20 Abstract

21
22 The Arctic is warming two to three times faster than the global average, partly due to changes
23 in short-lived climate forcers (SLCFs) including aerosols. In order to study the effects of
24 atmospheric aerosols in this warming, recent past (1990-2014) and future (2015-2050)
25 simulations have been carried out using the GISS-E2.1 Earth system model to study the
26 aerosol burdens and their radiative and climate impacts over the Arctic (>60 °N), using
27 anthropogenic emissions from the Eclipse V6b and the Coupled Model Intercomparison
28 Project Phase 6 (CMIP6) databases, while global annual mean greenhouse gas concentrations
29 were prescribed and kept fixed in all simulations.

30
31 Results showed that the simulations have underestimated observed surface aerosol levels, in
32 particular black carbon (BC) and sulfate (SO₄²⁻), by more than 50%, with the smallest biases
33 calculated for the atmosphere-only simulations, where winds are nudged to reanalysis data.
34 CMIP6 simulations performed slightly better in reproducing the observed surface aerosol
35 concentrations and climate parameters, compared to the Eclipse simulations. In addition,
36 simulations, where atmosphere and ocean are fully-coupled, had slightly smaller biases in
37 aerosol levels compared to atmosphere only simulations without nudging.

38
39 Arctic BC, organic aerosol (OA) and SO₄²⁻ burdens decrease significantly in all simulations
40 by 10-60% following the reductions of 7-78% in emission projections, with the Eclipse
41 ensemble showing larger reductions in Arctic aerosol burdens compared to the CMIP6
42 ensemble. For the 2030-2050 period, the Eclipse ensemble simulated a radiative forcing due
43 to aerosol-radiation interactions (RF_{ARI}) of -0.39±0.01 W m⁻², that is -0.08 W m⁻² larger than
44 the 1990-2010 mean forcing (-0.32 W m⁻²), of which -0.24±0.01 W m⁻² were attributed to the
45 anthropogenic aerosols. The CMIP6 ensemble simulated a RF_{ARI} of -0.35 to -0.40 W m⁻² for

46 the same period, which is -0.01 to -0.06 W m^{-2} larger than the 1990-2010 mean forcing of -
47 0.35 W m^{-2} . The scenarios with little to no mitigation (worst-case scenarios) led to very small
48 changes in the RF_{ARI} , while scenarios with medium to large emission mitigations led to
49 increases in the negative RF_{ARI} , mainly due to the decrease of the positive BC forcing and the
50 decrease in the negative SO_4^{2-} forcing. The anthropogenic aerosols accounted for -0.24 to -
51 0.26 W m^{-2} of the net RF_{ARI} in 2030-2050 period, in Eclipse and CMIP6 ensembles,
52 respectively. Finally, all simulations showed an increase in the Arctic surface air
53 temperatures throughout the simulation period. By 2050, surface air temperatures are
54 projected to increase by $2.4 \text{ }^\circ\text{C}$ to $2.6 \text{ }^\circ\text{C}$ in the Eclipse ensemble and $1.9 \text{ }^\circ\text{C}$ to $2.6 \text{ }^\circ\text{C}$ in the
55 CMIP6 ensemble, compared to the 1990-2010 mean.

56

57 Overall, results show that even the scenarios with largest emission reductions leads to similar
58 impact on the future Arctic surface air temperatures and sea-ice extent compared to scenarios
59 with smaller emission reductions, implying reductions of greenhouse emissions are still
60 necessary to mitigate climate change.

61

62 1. Introduction

63

64 The Arctic is warming two to three times faster than the global average (IPCC, 2013;
65 Lenssen et al., 2019). This is partly due to internal Arctic feedback mechanisms, such as the
66 snow and sea-ice-albedo feedback, where melting ice leads to increased absorption of solar
67 radiation, which further enhances warming in the Arctic (Serreze and Francis, 2006).
68 However, Arctic temperatures are also affected by interactions with warming at lower
69 latitudes (e.g., Stuecker et al., 2018; Graversen and Langen, 2019; Semmler et al., 2020) and
70 by local in situ response to radiative forcing due to changes in greenhouse gases and aerosols
71 in the area (Shindell, 2007; Stuecker et al., 2018). In addition to warming induced by
72 increases in global atmospheric carbon dioxide (CO_2) concentrations, changes in short-lived
73 climate forcers (SLCFs) such as tropospheric ozone (O_3), methane (CH_4) and aerosols (e.g.
74 black carbon (BC) and sulfate (SO_4^{2-})) in the Northern Hemisphere (NH), have contributed
75 substantially to the Arctic warming since 1890 (Shindell and Faluvegi, 2009; Ren et al.,
76 2020). This contribution from SLCFs to Arctic heating together with efficient local
77 amplification mechanisms puts a high priority on understanding the sources and sinks of
78 SLCFs at high latitudes and their corresponding climatic effects.

79

80 SLCFs include all atmospheric species, which have short residence times in the atmosphere
81 relative to long-lived greenhouse gases and have the potential to affect Earth's radiative
82 energy budget. Aerosols are important SLCFs and are a predominant component of air
83 quality that affects human health (Burnett et al., 2018, Lelieveld et al., 2019). They mostly
84 affect climate by altering the amount of solar energy absorbed by Earth, as well as changing
85 the cloud properties and indirectly affecting the scattering of radiation, and are efficiently
86 removed from the troposphere within several days to weeks. BC, which is a product of
87 incomplete combustion and open biomass/biofuel burning (Bond et al., 2004: 2013), absorbs
88 a high proportion of incident solar radiation and therefore warms the climate system
89 (*Jacobson, 2001*). SO_4^{2-} , which is formed primarily through oxidation of sulphur dioxide

90 (SO₂), absorbs negligible solar radiation and cools climate by scattering solar radiation back
91 to space. Organic carbon (OC), which is co-emitted with BC during combustion, both scatters
92 and absorbs solar radiation and therefore causes cooling in some environments and warming
93 in others. Highly reflective regions such as the Arctic are more likely to experience warming
94 effects from these organic aerosols (e.g., Myhre et al, 2013).

