10 **Abstract.** For decades, measured ice crystal number concentrations have been found to be orders
11 of magnitude higher than measured ice nucleating particle number concentrations in moderately
12 cold clouds. This observed discrepancy reveals the existence of secondary ice production (SIP) in
13 addition to the primary ice nucleation. However, the importance of SIP relative to primary ice
14 nucleation remains highly unclear. Furthermore, most weather and climate models do not represent
15 well the SIP processes, leading to large biases in simulated cloud properties. This study
16 demonstrates a first attempt to represent different SIP mechanisms (frozen raindrop shattering, ice-
17 ice collisional break-up, and rime splintering) in a global climate model (GCM). The model is run
18 in the single column mode to facilitate comparisons with the Department of Energy (DOE)'s

19 Atmospheric Radiation Measurement (ARM) Mixed-Phase Arctic Cloud Experiment (M-PACE)

20 observations.

21 We show the SIP importance in the four types of clouds during M-PACE (i.e., multilayer clouds,

22 single-layer stratus, transition and frontal clouds), with the maximum enhancement in ice crystal

23 number concentrations by up to 4 orders of magnitude in moderately supercooled clouds. We reveal

24 that SIP is the dominant source of ice crystals near the cloud base for the long-lived Arctic single-

25 layer mixed-phase clouds. The model with SIP improves the occurrence and phase partitioning of

26 the mixed-phase clouds, reverses the vertical distribution pattern of ice number concentrations, and

27 provides a better agreement with observations. The findings of this study highlight the importance

28 of considering the SIP in GCMs.

29

30

31 **1 Introduction**

32 Clouds play a critical role in the surface energy budget of the Arctic, thereby
33 affecting the Arctic sea ice and regional climate (Kay et al., 2009; Bennartz et al., 2013).
34 Clouds occur frequently in the Arctic (Beaufort Sea) with an observed annual mean
35 occurrence of 85%, a maximum of 97% in September, and a minimum of 63% in February
36 (Intrieri et al., 2002). Along with the occurrence frequency, the phase partitioning between
37 liquid and ice in mixed-phase clouds, i.e., the clouds where liquid and ice coexist at
38 subfreezing temperatures, is also important, since even a small amount of liquid content in
39 clouds can substantially change the radiative properties of the cloud (Shupe et al., 2004;
40 Cesana and Chepfer, 2013). Shupe et al. (2006) showed that over the Beaufort Sea, 59%
41 of observed clouds were mixed-phase, while another study indicated 90% over the western
42 Arctic Basin (Pinto, 1998). Cloud properties further play a key role in the Arctic climate
43 change through cloud feedbacks (Vavrus, 2004; Zhang et al., 2018; Tan and Storelvmo,
44 2019).

45 Mixed-phase clouds are microphysically unstable. Even a small amount of cloud
46 ice can glaciare the mixed-phase clouds in a few hours via the Wegener–Bergeron–
47 Findeisen (WBF) mechanism (Morrison et al., 2012). Mixed-phase clouds in the Arctic are
48 long-lived and characterized by a structure with liquid water at the cloud top and ice water
49 underneath. Interaction and feedback among multiple processes, including longwave

50 radiative cooling, turbulence entrainment, and condensation of liquid water, provide
51 sufficient moistening and cooling at the cloud top. This sustains enough formation of liquid
52 mass against the depletion by the WBF process. In order to support the self-maintenance
53 of liquid water, low concentrations of small ice particles must be present near the cloud
54 base (Shupe et al., 2006; Korolev and Field, 2008). In this way, they are efficient in
55 sedimentation (Jiang et al., 2000) but less active in the WBF and vapor deposition
56 processes. Previous studies indicated that 90% of Arctic mixed-phase cloud temperatures
57 were between -25°C and -5°C from an annual mean perspective (Shupe et al., 2006),
58 indicating that ice exists in moderately supercooled clouds. However, the mechanisms
59 contributing to ice formation in these clouds are still unclear (Shupe et al., 2006; Morrison
60 et al., 2012). One objective of this study is to better understand the ice formation processes
61 in the Arctic mixed-phase clouds.

62 Previous studies have shown the important role of SIP in the Arctic clouds from
63 observations (Schwarzenboeck et al., 2009) and small-scale model simulations
64 (Sotiropoulou et al., 2020a; Fu et al., 2019). Using a large-eddy simulation (LES) model
65 and a Lagrangian parcel model, Sotiropoulou et al. (2020a) found that a combination of
66 ice-ice collisional fragmentation and rime splintering provides a better agreement of the
67 simulated ice crystal number concentrations (ICNCs) with observations in the summer
68 Arctic stratocumulus. They found a low sensitivity of SIP to prescribed number
69 concentrations of cloud condensation nuclei (CCN) and ice nucleating particles (INPs). Fu

70 et al. (2019) simulated an autumnal Arctic single-layer boundary-layer mixed-phase cloud
71 using the Weather Research and Forecasting (WRF) model and showed that the model
72 without considering SIP needs an increase of INP concentrations by two orders of
73 magnitude to match the observed ICNCs. In comparison, the model that only considers the
74 SIP through droplet shattering needs an INP increase of 50 times to match the observed
75 ICNCs.

76 The roles of SIP have also been investigated in other geographical regions and for
77 other cloud types. Sotiropoulou et al. (2020b) simulated a summer boundary layer coastal
78 cloud in West Antarctica using the WRF model and found that the model with collisional
79 break-up between ice-phase particles can reproduce the observed ICNCs, which could not
80 be explained by the rime splintering or primary ice nucleation. Sullivan et al. (2017) used
81 a parcel model with rime splintering and graupel-graupel collisional break-up and found
82 that these two SIP processes can enhance the ICNCs by four orders of magnitude. Sullivan
83 et al. (2018a) showed that among the different SIP mechanisms, only ice–ice collisional
84 fragmentation contributes to a meaningful ice enhancement (larger than 0.002 L^{-1}) in a
85 parcel model simulation. Other studies have shown the impact of SIP on ICNCs in a cold
86 frontal rain band over the UK (Sullivan et al., 2018b), on surface precipitation of a tropical
87 thunderstorm (Connolly et al., 2006), and on the summertime cyclones (Dearden et al.,
88 2016).

89 Previous modeling studies have used small-scale (e.g., parcel models and LES
90 models) and regional-scale models, to investigate the impacts of SIP on cloud properties.
91 There is still a lack of large-scale perspective based on global climate models (GCMs).
92 Moreover, the mechanisms contributing to ice production in the Arctic mixed-phase clouds
93 at moderately cold temperatures are still unknown. In this study, for the first time, we
94 implemented the representation of two new SIP mechanisms (i.e., raindrop shattering, ice-
95 ice collisional break-up) in a GCM. We tested the model performance by running the model
96 in the single column mode (SCM) and compared the SCM simulations of Arctic clouds
97 with observations. The objectives of this study are to examine the impact of SIP on different
98 types of the Arctic clouds and, ultimately to improve the model capability of representing
99 ice processes.

100 This paper is organized as follows. In section 2, we describe the GCM, associated
101 parameterizations, and the three SIP mechanisms represented in the model. In section 3,
102 we present the model experiments and observation data used for model evaluation. The
103 model results are presented in section 4. The main conclusions of this study and future
104 work are summarized in section 5.

105 **2 Model and Parameterizations**

106 **2.1 Model description**

107 The Community Atmosphere Model version 6 (CAM6) used in this study is the
108 atmosphere component of the Community Earth System Model version 2 (CESM2). It
109 includes multiple physical parameterizations that are related to ice formation and evolution.
110 Cloud microphysics is described by a double-moment scheme (Gettelman and Morrison,
111 2015, hereafter as MG). The scheme considers homogeneous freezing of cloud droplets
112 (with temperatures below -40 °C), heterogeneous freezing of cloud droplets, the WBF
113 process, accretion of cloud droplets by snow, and the rime splintering. SIP from rime
114 splintering is parameterized based on Cotton et al. (1986). The condensation process is also
115 known as cloud macrophysics, which is governed by the Cloud Layers Unified by Binormals
116 (CLUBB) scheme, assuming that all the condensate is in the liquid phase (Golaz et al., 2002;
117 Larson et al., 2002). Furthermore, CLUBB also treats boundary layer turbulence and shallow
118 convection. In the mixed-phase clouds, heterogeneous ice nucleation is represented by the
119 classical nucleation theory (CNT), which relates ice nucleation rate to mineral dust and black
120 carbon aerosols (Wang et al., 2014). In cirrus clouds, where temperatures are below -37 °C,
121 heterogeneous immersion freezing on dust can compete with homogeneous freezing of
122 sulfate (Liu and Penner, 2005). The aerosol species involved in ice nucleation processes are

123 represented by the four-mode version of the Modal Aerosol Module (MAM4) (Liu et al.,
124 2012; Liu et al., 2016).

