 15 column). The first row (00:00 December 2, 2017) represents the transport stage, the second row (10:00  
 16 December 2, 2017) represents the accumulation stage, the third row (00:00, December 3, 2017) and the  
 17 fourth row (14:00, December 4, 2017) represent the removal stage.

1 To investigate the vertical variation of PM<sub>2.5</sub> inflow or outflow at different heights and  
 2 determine the height at which the main transport occurred (Zhang, Cheng, et al. 2019), we  
 3 plotted the vertical distribution of PM<sub>2.5</sub> transport flux in different directions (Fig. 9). Here the  
 4 PM<sub>2.5</sub> transport flux is defined as the product of PM<sub>2.5</sub> mass concentration ( $\mu\text{g m}^{-3}$ ), wind speed  
 5 ( $\text{m s}^{-1}$ ), and wind direction projection in the current pathway (Xiang et al. 2020). The southwest,  
 6 southeast, and east pathways in Fig. 9 were represented by BD, LF, and TJ, respectively, which  
 7 are the three lidar stations closest to BJ (Fig. 1).  $\text{TF} > 0$  indicates that the pollutants were  
 8 imported to Beijing, while  $\text{TF} < 0$  indicates that the pollutants were exported from Beijing. The  
 9 results revealed that below the height of 3 km, the order of the maximum values of imported  
 10 pollutants to Beijing direction was southwest pathway ( $1122.8 \mu\text{g m}^{-2} \text{s}^{-1}$ ) > southeast pathway  
 11 ( $423.6 \mu\text{g m}^{-2} \text{s}^{-1}$ ) > east pathway ( $278.3 \mu\text{g m}^{-2} \text{s}^{-1}$ ), while the exported pollutants from Beijing  
 12 direction was southwest pathway ( $-1571.4 \mu\text{g m}^{-2} \text{s}^{-1}$ ) > east pathway ( $-877.7 \mu\text{g m}^{-2} \text{s}^{-1}$ ) >  
 13 southeast pathway ( $-772.4 \mu\text{g m}^{-2} \text{s}^{-1}$ ). Compared with the PM<sub>2.5</sub> transport flux on the ground  
 14 surface, the relatively high value ( $\sim 200 \mu\text{g m}^{-2} \text{s}^{-1}$ ) in the southwest pathway (Fig. 9a) occurred  
 15 on November 29 and early morning on December 4, while the relatively extreme value ( $\sim -400$   
 16  $\mu\text{g m}^{-2} \text{s}^{-1}$ ) on the east pathway (Fig. 9c) was recorded at the night of December 2.

17  
 18 **Figure 9.** Time series of PM<sub>2.5</sub> transport flux from different transport pathways. The corresponding  
 19 directions of the southwest, southeast, and east pathways are shown in Fig. 1.

1 To further obtain insights into the total transport characteristics in the target area (BJ)  
 2 and its surrounding area (BD, LF, and TJ) during different evolutionary stages, the time series  
 3 of the PM<sub>2.5</sub> transport flux intensity (TFI) was shown in Fig. 10. The TFI was calculated by  
 4 integrating the PM<sub>2.5</sub> transport flux from the ground to a certain height, and the height was  
 5 selected as 1.5 km, which is consistent with the main transport height of pollutants (Fig. 8) and  
 6 the height of the boundary layer (Fig. 7). The TFI of PM<sub>2.5</sub> further reveals that pollutants  
 7 imported into the Beijing area with a maximum PM<sub>2.5</sub> TFI of  $\sim 4.6 \times 10^5 \mu\text{g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$  were  
 8 transported mainly via the southwest pathway during the TP, while the extreme TFI of  
 9 pollutants exported from Beijing via the east pathway was approximately  $-1.4 \times 10^5 \mu\text{g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$ .  
 10 In addition, during the RP, the pollutants from Beijing were exported to the southwest and  
 11 southeast, with extreme values of approximately  $-1.03 \times 10^6$  and  $-4.3 \times 10^5 \mu\text{g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$ ,  
 12 respectively. In contrast, the absolute value of TFI on the southwest pathway was  $< \sim 1.0 \times 10^4$   
 13  $\mu\text{g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$  during the EP (Fig. 10), which indicates that there was no significant inflow or  
 14 outflow of pollutants. However, this reason was mainly due to the offsetting of the inflow of  
 15 pollutants in the upper-air and the outflow of pollutants near the ground (Fig. 9a). This special  
 16 phenomenon also demonstrates that the study of vertical distribution of pollutants has great  
 17 significance, which can better explain the transport characteristics (Zhang, Cheng, et al. 2019).

18  
 19 **Figure 10.** Time series of PM<sub>2.5</sub> transport flux intensity from different transport pathways. The  
 20 corresponding directions of the southwest, southeast, and east pathways are shown in Fig. 1.

## 21 4 Conclusions

22 Accurate quantification of the distribution of particulate matter in the atmosphere is a  
 23 key requirement for predicting air quality and estimating atmospheric environmental capacity  
 24 from atmospheric observations. We utilized a vertical observation network composed of 13

1 aerosol lidars, combined with data assimilation technology, to improve the simulation accuracy  
2 of PM<sub>2.5</sub>, and further analyzed the multi-dimensional evolutionary characteristics of pollutants  
3 in the surface layer, vertical layer, and 3-D space, thereby providing effective data support for  
4 clarifying the spatial transport characteristics of heavy pollution.

5 We found that the average height of the atmospheric boundary layer was < 0.5 km  
6 during the HAP period. We further demonstrated that the transport of pollutants in the NCP  
7 region was mainly via three pathways: southwest, southeast, and east. During the TP, the PM<sub>2.5</sub>  
8 advected into Beijing with a maximum transport flux intensity (TFI) of  $\sim 4.6 \times 10^5 \mu\text{g} \cdot \text{m}^{-1} \cdot \text{s}^{-1}$   
9 was mainly via the southwest pathway, while the polluted air mass in the RP dissipated from  
10 Beijing via the southwest and southeast pathways, with extreme PM<sub>2.5</sub> TFI values of  
11 approximately  $-1.03 \times 10^6$  and  $-4.3 \times 10^5 \mu\text{g} \cdot \text{m}^{-1} \cdot \text{s}^{-1}$ , respectively. In addition, the transport of  
12 regional pollutants to the Yangtze River Delta was due to the continuous southward flow of  
13 northwest and northeast winds. Our results directly revealed that pollutants in the North China  
14 Plain can be transported to the Yellow Sea and the Bohai Sea, providing a dataset for a further  
15 in-depth study of the mechanism of air pollution in the coastal areas of eastern China. This  
16 study also captured the regional transport of air pollutants stretching over 1000 km, proving  
17 the necessity and importance of the joint prevention and control of regional air pollution.

## 18 **Data availability**

19 The FNL data are available from the following website  
20 (<https://rda.ucar.edu/datasets/ds083.2/>). The data in this study are analyzed using the NCAR  
21 Command Language (<http://www.ncl.ucar.edu/>). The authors are gratefully acknowledging the  
22 China National Environmental Monitoring Center for providing monitoring data for the PM<sub>2.5</sub>  
23 (<http://106.37.208.233:20035>). The lidar data in this study are available upon request from the  
24 corresponding author (yxiang@ahu.edu.cn).

## 25 **Author contributions**

26 YX and TZ designed this study. YX wrote the manuscript; YC and CM edited it. LL  
27 and TZ helped to analyze the data. YC, CM, WL, and JL provided constructive comments on  
28 this study. All authors contributed to the discussion and final version of the manuscript.

## 29 **Competing interests**

30 The authors declare that they have no conflict of interest.