95
96 Aerosols also influence climate via indirect mechanisms. After being deposited on snow and
97 ice surfaces, BC can amplify ice melt by lowering the albedo and increasing solar heating of
98 the surface (AMAP, 2015). Aerosols also affect cloud properties, including their droplet size,
99 lifetime, and vertical extent, thereby influencing both the shortwave cooling and longwave
100 warming effects of clouds. Globally, this indirect cloud forcing from aerosols is likely larger
101 than their direct forcing, although the indirect effects are more uncertain and difficult to
102 accurately quantify (IPCC, 2013). Moreover, Arctic cloud impacts are distinct from global
103 impacts, owing to the extreme seasonality of solar radiation in the Arctic, unique
104 characteristics of Arctic clouds (e.g., high frequency of mixed-phase occurrence), and rapidly
105 evolving sea-ice distributions. Together, they lead to complicated and unique phenomena that
106 govern Arctic aerosol abundances and climate impacts (e.g., Willis et al., 2018; Abbatt et al.,
107 2019). The changes taking place in the Arctic have consequences for how SLCFs affect the
108 region. For example, reductions in sea-ice extent, thawing of permafrost, and humidification
109 of the Arctic troposphere can affect the emissions, lifetime and radiative forcing of SLCFs
110 within the Arctic (Thomas et al., 2019).

111
112 The effect of aerosols on the Arctic climate through the effects of scattering and absorption of
113 radiation, clouds, and surface ice/snow albedo has been investigated in previous studies (i.e.
114 Clarke and Noone, 1985; Flanner et al., 2007; Shindell et al., 2012; Bond et al., 2013;
115 Dumont et al., 2014). The impact of aerosols on the Arctic climate change is mainly driven
116 by a response to remote forcings (Gagné et al., 2015; Sand et al., 2015; Westervelt et al.,
117 2015). Long-range transport is known to play an important role in the Arctic air pollution
118 levels and much of the attention on aerosol climatic effects in the Arctic was focused on
119 long-range transported anthropogenic pollution (Arctic haze) in the past (Quinn et al., 2017;
120 AMAP, 2015; Abbatt et al., 2019). Long-range transport of BC and SO₄²⁻, in particular from
121 Asia, travelling at a relatively high altitude to the Arctic, can be deposited on the snow and
122 ice, contributing to surface albedo reduction. On the other hand, there has been increasing
123 attention on the local Arctic aerosol sources, in particular natural aerosol sources (Schmale et
124 al., 2021). Lewinschal et al. (2019) estimated an Arctic surface temperature change per unit
125 global sulfur emission of -0.020 to -0.025 K per TgS yr⁻¹. Sand et al. (2020) calculated an
126 Arctic surface air temperature response of 0.06 - 0.1 K per Tg BC yr⁻¹ to BC emissions in
127 Europe and North America, and slightly lower response (0.05-0.08 K per Tg BC yr⁻¹) to
128 Asian emissions. Breider et al. (2017) reported a short-wave (SW) aerosol radiative forcing
129 (ARF) of $-0.19 \pm 0.05 \text{ W m}^{-2}$ at the top of the atmosphere (TOA) over the Arctic, which
130 reflects the balance between sulphate cooling (-0.60 W m^{-2}) and black carbon (BC) warming
131 ($+0.44 \text{ W m}^{-2}$). Schacht et al. (2019) calculated a direct radiative forcing of up to 0.4 W m^{-2}
132 over the Arctic using the ECHAM6.3-HAM2.3 global aerosol-climate model. Markowicz et
133 al. (2021), using the NAAPS radiative transfer model, calculated the total aerosol forcing

134 over the Arctic ($>70.5^\circ\text{N}$) of -0.4 W m^{-2} . Ren et al. (2020) simulated 0.11 and 0.25 W m^{-2}
135 direct and indirect warming in 2014-2018 compared to 1980-1984 due to reductions in
136 sulfate, using the CAM5-EAST global aerosol-climate model. They also reported that the
137 aerosols produced an Arctic surface warming of $+0.30^\circ\text{C}$ during 1980–2018, explaining
138 about 20% of the observed Arctic warming observed during the last four decades, while
139 according to Shindell and Faluvegi (2009), aerosols contributed $1.09 \pm 0.81^\circ\text{C}$ to the
140 observed Arctic surface air temperature increase of $1.48 \pm 0.28^\circ\text{C}$ observed in 1976-2007.
141 AMAP (2015), based on four ESMs, estimated a total Arctic surface air temperature response
142 due to the direct effect of current global combustion derived BC, OC and sulfur emissions to
143 be $+0.35^\circ\text{C}$, of which $+0.40^\circ\text{C}$ was attributed to BC in the atmosphere, $+0.22^\circ\text{C}$ to BC in
144 snow, -0.04°C to OC and -0.23°C to SO_4^{2-} . On the other hand, Stjern et al. (20117) and
145 Takemura and Suzuki (2019) showed that due to the rapid adjustments from BC, mitigation
146 of BC emissions can lead to weak responses in the surface temperatures. Samset et al. (2018),
147 using a multi-model ensemble of ocean coupled Earth system models (ESMs), where aerosol
148 emissions were either kept at present-day conditions, or anthropogenic emissions of SO_2 , and
149 fossil fuel BC and OC were set to zero, showed that Arctic surface warming due to aerosol
150 reductions can reach up to 4°C in some locations, with a multi-model increase for the 60°N –
151 90°N region being 2.8°C . In addition, recent studies also suggest that as global emissions of
152 anthropogenic aerosols decrease, natural aerosol feedbacks may become increasingly
153 important for Arctic climate (Boy et al., 2019; Mahmood et al., 2019).