125 In this study, we conducted the simulations using the SCM version of CAM6 (i.e.,
126 SCAM). SCAM is a one-column, time-dependent model configuration of CAM6 that
127 provides an efficient way to understand the behavior of model physical parameterizations
128 without the influence of nonlinear feedbacks from the large-scale circulation. In this way, the
129 biases of the modeled clouds can be exclusively identified from model evaluation against
130 observations.

131 **2.2 Implementation of secondary ice production in CESM2**

132 In addition to the existing SIP mechanism (i.e., rime splintering) in CAM6, we
133 implemented two new mechanisms of SIP, including ice-ice fragmentation and droplet
134 shattering (Phillips et al., 2017a, 2018) that are parameterized based on theoretical and
135 measurement research.

136 **a. An emulated bin framework**

137 Ideally, a bin microphysics scheme is the most suitable model setup for the
138 representation of SIP mechanisms in a model. However, running a GCM model with a bin
139 microphysics scheme is computationally too expensive under current computational
140 resources. To solve this problem, we developed an emulated bin framework for the existing

141 bulk MG microphysics scheme to facilitate the collisions of ice hydrometeors and
142 raindrops. First, we selected the bin bounds for each hydrometeor, including cloud ice,
143 snow, and rain. A logarithmically equidistant size grid is adopted, that is,

$$144 \quad D_{k+1} = CD_k, \quad (1)$$

145 where $C = \sqrt[4]{2}$. The bin diameter ranges from 0.1 to 6 mm for raindrops and 0.1 to 50 mm
146 for snow and cloud ice particles. Based on the assumption of the particle size distribution,
147 the number concentration and mass mixing ratio of all hydrometeor types were calculated
148 in each temporary bin at each time step and grid point. The estimated particle size
149 distribution from the emulated bin framework served as inputs for the SIP schemes. The
150 SIP schemes were applied to each permutation of the bin during collisions of ice, snow,
151 and rain to calculate the secondary ice fragments. Finally, we summed up the fragment
152 from SIP over all pairs of bins.

153 The bin approach is only adopted in the SIP processes, while other processes,
154 including the existing collisions in the standard MG scheme, still use the bulk
155 microphysical approach. Thus, the modified MG scheme becomes a hybrid scheme that
156 combines the bulk and bin parameterizations. The advantage of this hybrid scheme is that
157 the scheme can provide an accurate representation of the SIP processes while still maintains
158 a relatively high computational efficiency, which is very important for GCMs. The hybrid
159 schemes have been widely used. For example, previous studies used the bin approach for
160 the warm rain processes, while adopted the bulk approach for the ice-related processes

161 (Onishi and Takahashi, 2012; Grabowski et al., 2010; Kuba and Murakami, 2010). Other
162 previous studies used the bin approach for the sedimentation (Morrison, 2012) or look-up
163 tables for the collision processes in the bulk schemes (Feingold et al., 1998).

164

165 **b. Ice-ice fragmentation**

166 Phillips et al. (2017a, b) developed a scheme for SIP during an ice-ice collision
167 based on the principle of energy conservation. This scheme relates the fragment numbers
168 to particle initial kinetic energy and ice particle habits (i.e., ice morphology), which can be
169 explained in terms of environmental temperature, particle size, and riming intensity of ice
170 particles (Fig. 1). The production of new ice particles per collision is calculated as:

171

$$172 \quad \mathcal{N} = \alpha A \left[1 - e^{-\left(\frac{Ck_0}{\alpha A}\right)^\gamma} \right] \quad (2)$$

173

174 in which α is the surface area of ice particle, i.e., the equivalent spherical area in a unit of
175 m^2 , $\alpha = \pi D^2$; A is the number density of breakable asperities of ice particles, which is
176 related to riming intensity and ice particle size; C is the asperity-fragility coefficient,
177 prescribed to be 10815 for dendrites and 24780 for spatial planar; γ is a parameter related
178 to riming intensity (rim), $\gamma = 0.5 - (0.25 \times rim)$, and rim is assumed to be 0.1; k_0 is
179 the initial kinetic energy, which is given as:

180
$$k_0 = \frac{1}{2} \frac{m_1 m_2}{m_1 + m_2} (v_1 - v_2)^2 \quad (3)$$

181 in which m_1 and m_2 are the particle masses of two colliding particles, and v_1 and v_2
 182 are the terminal velocities of the two colliding particles.

183 In this method, three types of collision are identified based on the type of collision
 184 particles: (1) cloud ice/snow collide with hail/graupel; (2) cloud ice/snow collide with
 185 cloud ice/snow; (3) hail/graupel collide with hail/graupel (not included currently, since
 186 CESM2-CAM6 does not treat graupel currently); For each collision type, different values
 187 of parameters α , A , C , and γ in Eq. (2) are yielded based on the measured relationship
 188 between fragment number and collisional kinetic energy (Phillips et al., 2017a).

189 Under the emulated bin framework, the new fragment production rate for each
 190 permutation of a bin is written as:

191
$$N_{iic} = \mathcal{N} E_c \delta N_1 \delta N_2 \pi (r_1 + r_2)^2 |v_1 - v_2| \quad (4)$$

192 in which E_c is the accretion efficiency, assumed to be 0.5 to be consistent with the MG
 193 microphysics scheme, and δN_1 and δN_2 are the particle number concentrations in the
 194 two bins with particle sizes of r_1 and r_2 , respectively.

195 The ice production rate for cloud ice mixing ratio is:

196
$$P_{iic} = N_{iic} \delta m_{ice} \quad (5)$$

197 in which δm_{ice} is mass for single ice particle, prescribed as 2.09×10^{-15} kg.

198 **c. Droplet shattering during rain freezing**

199 Phillips et al. (2018) proposed numerical formulations for ice multiplication during
 200 the raindrop freezing. They suggested two modes of droplet break-up during the rain
 201 freezing based on the relative weight of raindrop and ice particle (Fig. 2).

202 In mode 1, the freezing of rain is triggered by a collision with less massive ice
 203 crystals or with INPs. By fitting to the laboratory data, Phillips et al. (2018) derived an
 204 empirical formulation for the number of ice fragments per frozen raindrop as a function of
 205 drop diameter and temperature. A Lorentzian distribution as a function of temperature was
 206 adopted to represent the number of ice fragments per frozen raindrop. There are two types
 207 of raindrop fragmentation: shattering to form “big” fragments and “tiny” splinters. The
 208 total (big plus tiny) and big ice fragments per frozen raindrop emitted in the mode 1 of
 209 droplet shattering are given in Eqs. (6) and (7), respectively:

$$210 \quad \mathcal{N}_T = F(D)\Omega(T) \left[\frac{\zeta\eta^2}{(T-T_0)^2+\eta^2} + \beta T \right] \quad (6)$$

$$211 \quad \mathcal{N}_B = \min \left\{ F(D)\Omega(T) \left[\frac{\zeta_B\eta_B^2}{(T-T_{B0})^2+\eta_B^2} \right], \mathcal{N}_T \right\} \quad (7)$$

212 where the parameters $\zeta, \eta, \beta, \zeta_B, \eta_B, T_0, T_{B0}$ are derived by fitting the formulations to a
 213 collection of laboratory data. Further details about empirical formulae can be found in
 214 Phillips et al. (2018). $F(D)$ and $\Omega(T)$ are the interpolating functions for the onset of
 215 fragmentation and T is the temperature in K. The mass of a big fragment is $m_B = \chi_B m_{rain}$,

216 in which $\chi_B = 0.4$, and the mass of a small fragment is $m_S = \frac{\pi\rho_i}{6} D^3$, in which $\rho_i =$
 217 500 kg m^{-3} .

218 The observational data used for the formulations of raindrop freezing by mode 1
 219 was limited to drop diameter of 1.6 mm and a temperature range between $-4 \text{ }^\circ\text{C}$ to $-25 \text{ }^\circ\text{C}$.
 220 Phillips et al. (2018) linearly extrapolated their algorithm for larger particles and other
 221 temperatures in the mixed-phase cloud regime. As shown in Fig. 2a, b, mode 1 of the
 222 droplet shattering is most effective near -15°C .

223 In mode 2, a theoretical approach is adopted which is based on the assumption that
 224 the number of fragments generated when a drop collides with a more massive ice particle
 225 is controlled by the initial kinetic energy and surface energy (Fig. 2c). The number of
 226 fragments generated per frozen drop in mode 2 is given as:

$$227 \quad \mathcal{N}_{fr2} = 3\Phi(T) \times [1 - f(T)] \times \max(DE - DE_c), \quad (8)$$

228 where DE is the dimensionless energy and is expressed as:

$$229 \quad DE = \frac{k_0}{S_e}, \quad (9)$$

230 where k_0 is the initial kinetic energy which is given in Eq. (3), S_e is the surface energy,
 231 expressed as $S_e = \gamma_{liq}\pi D^2$ (for $D > 150 \text{ } \mu\text{m}$), γ_{liq} is the surface tension of liquid water
 232 which is 0.073 J m^{-2} . DE_c in Eq. (8) is set to be 0.2. $f(T)$ is the frozen fraction (Phillips
 233 et al., 2018), and is given as:

234
$$f(T) = \frac{-C_w T}{L_f}. \quad (10)$$

235 where C_w is the specific heat capacity of liquid water ($4200 \text{ J kg}^{-1} \text{ K}^{-1}$) and L_f is the specific
 236 latent heat of freezing ($3.3 \times 10^5 \text{ J kg}^{-1}$), $\Phi(T) = 0.5$ at -1°C and $\Phi(T) = \min [4f(T), 1]$.