154
155 In this study, we carry out several simulations with the fully coupled NASA Goddard
156 Institute of Space Sciences (GISS) earth system model, GISS-E2.1 (Kelley et al., 2020) to
157 study the recent past and future burdens of aerosols as well as their impacts on TOA radiative
158 forcing and climate-relevant parameters such as surface air temperatures, sea-ice, and snow
159 over the Arctic ($>60^\circ\text{N}$). In addition, we investigate the impacts from two different emission
160 inventories; Eclipse V6b (Höglund-Isaksson et al., 2020; Klimont et al., 2021) vs. CMIP6
161 (Hoesly et al., 2018; van Marle et al., 2017; Feng et al., 2020), as well as differences between
162 atmosphere-only vs. fully-coupled simulations, on the evaluation of the model and the
163 climate impact. Section 2 introduces the GISS-E2.1 model, the anthropogenic emissions, and
164 the observation datasets used in model evaluation. Section 3 presents results from the model
165 evaluation as well as recent past and future trends in simulated aerosol burdens, radiative
166 forcing, and climate change over the Arctic. Section 4 summarizes the overall findings and
167 the conclusions.

168

169 2. Materials and methods

170

171 2.1. Model description

172

173 GISS-E2.1 is the CMIP6 version of the GISS modelE Earth system model, which has been
174 validated extensively over the globe (Kelly et al., 2020; Bauer et al., 2020) as well as
175 regionally for air pollutants (Turnock et al., 2020). A full description of GISS-E2.1 and
176 evaluation of its coupled climatology during the satellite era (1979–2014) and the recent past
177 ensemble simulation of the atmosphere and ocean component models (1850-2014) are

178 described in Kelly et al. (2020) and Miller et al. (2020), respectively. GISS-E2.1 has a
179 horizontal resolution of 2° in latitude by 2.5° in longitude and 40 vertical layers extending
180 from the surface to 0.1 hPa in the lower mesosphere. The tropospheric chemistry scheme
181 used in GISS-E2.1 (Shindell et al., 2013) includes inorganic chemistry of O_x , NO_x , HO_x , CO ,
182 and organic chemistry of CH_4 and higher hydrocarbons using the CBM4 scheme (Gery et al.,
183 1989), and the stratospheric chemistry scheme (Shindell et al., 2013), which includes chlorine
184 and bromine chemistry together with polar stratospheric clouds.

185
186 In the present work, we used the One-Moment Aerosol scheme (OMA: Bauer et al., 2020 and
187 references therein), which is a mass-based scheme in which aerosols are assumed to remain
188 externally mixed. All aerosols have a prescribed and constant size distribution, with the
189 exception of sea salt that has two distinct size classes, and dust that is described by a
190 sectional model with an option from 4 to 6 bins. The default dust configuration that is used in
191 this work includes 5 bins, a clay and 4 silt ones, from submicron to $16\ \mu m$ in size. The first
192 three dust size bins can be coated by sulfate and nitrate aerosols (Bauer & Koch, 2005). The
193 scheme treats sulfate, nitrate, ammonium, carbonaceous aerosols (black carbon and organic
194 carbon, including the NO_x -dependent formation of secondary organic aerosol (SOA) and
195 methanesulfonic acid formation), dust and sea-salt. The model includes secondary organic
196 aerosol production, as described by Tsigaridis and Kanakidou, (2007). SOA is calculated
197 from terpenes and other reactive volatile organic compounds (VOCs) using NO_x -dependent
198 calculations of the 2-product model, as described in Tsigaridis and Kanakidou (2007).
199 Isoprene is explicitly used as a source, while terpenes and other reactive VOCs are lumped on
200 α -pinene, taking into account their different reactivity against oxidation. The semi-volatile
201 compounds formed can condense on all submicron particles except sea salt and dust. In the
202 model, an OA to OC ratio of 1.4 used. OMA only includes the first indirect effect, in which
203 the aerosol number concentration that impacts clouds is obtained from the aerosol mass as
204 described in (Menon & Rotstayn, 2006). The parameterization described by Menon and
205 Rotstayn (2006) that we use only affects the cloud droplet number concentration (CDNC),
206 not cloud droplet size, which is not explicitly calculated in GISS-E2.1. Following the change
207 in CDNC, we do not stop the model from changing either liquid water path (LWP) or
208 precipitation rates, since the clouds code sees the different CDNC and responds accordingly.
209 What we do not include is the 2nd indirect effect (autoconversion). In addition to OMA, we
210 have also conducted a non-interactive tracers (NINT: Kelley et al., 2020) simulation from
211 1850 to 2014, with noninteractive (through monthly varying) fields of radiatively active
212 components (ozone and multiple aerosol species) read in from previously calculated offline
213 fields from the OMA version of the model, ran using the Atmospheric Model
214 Intercomparison Project (AMIP) configuration in Bauer et al. (2020) as described in Kelley et
215 al. (2020). The NINT model includes a tuned aerosol first indirect effect following Hansen et
216 al. (2005).