237 **d. Rime splintering**

238 The MG microphysics already includes the SIP associated with rime splintering,
 239 which is also known as Hallet-Mossop (HM) process. In this process, secondary ice
 240 particles are generated during the accretion of cloud droplets by snow, and a part of rimed
 241 mass is converted to cloud ice. The ice number production rate is based on the
 242 parameterization of Cotton et al. (1986), which is given as:

243
$$N_{HM} = C_{sip_{HM}} \times p_{sacws} \quad (11)$$

244 where p_{sacws} is the riming rate of cloud droplets by snow and is expressed as:

245
$$p_{sacws} = \frac{\pi \times a_{vs} \times \rho \times N_{0s} \times E_{ci} \times \Gamma(b_{vs} + 3)}{4 \times \lambda b_{vs} + 3} \quad (12)$$

246 in which E_{ci} is the collection efficiency for the riming of cloud droplets by snow, a_{vs}
 247 and b_{vs} are the fall speed parameters for snow particles, $b_{vs} = 0.41$, and $a_{vs} =$
 248 $11.72 \times \frac{\rho_{850}}{\rho}$, ρ and ρ_{850} are air density and typical air density at 850 hPa, respectively,
 249 and N_{0s} and λ are the parameters for the snow particle size distribution.

250 The conversion coefficient $C_{sip_{HM}}$ in Equation (11) depends on temperature T_c in
 251 $^\circ\text{C}$:

252
$$C_{sip_{HM}} = \frac{3.5 \times 10^8 \times (-3 - T)}{2}, \text{ when } -5 < T_c < -3, \text{ and} \quad (13)$$

253
$$C_{sip_HM} = \frac{3.5 \times 10^8 \times (T - (-8))}{3}, \text{ when } -8 < T_c < -5 \quad (14)$$

254 The production rate for cloud ice mixing ratio is given as:

255
$$P_{HM} = N_{HM} \delta m_{ice} \quad (15)$$

256 in which δm_{ice} is mass for single ice particle in the HM process, prescribed as 2.09×10^{-15}
257 kg. The rime splintering rate as a function of p_{sacws} and temperature is shown in Fig. 3.

258 **3 Case Description, Observations, and Model Experiments**

259 **3.1 M-PACE case**

260 In this study, we focus on the Arctic mixed-phase clouds observed during the
261 Department of Energy (DOE)'s Atmospheric Radiation Measurement (ARM) Mixed-
262 Phase Arctic Cloud Experiment (M-PACE). The M-PACE campaign was conducted over
263 the North Slope of Alaska (NSA) during the autumn from 27 September to 22 October 2004.

264 Various types of clouds were observed during M-PACE, including multilayer clouds,
265 boundary layer mixed-phase stratus, cirrus, and altostratus clouds associated with the frontal
266 system (Verlinde et al., 2007; Liu et al., 2007; Xie et al., 2008; Liu et al., 2011). Single-
267 layer mixed-phase clouds were formed under moderately supercooled conditions with the
268 cloud temperature at around -10 °C (Verlinde et al., 2007; McFarquhar et al., 2007),
269 providing a favorable condition for studying the influence of SIP on cloud evolution (Field
270 et al., 2016).

271 The synoptic-scale systems regulated the properties of clouds observed during the M-
272 PACE campaign. Hence, Verlinde et al. (2007) divided the M-PACE period into three
273 synoptic regimes and two transition periods based on the synoptic weather conditions. The
274 first synoptic regime began on 24 September and lasted until 1 October, 2004, when a well-
275 developed trough dominated aloft with several low-pressure systems that influenced the
276 surface. Followed by the first transition period between 2 and 3 October, the second synoptic
277 regime occurred between 4 and 14 October (Fig. 4), which was controlled by a pronounced
278 high-pressure system. The second transition period was from 15-17 October. By 18 October,
279 a fast-developing strong frontal system controlled the cloud formation over the NSA in the
280 third synoptic regime (Fig. 4). During M-PACE, the surface flux of water vapor, sensible
281 heat, and latent heat played different roles in the cloud formation. For example, clouds
282 formed in response to a strong surface forcing during the second regime, while clouds formed
283 under a relatively weak surface forcing during the third regime. In this study, we evaluate the
284 modeled cloud properties with M-PACE observations in the second and third synoptic
285 regimes focusing on the boundary layer mixed-phase stratus during 9-12 October in the
286 second regime.

287 **3.2 Observation data**

288 The observed cloud occurrence data at Barrow (located at 71.3° N, 156.6° W) are
289 from the ARM Climate Modeling Best Estimate product (Xie et al., 2010). The liquid water

290 path (LWP) and ice water path (IWP) data are obtained from Zhao et al. (2012).
291 Specifically, the Shupe and Turner's data are based on the retrievals of cloud properties
292 measured by the ARM Millimeter-Wavelength Cloud Radar (Shupe et al., 2005) and the
293 Microwave Radiometer (MWR) (Turner et al., 2007), with the uncertainties for liquid water
294 content (LWC) within 50% and for ice water content (IWC) within a factor of 2. For
295 Wang's data, IWP is retrieved from the combined ARM Millimeter-Wavelength Cloud
296 Radar and Micropulse lidar measurements (Wang and Sassen, 2002) with an uncertainty
297 of 35% (Khanal and Wang, 2015). LWP is retrieved from the ARM MWR measurements
298 with an uncertainty of 50% (Wang, 2007). For Deng's data, IWC is retrieved based on the
299 Millimeter-Wavelength Cloud Radar measurements with a retrieval error within 85%
300 (Deng and Mace, 2006). For Dong's data, LWC is retrieved from the MWR measurements
301 with an uncertainty within 113% (Dong and Mace, 2003). Note that measured IWC and
302 IWP cannot distinguish cloud ice from the snow. The simulated IWP and IWC therefore
303 include the snow component which is consistent with observations used in this study.

304 The ICNC was measured during the M-PACE single-layer mixed-phase stratus
305 period. The data includes 53 profiles measured in four flights over Barrow and Oliktok Point
306 (located at 70.5° N, 149.9° W) by the University of North Dakota Citation aircraft. By
307 combining measurements from different probes, McFarquhar et al. (2007) provided cloud
308 particle size distributions over a continuous size range. The forward scattering spectrometer
309 probe (FSSP) measured particle number concentrations with particle diameters between 3 to

310 53 μm , while the one-dimensional cloud probe (1DC) counted cloud particles ranging from
311 20 to 620 μm . The two-dimensional cloud probe (2DC) covered particle sizes from 30 to 960
312 μm , while the high-volume precipitation sampler (HVPS) sampled particles from 0.4 to 40
313 mm. The data were collected every 10 seconds but were averaged to 30 s^{-1} to ensure adequate
314 statistical sampling. The cloud phase was identified by detecting the presence of supercooled
315 droplets by the Rosemount Icing Detector (RICE). In mixed-phase clouds, any particles
316 larger than 125 μm are identified as ice particles, and cloud particles smaller than 53 μm are
317 counted as liquid-phase particles. Particles with a diameter ranging from 53 to 125 μm are
318 counted as a liquid when there is drizzle, and as ice, if there is no drizzle. A more detailed
319 description of the particle phase identification algorithm can be found in McFarquhar et al.
320 (2007). When comparing the simulated ICNC with the observations, we only consider ice
321 particles larger than 53 μm , as the observations were limited to ice particles larger than 53
322 μm .

323 However, the M-PACE data were collected before the advent of shatter mitigating
324 tips and before algorithms for removing the shattered particles had been developed. Thus,
325 there are no corrections for the shattering effect in these data. Previous studies indicated an
326 averaged reduction of ice number concentrations by 1-4.5 times and up to a factor of 10
327 (for some data samples) in other field campaigns, such as the Instrumentation Development
328 and Education in Airborne Science 2011 (IDEAS-2011), the Holographic Detector for
329 Clouds (HOLODEC), and the Indirect and Semidirect Aerosol Campaign (ISDAC), which

330 also used the 2DC cloud probe, but adopted anti-shattering tips and algorithms for
331 removing the shattered particles (Jackson and McFarquhar, 2014; Jackson et al., 2014). In
332 order to account for the anti-shattering effect, observed ice number concentrations were
333 scaled by a factor of 1/4 and 1/2, respectively, to consider the possible range of the
334 shattering effect. Furthermore, to be consistent with Figure 10 in Jackson et al. (2014), only
335 ice particles with diameters larger than 100 μm are included in our model and observation
336 intercomparisons.

337 **3.3 Model set up and description of model experiments**

338 In this study, we run SCAM with 32 vertical layers from the surface up to 3 hPa. The
339 model is initialized and driven by the large-scale forcing data at every 3 hours. The forcing
340 data developed by Xie et al. (2006) include the divergences and advections of moisture and
341 temperature as well as the surface flux. The simulation period is from 5 to 22 October 2004
342 and covers the second and third synoptic regimes and the transition period between them.

343 A detailed description of model experiments along with SIP mechanisms in these
344 experiments is provided in Table 1. The control experiment (CTL) uses the default CAM6
345 model that only includes the SIP due to the HM process. The impacts of two new SIP
346 mechanisms, including the ice-ice collision break-up and rain freezing fragmentation based
347 on Phillips et al. (2017a, 2018) are addressed in the SIP_PHIL experiment. To examine the

348 impact of rime splintering in the CTL experiment, we conducted CTL_no_HM experiment
349 that is similar to CTL but without the HM process.

350

351 **4 Results**

352 **4.1 SIP impacts on different types of clouds during M-PACE**

353 Figure 4 shows the temporal evolution of LWP, IWP, and cloud fractions from two
354 model simulations (CTL and SIP_PHIL) and their comparison to observations. The model
355 simulations cover the second and third synoptic regimes as well as the transition period
356 between them. Two different types of clouds were formed in response to the strong surface
357 forcing during the second synoptic regime from 4 to 14 October. As shown in Fig. 4c,
358 multilayer stratus occurred from 5 to 8 October, and the clouds extended from 950 hPa up to
359 500 hPa. Between 9 and 14 October, single-layer boundary layer stratus occurred between
360 800 and 950 hPa. Because of the dramatic change in cloud types in the second regime, we
361 further separate the second regime into two time periods. Then, we select typical days in the
362 four time periods for our analysis in this study, as shown in Fig. 4. The period from 6 to 8
363 October is selected as the “multilayer stratus” period. The period from 9 to 12 October is
364 selected as the “single-layer stratus” period, followed by the transition period marked on 16

365 October. The period between 18 and 20 October is selected to represent the “frontal cloud”
366 type during the third regime.

367 Figure 4 shows that the simulated IWP is systematically underestimated during M-
368 PACE in the CTL experiment. The maximum value of IWP in CTL is smaller than 50 g m^{-2}
369 2 during M-PACE, but up to 500 g m^{-2} in the measurements. The SIP_PHIL experiment
370 shows decreased LWP and increased IWP compared with CTL, reaching a better agreement
371 with the measurements. For example, IWP increases from 50 g m^{-2} in CTL to 425 g m^{-2} in
372 SIP_PHIL on 20 October, compared with $300 \sim 475 \text{ g m}^{-2}$ from different measurements (Fig.
373 4). The simulated LWP is overestimated during the “multilayer stratus”, the second half of
374 the “single-stratus”, and the “frontal cloud” periods in CTL, particularly on 20 October.
375 The SIP_PHIL experiment decreases the LWP from 550 g m^{-2} in CTL to 300 g m^{-2} on 11
376 October and from 425 g m^{-2} in CTL to 70 g m^{-2} on 20 October (Fig. 4a). The CTL_no_HM
377 experiment has similar results as the CTL experiment.

378 During the multilayer stratus period, the CTL and SIP_PHIL experiments show that the
379 cloud top is located at about 5 km with a temperature of $-20 \text{ }^\circ\text{C}$ (Fig. 5). These cloud
380 properties are consistent with the observations (Verlinde et al., 2007) that show a minimum
381 observed cloud temperature of -17°C (Fig. 4). However, we notice a significant
382 overestimation of cloud amount at 6–8 km on 7 October by the model simulations in Fig. 5,
383 as compared to the observation in Fig. 4c.

384 During this period, IWC is increased in the SIP_PHIL experiment compared to CTL,
385 while LWC is decreased. The mean vertical profiles of simulated IWC and LWC in this
386 period are shown in Fig. 6. The simulated values of LWC and IWC are lower than
387 observations, particularly for IWC. LWC decreases from 130 mg m^{-3} in CTL to 80 mg m^{-3}
388 in SIP_PHIL below 1 km. IWC increases from 3 mg m^{-3} in CTL to 5 mg m^{-3} in SIP_PHIL.
389 The time-averaged IWP increases from 11.2 g m^{-2} in CTL to 17.1 g m^{-2} in SIP_PHIL but is
390 still lower than the observed value of 55.6 g m^{-2} (Table 2). After considering the SIP in the
391 model, for the multilayer stratus period, ICNC is increased by 1 L^{-1} (Fig. 5) at an altitude of
392 1 to 4 km. Observations of ICNC are not available during this period.

393 Between 9 and 14 October, a persistent boundary-layer mixed-phase stratus occurred
394 between 800-950 hPa, with the cloud top temperature at around $-15 \text{ }^{\circ}\text{C}$ (Verlinde et al., 2007).
395 This single-layer stratus was separated from the surface based on the measurement (Fig. 4c).
396 However, modeled clouds extend to the surface in CTL (Fig. 5). This bias is alleviated in
397 SIP_PHIL on 8 and 11 October (Fig. 5). Previous studies also found that this bias partially
398 results from the overestimation of low-level moisture in the large-scale forcing data (Zhang
399 et al., 2019, 2020).

400 Observed cloud liquid is located above the cloud ice during this period, with the LWC
401 peak $\sim 0.5 \text{ km}$ above the IWC peak. Observed vertical profile of LWC shows a maximum of
402 300 mg m^{-3} (ranging from 210 to 500 mg m^{-3}) at $\sim 1.25 \text{ km}$, while observed IWC is peaked
403 at 0.75 km (Fig. 6). This characteristic is clearly captured by the SIP_PHIL experiment, with

404 the peaks of LWC and IWC located at 0.75 and 0.5 km, respectively (Fig. 6). A better relative
405 position of cloud liquid and ice in SIP_PHIL indicates a better simulation of interactions
406 between cloud physics and dynamics. This distinct feature also contributes to the longevity
407 of mixed-phase clouds in the Arctic, as discussed in Section 1. In SIP_PHIL, the maximum
408 IWC value is four times larger than that in CTL (2 versus 0.5 mg m⁻³); accordingly,
409 temporally-averaged IWP increases from 0.9 in CTL to 2.5 g m⁻² in SIP_PHIL (Table 2).
410 Meanwhile, ICNC in SIP_PHIL is higher than that in CTL, and the maximum ICNC goes
411 up by 5 L⁻¹ at 0.5 km on 11 October (Fig. 5). Thus, SIP adds an extra source of ice crystals
412 to the boundary-layer mixed-phase stratus clouds.

413 During the transition period, several distinct liquid layers are interrupted by the ice
414 enriched layers in the observation. Due to the coarse vertical resolution, the model may not
415 be able to capture this vertical variation accurately. Considerable variation was noticed in the
416 observed IWC with a maximum IWC of 0.8–1.8 mg m⁻³ (Fig. 7). The CTL experiment
417 substantially underestimates IWC, as it produces IWC less than 0.1 mg m⁻³. The maximum
418 IWC in SIP_PHIL is 1.15 mg m⁻³, providing a better agreement with the observation. The
419 simulated peak LWC is decreased from 80 in CTL to 65 mg m⁻³ in SIP_PHIL, which is
420 closer to the observed value of 55 mg m⁻³. The temporally-averaged IWP in SIP_PHIL is
421 10⁴ times larger than that in CTL, with values of 0.0001, 3.6, and 5.6 g m⁻² in CTL, SIP_PHIL,
422 and observation, respectively (Table 2). The vertically-integrated ICNC is 7.66 and 4.57×10⁵

423 L^{-1} in CTL and SIP_PHIL, respectively (Table 2). Considering SIP in the model increases
424 vertically-integrated ICNC by five orders of magnitude during the transition period.

425 During the frontal cloud period, stratocumulus and altostratus clouds associated with
426 the frontal system extended from the surface up to 8 km (Fig. 4). The SIP_PHIL experiment
427 shows the largest absolute increases in IWC and ICNC compared to the other periods (Fig.
428 5). The peak of modeled IWC is located at 2.5 km, with values of 2 and 8 $mg\ m^{-3}$ in CTL
429 and SIP_PHIL, respectively (Fig. 7), much lower than the observation (ranging from 8 to 40
430 $mg\ m^{-3}$). IWP is 10.4, 26.1, and 96 $g\ m^{-2}$ in CTL, SIP_PHIL, and the observation,
431 respectively (Table 2). ICNC is increased by up to 7 L^{-1} between 2 to 4 km on 20 October
432 from CTL to SIP_PHIL (Fig. 5). The simulated LWP is decreased from 127.6 to 41.2 $g\ m^{-2}$,
433 which is closer to the observed value of 50.2 $g\ m^{-2}$.