217
218 The natural emissions of sea salt, dimethylsulfide (DMS), isoprene and dust are calculated
219 interactively. Anthropogenic dust sources are not represented in GISS-E2.1. Dust emissions
220 vary spatially and temporally only with the evolution of climate variables like wind speed
221 and soil moisture (Miller et al., 2006). Dust concentrations are tuned to match the observed

222 dust aerosol optical depth (AOD). The AMIP type simulations (see section 2.3) uses
223 prescribed sea surface temperature (SST) and sea ice fraction during the recent past (Rayner
224 et al., 2003). The prescribed SST dataset in GISS-E2.1 is merged product based on the
225 HadISST and NOAA Optimum Interpolation (OI) Sea Surface Temperature (SST) V2
226 (Reynolds et al., 2002).

227

228 2.2. Emissions

229

230 In this study, we have used two different emission datasets; the ECLIPSE V6b (Höglund-
231 Isaksson et al., 2020; Klimont et al., 2021), which has been developed with support of the EU-
232 funded Action on Black Carbon in the Arctic (EUA-BCA) and used in the framework of the
233 ongoing AMAP Assessment (AMAP, 2021), referred to as *Eclipse* in this paper, and the
234 CEDS emissions (Hoesly et al., 2018; Feng et al., 2020) combined with selected Shared
235 Socio-economic Pathways (SSP) scenarios used in the CMIP6 future projections (Eyring et
236 al., 2016), collectively referred to as *CMIP6* in this paper.

237

238 2.2.1. EclipseV6b emissions

239

240 The ECLIPSE V6b emissions dataset is a further evolution of the scenarios established in the
241 EU funded ECLIPSE project (Stohl et al., 2015; Klimont et al., 2017). It has been developed
242 with the global implementation of the GAINS (Greenhouse gas – Air pollution Interactions
243 and Synergies) model (Amann et al., 2011). The GAINS model includes all key air pollutants
244 and Kyoto greenhouse gases, where emissions are estimated for nearly 200 country-regions
245 and several hundred source-sectors representing anthropogenic emissions. For this work,
246 annual emissions were spatially distributed on $0.5^{\circ} \times 0.5^{\circ}$ lon-lat grids for nine sectors: energy,
247 industry, solvent use, transport, residential combustion, agriculture, open burning of
248 agricultural waste, waste treatment, gas flaring and venting, and international shipping. A
249 monthly pattern for each gridded layer was provided at a $0.5^{\circ} \times 0.5^{\circ}$ grid level. The ECLIPSE
250 V6b dataset, used in this study, includes an estimate for 1990 to 2015 using statistical data
251 and two scenarios extending to 2050 that rely on the same energy projections from the World
252 Energy Outlook 2018 (IEA, 2018) but have different assumptions about the implementation
253 of air pollution reduction technologies, as described below.

254 The Current Legislation (CLE) scenario assumes efficient implementation of the current air
255 pollution legislation committed before 2018, while the Maximum Feasible Reduction (MFR)
256 scenario assumes implementation of best available emission reduction technologies included
257 in the GAINS model. The MFR scenario demonstrates the additional reduction potential of
258 SO_2 emissions by up to 60% and 40%, by 2030 for Arctic Council member and observer
259 countries respectively, with implementation of best available technologies mostly in the
260 energy and industrial sectors and to a smaller extent via measures in the residential sector.
261 The Arctic Council member countries' maximum reduction potential could be fully realized
262 by 2030 whereas in the observer countries additional reductions of 15% to 20% would
263 remain to be achieved between 2030 and 2050. The assumptions and the details for the CLE

264 and MFR scenarios (as well as other scenarios developed within the ECLIPSE V6b family)
265 can be found in Höglund-Isaksson et al. (2020) and Klimont et al. (in preparation).

266 2.2.2. CMIP6 emissions

267 The CMIP6 emission datasets include a historical time series generated by the Community
268 Emissions Data System (CEDS) for anthropogenic emissions (Hoesly et al., 2018; Feng et al.,
269 2020), open biomass burning emissions (van Marle et al., 2010), and the future emission
270 scenarios driven by the assumptions embedded in the Shared Socioeconomic Pathways
271 (SSPs) and Representative Concentration Pathways (RCPs) (Riahi et al., 2017) that include
272 specific air pollution storylines (Rao et al., 2017). Gridded CMIP6 emissions are aggregated
273 to nine sectors: agriculture, energy, industrial, transportation, residential–commercial–other,
274 solvents, waste, international shipping, and aircraft. SSP data for future emissions from
275 integrated assessment models (IAMs) are first harmonized to a common 2015 base-year
276 value by the native model per region and sector. This harmonization process adjusts the
277 native model data to match the 2015 starting year values with a smooth transition forward in
278 time, generally converging to native model results (Gidden et al., 2018). The production of
279 the harmonized future emissions data is described in Gidden et al. (2019).