434 The relative importance of primary and secondary ice production is shown as pie
435 charts in Fig. 8, to identify the dominant ice production mechanism in different types of
436 the Arctic clouds. The primary ice production (i.e., ice nucleation) is more important in the
437 clouds with colder cloud tops, such as multilayer stratus and frontal clouds with cloud top
438 temperatures colder than $-25\ ^\circ C$ and $-40\ ^\circ C$, respectively. The primary ice production
439 contributes 37% and 69% to the total ice production during the multilayer stratus and
440 frontal cloud periods, respectively. Primary ice production is more efficient in deep clouds
441 due to the inverse relationship between the ice nucleation rate and temperature. SIP is more
442 important than primary ice production in the boundary-layer stratus and in clouds during

443 the transition period when cloud top temperatures were at $-15\text{ }^{\circ}\text{C}$. The fragmentation of
444 freezing raindrops contributes the most (up to 80%) to the ice production in the single-layer
445 boundary-layer stratus. The break-up from ice-ice collisions contributes 22% to the total
446 ice production in the frontal clouds, while the rime splintering contributes 22% to the
447 multilayer stratus. These two SIP mechanisms (i.e., break-up from ice-ice collisions and
448 rime splintering) account for a small fraction of the ice production in the boundary-layer
449 stratus.

450 Next, we will focus on the SIP impacts on the boundary-layer stratus related to the
451 phase partitioning (section 4.2) and ICNC (section 4.3).

452 **4.2 SIP impact on occurrence and phase partitioning of the mixed-phase** 453 **clouds**

454 Figure 9 shows the liquid fraction (defined as $\text{LWC}/(\text{LWC}+\text{IWC})$) as a function of
455 normalized height in the single-layer boundary-layer stratus. The normalized height Z_n is 0
456 at cloud base and 1 at cloud top. IWC from the model includes all the ice hydrometeors to
457 compare it with observations. Fig. 9a reveals two features of the observed single-layer
458 boundary-layer clouds: (1) mixed-phase is dominant in the clouds, and (2) the liquid fraction
459 increases with cloud altitude. The liquid fraction is between 0.05 and 0.95 in most portions
460 of the clouds, indicating a mixed-phase feature in the observation. In the upper portion of the
461 clouds, observed liquid fraction is larger than 0.6 with the mean value increasing with height.

462 In the lower portion of the clouds ice mass fraction increases as a result of ice growth by
463 riming of cloud liquid and ice sedimentation from the upper levels. The CTL experiment
464 cannot reproduce the observed mixed-phase feature. A large portion of the clouds is in liquid
465 phase with the liquid fraction close to 1 in CTL, which significantly overestimates the liquid
466 fraction in the clouds. This is vastly different from previous versions of CAM. CAM5
467 showed an underestimation of the liquid fraction (Liu et al., 2011; Cesana et al., 2015; Tan
468 and Storelvmo, 2016; Zhang et al., 2019; Tan and Storelvmo, 2019), while CAM3 showed
469 a decrease of the liquid fraction with height due to its use of a temperature-dependent phase
470 partitioning (Liu et al., 2007).

471 The SIP_PHIL experiment improves the model simulation of cloud phase with
472 increased ice fraction in the bottom half of the clouds by adding an extra source of ice crystals
473 from SIP (Fig. 9c). The CTL_no_HM experiment gives very similar results as the CTL
474 experiment (Fig. 9d). Note that the modeled liquid fraction distributes on discrete vertical
475 levels (Fig. 9b, c, d) due to the coarse model vertical resolution (with only 10 vertical levels
476 below 2 km). In contrast, observed data were detected at 10 s^{-1} resolution during spiral
477 ascents and descents in the clouds so that the observed liquid fraction is distributed
478 continuously with height.

479 For the cloud occurrence, 62.7% of observed clouds are mixed-phase, and only 16%
480 are liquid-phase during the single-layer stratus period, as shown in Table 3. The liquid phase
481 cloud occurrence is 73% in CTL and only 26.9% for mixed-phase clouds, indicating too

482 much liquid-phase and too less mixed-phase occurrence in CAM6. The mixed-phase cloud
483 occurrence is 58.8% in SIP_PHIL and agrees much better with the observation. Thus, there
484 are more frequent mixed-phase clouds in SIP_PHIL. However, the occurrence of ice phase
485 is still underestimated and that of the liquid phase overestimated in SIP_PHIL. Note that, we
486 define the modeled clouds with total cloud water amount larger than 0.001 g m^{-3} and the
487 liquid fraction between 0.5% and 99.5% as the mixed-phase clouds, which are consistent
488 with the observation (McFarquhar et al., 2007).

489 **4.3 SIP impact on ice crystal number concentration**

490 **4.3.1 Vertical distribution of ice crystal number concentration**

491 The vertical distribution of ICNCs in the single-layer boundary-layer stratus clouds
492 on October 9, 10, and 11 from model simulations and observations is shown in Figure 10.
493 The measured ICNCs when applied with a correction factor of $\frac{1}{4}$ range from 0.02 to 20 L^{-1}
494 $^{-1}$, with an average value of 1 L^{-1} . The CTL and CTL_no_HM experiments have similar
495 results, and both underestimate the ICNCs in all the cloud layers, with a mean ICNC of
496 $\sim 0.1 \text{ L}^{-1}$ and the maximum concentration of 1 L^{-1} . The mean ICNC is increased to $\sim 1 \text{ L}^{-1}$
497 in the SIP_PHIL experiment with the maximum concentration of 30 L^{-1} , which are in better
498 agreement with the observations compared to CTL. ICNCs are increased by more than one

499 order of magnitude in the lower portion of the clouds, although they are still lower than
500 those observed in the upper portion of the clouds.

501 Figure 10 also shows the linear regressions of ICNCs as a function of cloud altitude
502 (black lines). ICNCs increase towards the cloud base in the observation, revealing ice
503 multiplication during the ice growth and sedimentation. The CTL experiment shows that
504 the ICNCs decrease towards the cloud base, an opposite pattern compared to the
505 observation. SIP_PHIL captures the observed pattern in the vertical profile of ICNCs (Fig.
506 10c), suggesting that SIP is an important source of ice crystals near the cloud base in the
507 Arctic boundary-layer mixed-phase stratus. Furthermore, the vertical distribution of ice
508 particles is important for the longevity of the Arctic mixed-phase clouds, which features
509 lower ICNCs in the upper portion of clouds and higher ICNCs towards the cloud base.

510 **4.3.2 PDF of ice crystal number concentration**

511 Figure 11 shows the probability density function (PDF) (i.e., the frequency of
512 occurrence) of ICNCs from model simulations and observations for the boundary-layer
513 mixed-phase stratus period (October 9-12, 2004). Note that only particles with a diameter
514 greater than 100 μm are included in the observed and modeled ICNCs. The PDF
515 distribution in SIP_PHIL shows a shift to the right, with the ICNC peak much closer to the
516 observations than CTL. The median ICNC is 0.13 L^{-1} in CTL, shifting to 0.27 L^{-1} in
517 SIP_PHIL, which is closer to the observed median value of 0.32 L^{-1} .

518 The PDF distribution in SIP_PHIL also has a broader distribution than CTL. A
519 broader distribution indicates that the maximum concentrations are higher in the
520 observation and SIP_PHIL compared to CTL. In the CTL experiment, the frequency of
521 occurrence of ICNCs is much lower (higher) than observations when their values are higher
522 (lower) than 0.1 L^{-1} . These biases in ICNCs PDF are much improved in SIP_PHIL, leading
523 to a better agreement with the observation. The frequency occurrence of ICNC at 1 L^{-1} is
524 2.12%, 10.37%, 13.77% in CTL, SIP_PHIL, and observation, respectively. Thus,
525 SIP_PHIL has an occurrence frequency of ICNC larger than 1 L^{-1} , which is 5 times of that
526 in CTL. We note that the agreement between modeled and observed ICNCs is improved
527 with a correction factor of $\frac{1}{4}$ (Figures 10 and 11) and a correction factor of $\frac{1}{2}$
528 (supplementary Figures S2 and S4) to the observed ICNCs, compared to that without a
529 correction factor (Supplementary Figures S1 and S3). This is because model simulations
530 including SIP_PHIL underestimate the observed ICNCs without the correction of the
531 shattering effect.

532 4.3.3 Dependence of ice enhancement on cloud temperature

533 The bivariate joint PDF defined in terms of temperature and ice enhancement
534 ($N_{\text{SIP_PHIL}}/N_{\text{CTL}}$) during the M-PACE is shown in Fig. S5. Strong ice enhancements are
535 noticed at temperatures from -3 to -16°C , and ICNCs are increased by nearly 4 orders of
536 magnitude in SIP_PHIL compared with CTL. As temperature decreases below -35°C , ice

537 enhancement happens again, but with a reduced magnitude. For example, the largest
538 enhancement at -44°C is around 3.2, with a frequency of 1% to 7%.

539 To investigate the dominant processes that contribute to the strong enhancement
540 near -10°C we plotted the bivariate joint PDF defined in terms of temperature and ice
541 production rate (Fig. 12). A clear relationship between ice enhancement and fragmentation
542 of freezing raindrops can be seen at temperatures from -20 to -4°C in Fig. 12 and Fig. S5.
543 The maximum ice production from the fragmentation of freezing raindrops is 160 L^{-1} (i.e.,
544 $10^{2.2}$) at temperatures ranging from -8 to -14°C . Even though rime splintering also
545 happens at temperatures between -8 to -3°C with a maximum value of 20 L^{-1} , its ice
546 production is almost one order of magnitude lower than that from the fragmentation of
547 freezing raindrops. Between -20 to -16°C , primary ice nucleation and fragmentation of
548 freezing raindrops coexist, with the fragmentation of freezing raindrops more efficient
549 (with a magnitude of 10 L^{-1}) comparing to the primary ice nucleation (about 1 L^{-1}). Primary
550 ice nucleation has the largest production of up to 250 L^{-1} at temperatures ranging from $-$
551 32 to -25°C . Below -35°C , ice-ice collision break-up frequently happens, but with a lower
552 process rate.

553 In summary, the strongest ice enhancement occurs in the moderately supercooled
554 clouds with temperatures around -10°C . ICNCs are increased by up to 4 orders of
555 magnitude mainly from the fragmentation of freezing raindrops. A weaker ice

556 enhancement is noticed frequently in ice clouds with temperatures below -35°C , which is
557 attributed to the ice-ice collision break-up.

558 **5 Summary, conclusions and outlook**

559 In this study, two new SIP mechanisms are implemented in a GCM model (CAM6)
560 to investigate their impacts on the Arctic mixed-phase clouds, which were observed during
561 the DOE ARM M-PACE field campaign. The CAM6 model with the new SIP provides a
562 better simulation of the distinct “liquid cloud top, ice cloud base” feature of long-lived
563 Arctic boundary-layer mixed-phase clouds.

564 We find that model biases of underestimation of mixed-phase cloud occurrence and
565 overestimation of pure liquid cloud occurrence are reduced for the single-layer stratus after
566 considering the new SIP processes. The mixed-phase cloud occurrence is 26.9%, 58.8%, and
567 62.7% in CTL, SIP_PHIL and the observation, respectively, while the pure liquid cloud
568 occurrence is reduced from 73% in CTL to 40% in SIP_PHIL, in a better agreement with
569 observed 16%.

570 We find that the pattern of the vertical distribution of ICNCs in the single-layer
571 stratus is reversed after considering the new SIP processes in the model. The measured
572 decrease of ICNCs with cloud height is captured by SIP_PHIL but not by CTL. SIP also
573 leads to a shift of PDF of ICNCs towards a more frequent occurrence of high ICNCs and

574 a less frequent occurrence of low ICNCs. We notice a taller PDF with higher peak and a
575 broader tail in SIP_PHIL, indicating that high ICNCs occur more frequently with the
576 occurrence of extreme high ICNCs ($>10^2 \text{ L}^{-1}$) in SIP_PHIL, which is absent in CTL.

577 The maximum ICNC is around 1, 30, and 20 L^{-1} in CTL, SIP_PHIL, and
578 observation, respectively, in the single-layer stratus. During the frontal cloud period, the
579 SIP_PHIL experiment shows the largest absolute increases in IWC and ICNC by 6 mg m^{-3}
580 and 7 L^{-1} , respectively. The largest ice enhancement ($N_{\text{SIP_PHIL}}/N_{\text{CTL}}$) is noticed during the
581 transition period with a moderately cold cloud top temperature. The column integrated ICNC
582 increases by five orders of magnitude and IWP increases by four orders of magnitude in
583 SIP_PHIL compared to CTL. When comparing the relative importance between primary
584 and secondary ice production, we notice that primary ice nucleation is more dominant in
585 the deep clouds with cloud tops reaching up to 10 km. At the same time, the fragmentation
586 of freezing raindrops contributes more to ICNCs in the boundary-layer clouds.

587 At temperatures from -4 to $-20 \text{ }^\circ\text{C}$, significant ice enhancement is attributed to the
588 fragmentation of freezing raindrops, with the maximum ice production of 160 L^{-1} at $-10 \text{ }^\circ\text{C}$.
589 A weaker ice enhancement due to ice-ice collision break-up is noticed in ice clouds with
590 temperatures below $-35 \text{ }^\circ\text{C}$ but with unneglectable occurrence frequencies. Primary ice
591 nucleation has the largest production by up to 251 L^{-1} in the relatively cold-mixed phase
592 clouds with temperatures between -32 to $-25 \text{ }^\circ\text{C}$.

593 In summary, the consideration of the new SIP processes in CAM6 results in a
594 significant improvement in the model simulated clouds during M-PACE. It underscores
595 the critical role of SIP in cloud microphysics, which should be considered in the
596 parameterizations of GCMs.

597 In this study, the parameterization of the HM process rate is based on Cotton et al.
598 (1986). In this parameterization the ice production rate does not have a dependence on
599 droplet size. Lacking the effect of cloud droplet spectrum in the HM process is supposed to
600 result in an overestimated splintering rate in the Arctic clouds, especially for the clouds with
601 cloud-bases close to the freezing level and with small droplets in the clouds. However, the
602 overestimation in the HM splintering rate due to lack of the cloud droplet spectrum might be
603 balanced by neglecting the raindrop splintering in the HM process in the MG microphysics.
604 In this study, we keep using the bulk approach to represent the HM process, to be the same
605 as that in the standard MG microphysics scheme. It would be interesting to examine the
606 impact of a bin approach to represent the HM process on modeled clouds, which will be a
607 topic of our future studies.

608 For the ice fragmentation from ice-ice collisions, the graupel related collisions are
609 not included in this study, because the current MG microphysical scheme does not treat
610 graupel. To quantify the impacts of graupel on SIP, the cloud microphysical scheme with
611 prognostic graupel (Gettelman et al., 2019) or a “Single-Ice” microphysical scheme
612 (Morrison and Milbrandt, 2015; Zhao et al., 2017) will be needed.

613 We note that the representation of ice properties is highly simplified in the current
614 model. Firstly, ice particles in nature are featured with continuous size distributions with
615 complex shapes and a wide range of densities. In contrast, the current model artificially
616 classifies them into two categories (i.e., cloud ice and snow) with fixed densities, e.g.,
617 densities of 500 kg m^{-3} for cloud ice and of 250 kg m^{-3} for snow. Moreover, the shape of
618 all ice particles is assumed to be spherical. The parameters, a and b in the relationship of
619 terminal velocity and diameter (V - D , $V=aD^b$) are fixed values for cloud ice and snow.
620 These assumptions cannot represent the complexities of ice properties (e.g., size
621 distribution, density, shape, and fall speed) in the measurement. Lastly, the riming intensity
622 of ice particles changes as ice collides with supercooled liquid, leading to significant
623 changes in density and fall speed of ice. This evolution of ice properties is currently not
624 represented in the model. A promising method is to represent the ice-phase microphysics
625 with varying ice properties (Morrison and Milbrandt, 2015; Zhao et al., 2017).

626

627 **Competing interests:** The authors declare that they have no conflict of interest.

628

629 **Data availability:** The code for the Community Earth System Model version 2 (CESM) is
630 freely available at <http://www.cesm.ucar.edu/models/cesm2> (last access: 3 March 2021,
631 Danabasoglu et al., 2020). The model datasets and secondary ice production code are
632 archived at the NCAR Cheyenne supercomputer and are available upon request. The

633 observation data of M-PACE campaign is obtained from the Atmospheric Radiation
634 Measurement (ARM) user facility, a U.S. Department of Energy Office of Science,
635 available at <https://www.arm.gov/research/campaigns/nsa2004arcticld> (last access: 3
636 March 2021; McFarquhar et al., 2007; Verlinde et al., 2007).

637

638 **Author contributions:** XZ and XL conceptualized the analysis and wrote the manuscript
639 with input from the co-authors. XZ modified the code, carried out the simulations, and
640 performed the analysis. VP and SP provided the model code for the secondary ice
641 production. VP and SP also provided scientific suggestions to the manuscript. XL was
642 involved with obtaining the project grant and supervised the study. All authors were
643 involved in helpful discussions and contributed to the manuscript.

644

645 **Acknowledgment:** This research was supported by the DOE Atmospheric System
646 Research (ASR) Program (grant DE-SC0020510). We thank Meng Zhang for helpful
647 discussions especially on processing the observation data. We thank Dr. Chuanfeng Zhao
648 and Dr. Greg McFarquhar for their suggestions on processing the observation data.

895

896

897 Figure 1. The number of fragments per collision as a function of initial collisional kinetic
 898 energy (CKE). The ice habit is assumed to be dendrites when the temperature (T) is
 899 between -12°C and -17°C and is assumed to be spatial planar when $-40^{\circ}\text{C} < T < -17^{\circ}\text{C}$
 900 and $-12^{\circ}\text{C} < T < -9^{\circ}\text{C}$, following Phillips et al. (2017).

901

902

903

904 Figure 2. The number of fragments per frozen drop (shown as $\log_{10}N$) as a function of
 905 temperature and particle diameter, from (a) mode 1 of the rain freezing fragmentation
 906 (FR1), (b) mode 1 of the rain freezing fragmentation but for the big fragments
 907 (FR1_BIG), and (c) mode 2 of the rain freezing fragmentation (FR2).