280

281 2.2.3. Implementation of the emissions in the GISS-E2.1

282 The Eclipse V6b and CEDS emissions on $0.5^\circ \times 0.5^\circ$ spatial resolution are regridded to $2^\circ \times$
283 2.5° resolution in order to be used in the various GISS-E2.1 simulations. In the GISS-E2.1
284 Eclipse simulations, the non-methane volatile organic carbons (NMVOC) emissions are
285 chemically speciated assuming the SSP2-4.5 VOC composition profiles. In the Eclipse
286 simulations, biomass burning emissions are taken from the CMIP6 emissions, which have
287 been pre-processed to include the agricultural waste burning emissions from the EclipseV6b
288 dataset, while the rest of the biomass burning emissions are taken as the original CMIP6
289 biomass burning emissions. In addition to the biomass burning emissions, the aircraft
290 emissions are also taken from the CMIP6 database to be used in the Eclipse simulations. As
291 seen in Figure 1, the emissions are consistently higher in the CMIP6 compared to the Eclipse
292 emissions. The main differences in the two datasets are mainly over south-east Asia (not
293 shown) . The CMIP6 emissions are also consistently higher on a sectoral basis compared to
294 the Eclipse emissions. The figure shows that for air pollutant emissions, the CMIP6 SSP1-2.6
295 scenario and the Eclipse MFR scenario follow each other closely, while the Eclipse CLE
296 scenario is comparable with the CMIP6 SSP2-4.5 scenario for most pollutants; that is to some
297 extent owing to the fact that the CO₂ trajectory of the Eclipse CLE and the SSP2-4.5 are very
298 similar (not shown). A more detailed discussion of differences between historical Eclipse and
299 CMIP6 as well as CMIP6 scenarios are provided in Klimont et al. (in preparation).

300 2.3. Simulations

301

302 In order to contribute to the AMAP Assessment report (AMAP, 2021), the GISS-E2.1 model
303 participated with AMIP-type simulations, which aim to assess the trends of Arctic air

304 pollution and climate change in the recent past, as well as with fully-coupled climate
305 simulations. Five fully-coupled Earth system models (ESMs) simulated the future (2015-
306 2050) changes of atmospheric composition and climate in the Arctic ($>60^{\circ}\text{N}$), as well as over
307 the globe. We have carried out two AMIP-type simulations, one with winds nudged to NCEP
308 (standard AMIP-type simulation in AMAP) and one with freely varying winds, where both
309 simulations used prescribed SSTs and sea-ice (Table 1). The nudging extents from the first
310 model layer up to 10 hPa, which is the top of the NCEP input. In the fully-coupled
311 simulations, we carried out two sets of simulations, each with three ensemble members, that
312 used the CLE and MFR emission scenarios. Each simulation in these two sets of scenarios
313 were initialized from a set of three fully-coupled ensemble recent past simulations (1990-
314 2014) to ensure a smooth continuation from CMIP6 to Eclipse emissions.

315
316 In addition to the AMAP simulations, we have also conducted CMIP6-type simulations in
317 order to compare the climate aerosol burdens and their impacts on radiative forcing and
318 climate impacts with those from the AMAP simulations. We have used the SSP1-2.6, 2-4.5,
319 3-7.0, and 3-7.0-lowNTCF scenarios representing different levels of emission mitigations in
320 the CMIP6 simulations. SSP1 and SSP3 define various combinations of high or low socio-
321 economic challenges to climate change adaptation and mitigation, while SSP2 describes
322 medium challenges of both kinds and is intended to represent a future in which development
323 trends are not extreme in any of the dimensions, but rather follow middle-of-the-road
324 pathways (Rao et al., 2017). SSP1-2.6 scenario aims to achieve a 2100 radiative forcing level
325 of 2.6 W m^{-2} , keeping the temperature increase below 2°C compared to the preindustrial
326 levels. The SSP2-4.5 describes a “middle of the road” socio-economic family with a 4.5 W
327 m^{-2} radiative forcing level by 2100. The SSP3-7.0 scenario is a medium-high reference
328 scenario. SSP3-7.0-lowNTCF is a variant of the SSP3-7.0 scenario with reduced near-term
329 climate forcer (NTCF) emissions. The SSP3-7.0 scenario has the highest methane and air
330 pollution precursor emissions, while SSP3-7.0-lowNTCF investigates an alternative pathway
331 for the Aerosols and Chemistry Model Intercomparison Project (AerChemMIP: Collins et al.,
332 2017), exhibiting very low methane, aerosol, and tropospheric-ozone precursor emissions –
333 approximately in line with SSP1-2.6. As seen in Table 1, we have conducted one transient
334 fully-coupled simulation from 1850 to 2014, and a number of future scenarios.

335
336 We have employed prescribed global and annual mean greenhouse (CO_2 and CH_4)
337 concentrations, where a linear increase in global mean temperature of $0.2^{\circ}\text{C}/\text{decade}$ from
338 2019 to 2050 was assumed, which are approximately in line with the simulated warming rates
339 for the SSP2-4.5 scenario (AMAP, 2021).

340 341 2.4. Observations

342
343 The GISS-E2.1 ensemble has been evaluated against surface observations of BC, organic
344 aerosols (sum of OC and secondary organic aerosols (SOA), referred as OA in the rest of the
345 paper) and SO_4^{2-} , ground-based and satellite-derived AOD at 550 nm, as well as surface and
346 satellite observations of surface air temperature, precipitation, sea surface temperature, sea-
347 ice extent, cloud fraction, and liquid and ice water content in 1995-2014 period. The surface

348 monitoring stations used to evaluate the simulated aerosol levels have been listed in Table S1
349 and S2 in the supplementary materials.