908

909 Figure 3. The rime splintering rate (shown as $\log_{10}N$) as a function of temperature and
 910 riming rate.

911

912 Figure 4. Temporal evolution of (a) LWP, (b) IWP from remote sensing retrievals shown
 913 as different markers, CTL experiment (orange solid line) and SIP_PHIL experiment (dark
 914 green solid line), and (c) observed time-pressure cross section of the cloud fraction. The
 915 shadings show the multilayer stratus, single-layer stratus, transition, and frontal periods.

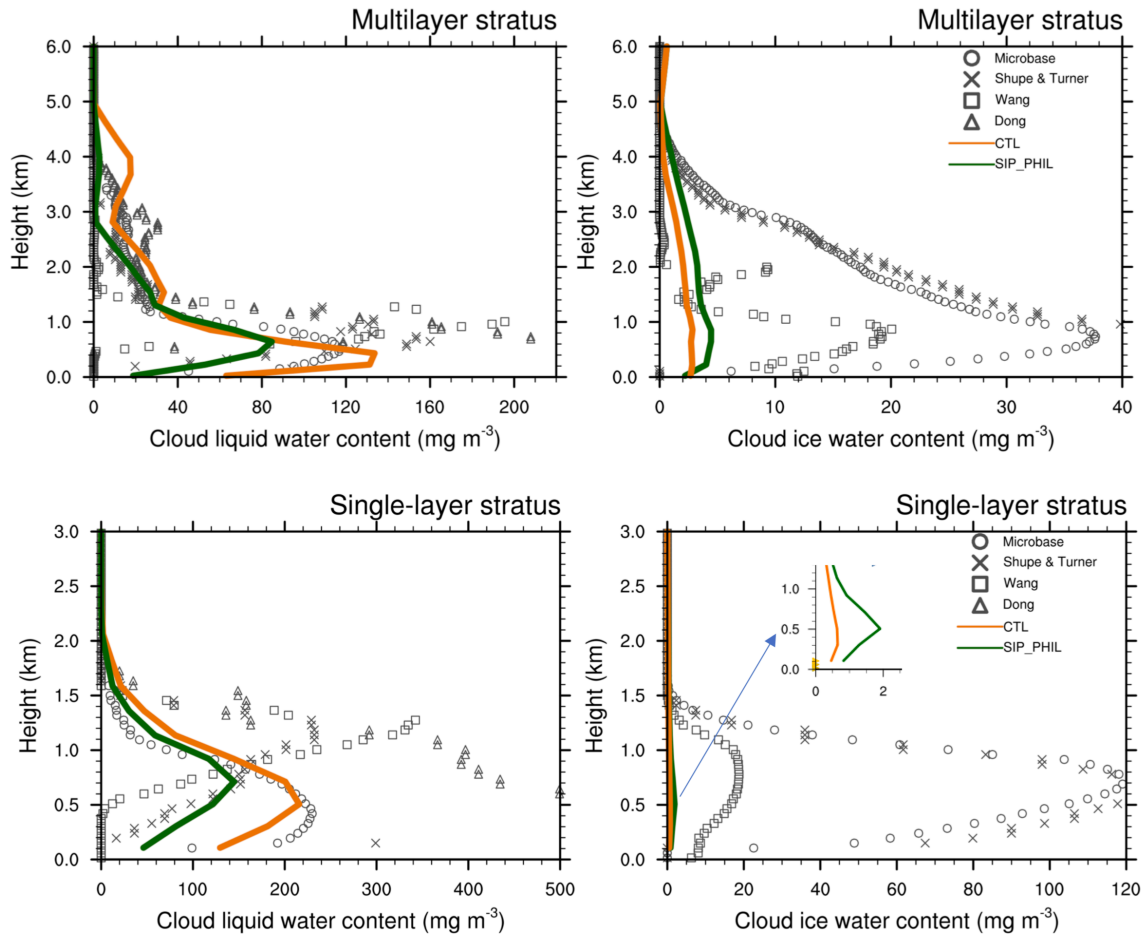

916

917

918 Figure 5. Time-height cross section of cloud fraction (first column), LWC (second
 919 column), IWC (third column) and ice crystal number concentration (fourth column) from
 920 CTL (first row), SIP_PHIL (second row) and the differences between SIP_PHIL and
 921 CTL (SIP_PHIL minus CTL, third row).

922

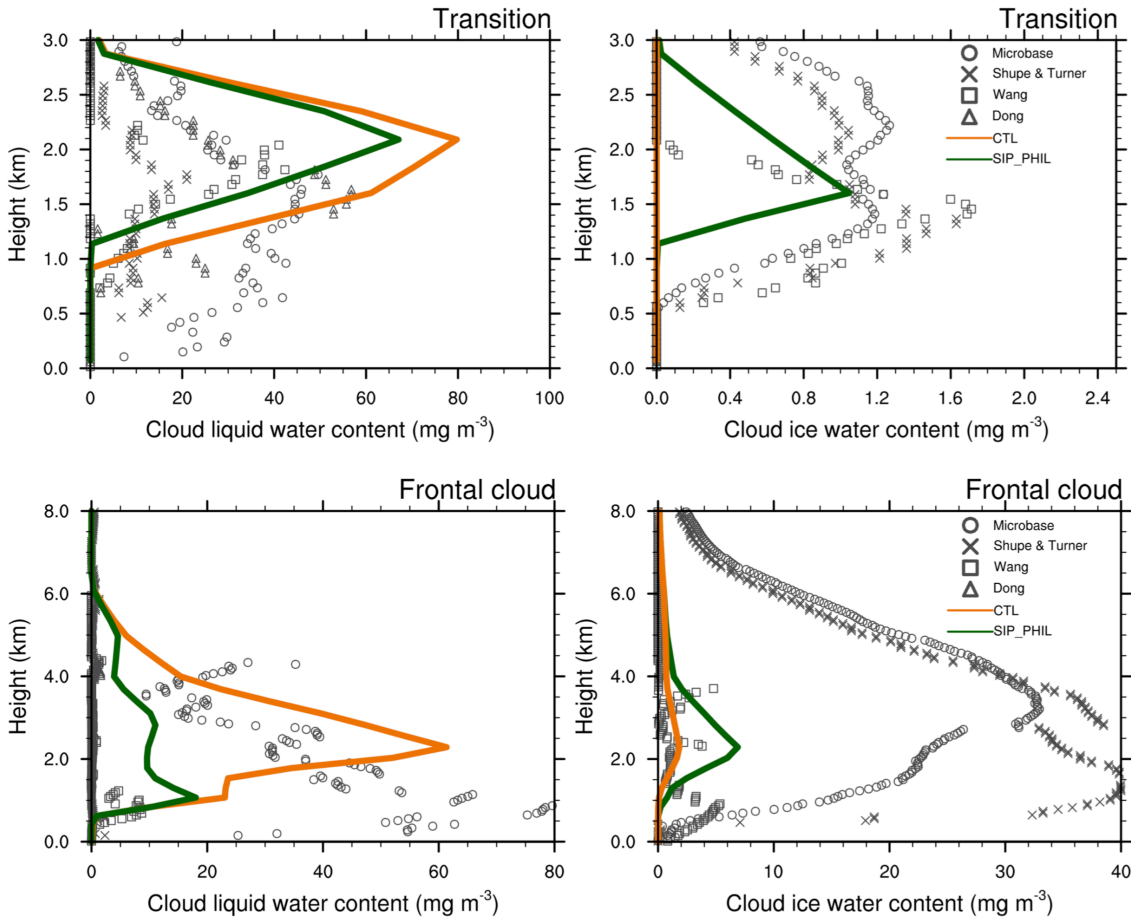

923

924 Figure 6. Vertical profiles of IWC and LWC during multilayer stratus and single-layer

925 stratus periods from remote sensing retrievals shown as different markers, CTL

926 experiment (orange solid line) and SIP_PHIL experiment (dark green solid line).

927

928

929 Figure 7. Vertical profiles of IWC and LWC during the transition and frontal cloud
 930 periods, from remote sensing retrievals shown as different markers, CTL experiment
 931 (orange solid line) and SIP_PHIL experiment (dark green solid line).