350

351 *2.4.1. Aerosols*

352

353 Measurements of speciated particulate matter (PM), BC, SO₄²⁻, and (OA) come from three
354 major networks: the Interagency Monitoring of Protected Visual Environments (IMPROVE)
355 for Alaska (The IMPROVE measurements that are in the Arctic (>60°N) are all in Alaska);
356 the European Monitoring and Evaluation Programme (EMEP) for Europe; and the Canadian
357 Air Baseline Measurements (CABM) for Canada (Table S1 and S2). In addition to these
358 monitoring networks, BC, OA, and SO₄²⁻ measurements from individual Arctic stations were
359 used in this study. The individual Arctic stations are Fairbanks and Utqiagvik, Alaska (part of
360 IMPROVE, though their measurements were obtained from their PIs); Gruvebadet and
361 Zeppelin mountain (Ny Alesund), Norway; Villum Research Station, Greenland; and Alert,
362 Nunavut (the latter being an observatory in Global Atmospheric Watch-WMO, and a part of
363 CABM). The measurement techniques are briefly described in the supplement.

364

365 AOD at 500 nm from the AErosol RObotic NETwork (AERONET, Holben et al., 1998) was
366 interpolated to 550 nm AOD using the Ångström formula (Ångström, 1929). We also used a
367 new merged AOD product developed by Sogacheva et al. (2020) using AOD from 10
368 different satellite-based products. According to Sogacheva et al. (2020), this merged product
369 could provide a better representation of temporal and spatial distribution of AOD. However,
370 it is important to note that the monthly aggregates of observations for both AERONET and
371 the satellite products depend on availability of data and are not likely to be the true aggregate
372 of observations for a whole month when only few data points exist during the course of a
373 month. In addition, many polar orbiting satellites take one observation during any given day,
374 and typically at the same local time. Nevertheless, these data sets are key observations
375 currently available for evaluating model performances. Information about the uncertain
376 nature of AOD observations can be found in previous studies (e.g. Sayer et al., 2018; Sayer
377 and Knobelspiesse, 2019; Wei et al., 2019; Schutgens et al., 2020, Schutgens, 2020;
378 Sogacheva et al., 2020).

379

380 *2.4.2. Surface air temperature, precipitation, and sea-ice*

381

382 Surface air temperature and precipitation observations used in this study are from University
383 of Delaware gridded monthly mean data sets (UDel; Willmott and Matsuura, 2001). UDel's
384 0.5° resolution gridded data sets are based on interpolations from station-based measurements
385 obtained from various sources including the Global Historical Climate Network, the archive
386 of Legates and Willmott and others. The Met Office Hadley Center's sea ice and sea surface
387 temperature (HadISST; Rayner et al., 2003) was used for evaluating model simulations of sea
388 ice and SSTs. HadISST data is an improved version of its predecessor known as global sea
389 ice and sea surface temperature (GISST). HadISST data is constructed using information
390 from a variety of data sources such as the Met Office Marine Database, Comprehensive
391 Ocean-Atmosphere Data Set, passive microwave remote sensing retrieval and sea ice charts.

392

393 2.4.3. Satellite observations used for cloud fraction and cloud liquid water and ice water

394

395 The Advanced Very High Resolution Radiometer (AVHRR-2) sensors onboard the NOAA
396 and EUMETSAT polar orbiting satellites have been flying since the early 1980s. These data
397 have been instrumental in providing the scientific community with climate data records
398 spanning nearly four decades. Tremendous progress has been made in recent decades in
399 improving, training and evaluating the cloud property retrievals from these AVHRR sensors.
400 In this study, we use the retrievals of total cloud fraction from the second edition of
401 EUMETSATs Climate Monitoring Satellite Application Facility (CM SAF) Cloud, Albedo
402 and surface Radiation data set from AVHRR data (CLARA-A2, Karlsson et al., 2017). This
403 cloud property climate data record is available for the period 1982-2018. Its strengths and
404 weaknesses and inter-comparison with the other similar climate data records are documented
405 in Karlsson and Devasthale (2018). Further data set documentation including Algorithm
406 Theoretical Basis and Validation reports can be found in Karlsson et al. (2017).

407

408 Cloud liquid and ice water path estimates derived from the cloud profiling radar on board
409 CloudSat (Stephens et al., 2002) and constrained with another sensor onboard NASA's A-
410 Train constellation, MODIS-Aqua (Platnick et al., 2015), are used for the model evaluation.
411 These Level 2b retrievals, available through 2B-CWC-RVOD product (Version 5), for the
412 period 2007-2016 are analysed. This constrained version is used instead of its radar-only
413 counterpart, as it uses additional information about visible cloud optical depths from MODIS,
414 leading to better estimates of cloud liquid water paths. Because of this constraint the data are
415 available only for the day-lit conditions, and hence, are missing over the polar regions during
416 the respective winter seasons. The theoretical basis for these retrievals can be found in
417 [http://www.cloudsat.cira.colostate.edu/sites/default/files/products/files/2B-CWC-](http://www.cloudsat.cira.colostate.edu/sites/default/files/products/files/2B-CWC-RVOD_PDICD.P1_R05.rev0_.pdf)
418 [RVOD_PDICD.P1_R05.rev0_.pdf](http://www.cloudsat.cira.colostate.edu/sites/default/files/products/files/2B-CWC-RVOD_PDICD.P1_R05.rev0_.pdf) (last access: October 26th 2020). Being an active cloud
419 radar, CloudSat provides orbital curtains with a swath width of just about 1.4 km. Therefore,
420 the data are gridded at 5°x5° to avoid too many gaps or patchiness and to provide robust
421 statistics.

422

423 3. Results

424

425 3.1. Evaluation

426

427 The simulations are compared against surface measurements of BC, OA, SO₄²⁻ and AOD, as
428 well as surface and satellite measurements of surface air temperature, precipitation, sea
429 surface temperature, sea-ice extent, total cloud fraction, liquid water path, and ice water path
430 described in section 2.4, by calculating the correlation coefficient (r) and normalized mean
431 bias (NMB). OA refers to the sum of primary organic carbon (OC) and secondary organic
432 aerosols (SOA).

433

434 3.1.1. Aerosols

435 The recent past simulations are for BC, OA, SO₄ and AOD (Table 2) against available
436 surface measurements. The monthly observed and simulated time series for each station are
437 accumulated per species in order to get a full Arctic timeseries data, which also includes
438 spatial variation, to be used for the evaluation of the model. In addition to Table 2, the
439 climatological mean (1995-2014) of the observed and simulated monthly surface
440 concentrations of BC, OA, SO₄²⁻ and AOD at 550 nm (note that AOD is averaged over 2008,
441 2009 and 2014) are shown in Figure 2. The AOD observation data for years 2008, 2009, and
442 2014 are used in order to keep the comparisons in line with the multi-model evaluations
443 being carried out in the AMAP assessment report (AMAP, 2021). We also provide spatial
444 distributions of the NMB, calculated as the mean of all simulations for BC, OA, SO₄ and
445 AOD in Figure 3. The statistics for the individual stations are provided in the Supplementary
446 Material, Tables S3-S6.

447

448 Results showed overall an underestimation of aerosol species over the Arctic, as discussed
449 below. Surface BC levels are underestimated at all Arctic stations from 15% to 90%. Surface
450 OA levels are also underestimated from -5% to -70%, except for a slight overestimation of
451 <1% over Karvatn (B5) and a large overestimation of 90% over Trapper Creek (B6). Surface
452 SO₄²⁻ concentrations are also consistently underestimated from -10% to -70%, except for
453 Villum Research Station (S11) over northeastern Greenland where there is an overestimation
454 of 45%. Finally, AODs are also underestimated over all stations from 20% to 60%. Such
455 underestimations at high latitudes have also been reported by many previous studies (e.g.
456 Skeike et al., 2011; Eckhardt et al., 2015; Lund et al., 2017, 2018; Schacht et al., 2019;
457 Turnock et al., 2020), pointing to a variety of reasons including uncertainties in emission
458 inventories, errors in the wet and dry deposition schemes, the absence or underrepresentation
459 of new aerosol formation processes, and the coarse resolution of global models leading to
460 errors in emissions and simulated meteorology, as well as in representation of point
461 observations in coarse model grid cells. Turnock et al. (2020) evaluated the air pollutant
462 concentrations in the CMIP6 models, including the GISS-E2.1 ESM, and found that observed
463 surface PM_{2.5} concentrations are consistently underestimated in CMIP6 models by up to 10
464 µg m⁻³, particularly for the Northern Hemisphere winter months, with the largest model
465 diversity near natural emission source regions and the Polar regions.

466

467 The BC levels are largely underestimated in simulations by 50% (CMIP6_Cpl_Hist) to 67%
468 (Eclipse_AMIP). The CMIP6 simulations have lower bias compared to EclipseV6b
469 simulations due to higher emissions in the CMIP6 emission inventory (Figure 1). Within the
470 EclipseV6b simulations, the lowest bias (-57%) is calculated for the Eclipse_AMIP_NCEP
471 simulation, while the free climate and coupled simulations showed a larger underestimation
472 (>62%), which can be attributed to a better simulation of transport to the Arctic when nudged
473 winds are used. The Eclipse simulations also show that the coupled simulations had slightly
474 smaller biases (NMB=-63%) compared to the AMIP-type free climate simulation (AMIP-
475 OnlyAtm: NMB=-67%). The climatological monthly variation of the observed levels is
476 poorly reproduced by the model with *r* values around 0.3. BC levels are mainly
477 underestimated in winter and spring, which can be attributed to the underestimation of the

478 anthropogenic emissions of BC, while the summer levels are well captured by the majority of
479 the simulations (Figure 2).

480

481 Surface OA concentrations are underestimated from 8% (Eclipse_AMIP_NCEP) to 35%
482 (Eclipse_AMIP) by the Eclipse ensemble, while the CMIP6_Cpl_Hist simulation
483 overestimated surface OA by 13%. The Eclipse simulations suggest that the nudged winds
484 lead to a better representation of transport to the Arctic, while the coupled simulations had
485 smaller biases compared to the AMIP-type free climate simulation (AMIP-OnlyAtm), similar
486 to BC. The climatological monthly variation of the observed concentrations are reasonably
487 simulated, with r values between 0.51 and 0.69 (Table 2 and Figure 2). As can be seen in
488 Figure S1, the OA levels are dominated by the biogenic SOA, in particular via α -pinene
489 (monoterpenes) oxidation, compared to anthropogenic (by a factor of 4-9) and biomass
490 burning (by a factor of 2-3) OA. While OC and BC are emitted almost from similar sources,
491 this biogenic-dominated OA seasonality also explains why simulated BC seasonality is not as
492 well captured, suggesting the underestimations in the anthropogenic emissions of these
493 species, in particular during the winter. It should also be noted that GISS-E2.1 does not
494 include marine VOC emissions except for DMS, while these missing VOCs such as isoprene
495 and monoterpenes are suggested to be important sources for the summer time aerosol levels
496 over the Arctic (Ornella et al., 2011; Karl et al., 2013; Schmale et al., 2021).