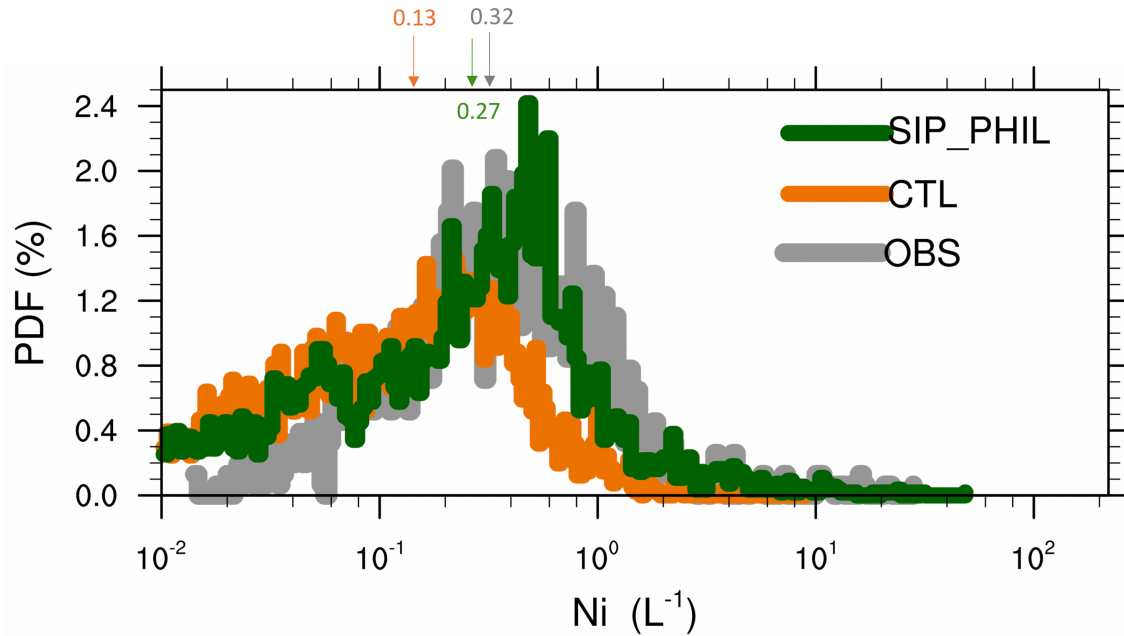

932

933

Figure 8. Pie charts showing the relative contributions to total ice production from primary production (i.e., ice nucleation), rime splintering (HM), fragmentation of frozen rain (including the small fragments in the first mode (FR1), big fragments in the first mode (FRB), and the second mode (FR2)), breakup from ice–ice collisions (including snow and cloud ice collision (ISC) and snow and snow collision (SSC)) during the four M-PACE periods, the vertically integrated process rates are used in the plot.

939

955

956 Figure 11. The probability density function (PDF) of ice crystal number concentrations
 957 from observation (gray line), CTL (orange line), and SIP_PHIL simulations (green line).

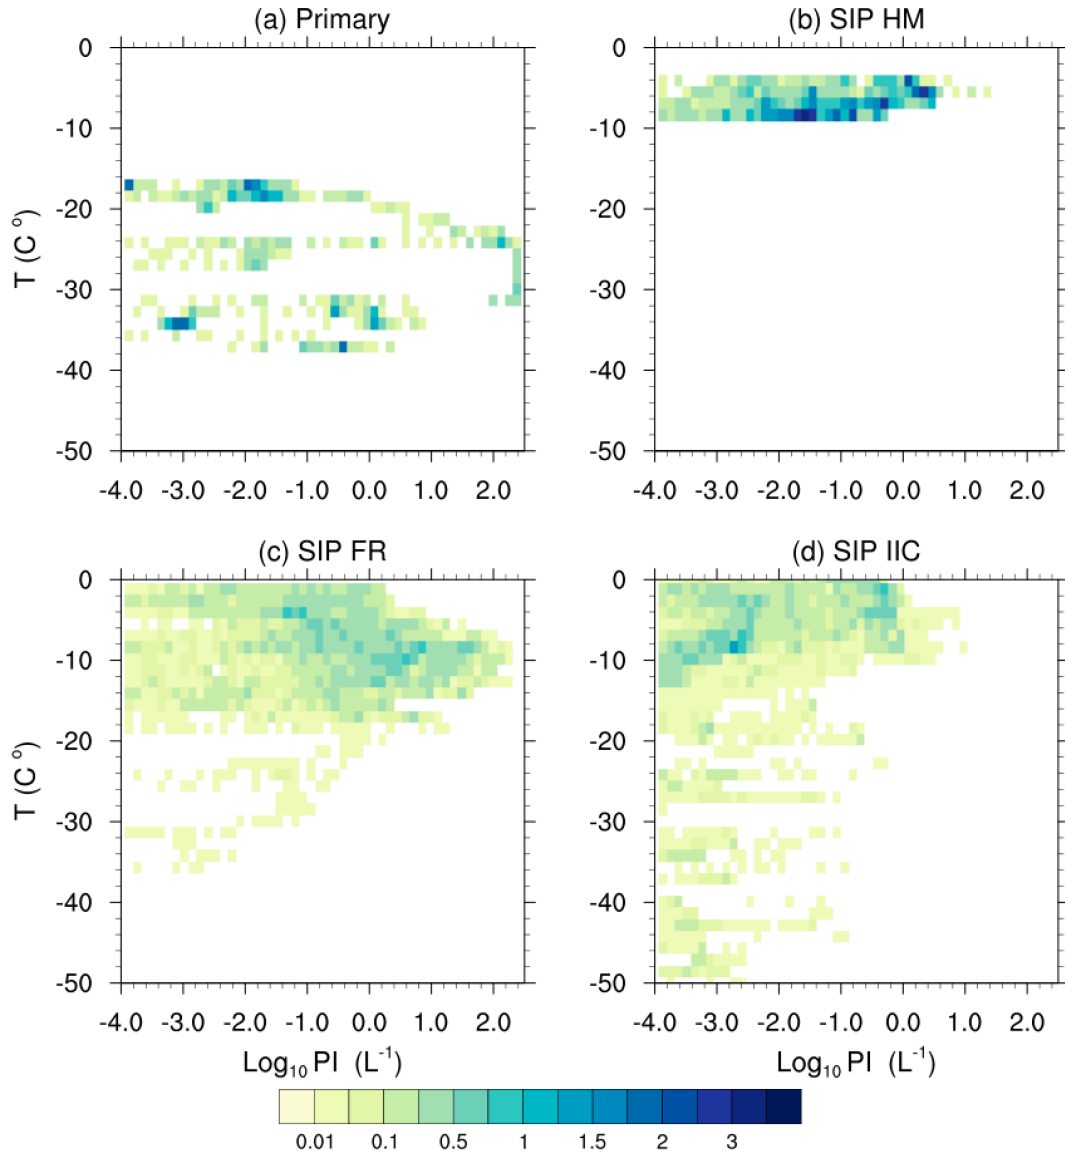

958 The arrow indicates the median of each distribution which means that the set of values
 959 less (or greater) than the median has a probability of 50%. Only ice particles with
 960 diameters larger than 100 μm from observations and model simulations are included in
 961 the comparison. A correction factor of $\frac{1}{4}$ is applied to the observed ice number
 962 concentrations based on Jackson and McFarquhar (2014) and Jackson et al. (2014).

963

964

965

966

967

968 Figure 12. Bivariate joint probability density function of ice production defined in terms
969 of temperature and ice production, (a) primary ice production; (b) ice production from
970 riming splintering; (c) ice production from rain fragmentation; (d) ice production from
971 ice-ice collision. The ice production (PI, with unit of $\# L^{-1}$) is calculated as ice production
972 rate ($L^{-1}s^{-1}$) multiplied by model time step (20 mins), shown in Log_{10} .

973

974

975 Table 1. List of experiments.

976

	Type of Secondary ice production	References
CTL	Rime splintering	[Cotton et al., 1986]
SIP_PHIL	Rime splintering	[Cotton et al., 1986]
	Ice-ice collision fragmentation	[Phillips et al., 2017]
	Rain freezing fragmentation	[Phillips et al., 2018]
CTL_no_HM	Same as CTL, but no HM process	

977

978

979

980

981

982 Table 2. The temporally-averaged IWP, LWP (unit: g m^{-2}), and vertically-integrated ice
 983 crystal number concentration (unit: m^{-2}) during the four periods from observation, and CTL,
 984 CTL_no_HM, and SIP_PHIL experiments.

985

		Multilayer stratus	Single-layer stratus	Transition	Frontal cloud
IWP	OBS	55.6	74.7	5.6	97.0
	CTL	11.2	0.9	0.0001	10.4
	CTL_no_HM	11.1	0.9	0.0001	8.2
	SIP_PHIL	17.1	2.5	3.6	26.1
LWP	OBS	134.4	190.2	58.3	50.2
	CTL	165.1	217.6	88.4	127.6
	CTL_no_HM	166.0	218.0	88.4	129.8
	SIP_PHIL	102.8	131.0	62.1	41.2
ICNC	CTL	5.77×10^6	3.22×10^5	7.66	2.26×10^6
	CTL_no_HM	5.70×10^6	3.17×10^5	0.77	1.57×10^6
	SIP_PHIL	7.09×10^6	1.30×10^6	4.57×10^5	4.67×10^6

986

987

988

989

990 Table 3. Percentage of occurrence of liquid, mixed-phase, and ice clouds during single
 991 layer mixed-phase clouds from observation, and CTL, CTL_no_HM, and SIP_PHIL
 992 experiments.

993

	Liquid	Mixed-phase	Ice
OBS (%)	16.0	62.7	22.3
CTL (%)	73.0	26.9	0.1
CTL_no_HM (%)	73.0	26.9	0.1
SIP_PHIL (%)	40.8	58.0	1.2