497

498 Surface SO_4^{2-} levels are simulated with a smaller bias compared to the BC levels, however
499 still underestimated by 40% (CMIP6_Cpl_Hist) to 53% (Eclipse_AMIP_NCEP). The
500 Eclipse_AMIP_NCEP simulation is biased higher (NMB=-53%) compared to the
501 Eclipse_AMIP (NMB=-50%), probably due to higher cloud fraction simulated by the nudged
502 version (see section 3.1.6), leading to higher in-cloud SO_4^{2-} production. The climatological
503 monthly variation of observed SO_4^{2-} concentrations are reasonably simulated in all
504 simulations ($r=0.65-0.74$). The observed springtime maximum is well captured by the GISS-
505 E2.1 ensemble, with underestimations in all seasons, mainly suggesting underestimations in
506 anthropogenic SO_2 emissions (Figure 2), as well as simulated cloud fractions, which have
507 high positive bias in winter and transition seasons, while in summer, the cloud fraction is well
508 captured with a slight underestimation. The clear sky AOD over the Aeronet stations in the
509 Arctic region is underestimated by 33% (Eclipse_AMIP) to 47% (Eclipse_CplHist1). Similar
510 negative biases are found with comparison to the satellite based AOD product (Table 2). The
511 climatological monthly variation is poorly captured with r values between -0.07 to 0.07
512 compared to AERONET AOD and 0 to 0.13 compared to satellite AOD. The simulations
513 could not represent the climatological monthly variation of the observed AERONET AODs
514 (Figure 2).

515

516 3.1.2. Climate

517 The different simulations are evaluated against a set of climate variables and the statistics are
518 presented in Table 3a and 3b, and in Figures 4 and 5. The climatological mean (1995-2014)
519 monthly Arctic surface air temperatures are slightly overestimated by up to 0.55 °C in the
520 AMIP simulations, while the coupled ocean simulations underestimate the surface air
521 temperatures by up to -0.17 °C. All simulations were able to reproduce the monthly

522 climatological variation with r values of 0.99 and higher (Figure 4). Results show that both
523 absorbing (BC) and scattering aerosols (OC and SO_4^{2-}) are underestimated by the GISS-E2.1
524 model, implying that these biases can partly cancel out their impacts on radiative forcing due
525 to aerosol-radiation interactions. This, together with the very low biases in surface
526 temperatures suggests that the effects of the anthropogenic aerosols on the Arctic climate via
527 radiation is not the main driver in comparison to cloud indirect effects and forcing from
528 greenhouse gases. The monthly mean precipitation has been underestimated by around 50%
529 by all simulations (Table 3a), with largest biases during the summer and autumn (Figure 4).
530 The observed monthly climatological mean variation was very well simulated by all
531 simulations, with r values between 0.80 and 0.90.

532
533 Arctic SSTs are underestimated by the ocean-coupled simulation up to -1.96 °C, while the
534 atmosphere-only runs underestimated SSTs by -1.5 °C (Table 3a). The negative bias in
535 atmosphere-only simulations is due to the different datasets used to drive the model, which a
536 combined product of HadISST and NOAA-OI2 (Reynolds et al., 2002) and to evaluate the
537 model (Rayner et al., 2003), which is only HadISST. The monthly climatological mean
538 variation is well captured with r values above 0.99 (Table 3a, Figure 4), with a similar cold
539 bias in almost all seasons. The sea-ice extent was overestimated by all coupled simulations by
540 about 12%, while the AMIP-type Eclipse simulations slightly underestimated the extent by
541 3% (Table 3a). The observed variation was also very well captured with very high r values.
542 The winter and spring biases were slightly higher compared to the summer and autumn biases
543 (Figure 4).

544
545 All simulations overestimate the climatological (1995-2014) mean total cloud fraction by
546 21% to 25% during the extended winter months (October through February), where the
547 simulated seasonality is anti-correlated in comparison to AVHRR CLARA-A2 observations,
548 whereas, a good correlation is seen during the summer months irrespective of the
549 observational data reference. The largest biases were simulated by the atmosphere-only
550 simulations, with the nudged simulation having the largest bias ($NMB=25\%$). The coupled
551 model simulations are closer to the observations during the recent past. On the other hand, the
552 climatology of the annual-mean cloud fraction was best simulated by the nudged atmosphere-
553 only simulation (Eclipse_AMIP_NCEP) with a r value of 0.40, while other simulations
554 showed a poor performance ($r=-0.17$ to $+0.10$), except for the summer where the bias is
555 lowest (Figure 5). The evaluation against CALIPSO data however shows much smaller biases
556 ($NMB = +3\%$ to $+6\%$). This is because in comparison to CALIPSO satellite that carries an
557 active lidar instrument (CALIOP), the CLARA-A2 dataset has difficulties in separating cold
558 and bright ice/snow surfaces from clouds thereby underestimating the cloudiness during
559 Arctic winters. Here both datasets are used for the evaluation as they provide different
560 observational perspectives and cover the typical range of uncertainty expected from the
561 satellite observations. Furthermore, while the CLARA-A2 covers the entire evaluation period
562 in current climate scenario, CALIPSO observations are based on 10-year data covering the
563 2007-2016 period.

564

565 Figure 5 shows the evaluation of the simulations with respect to LWP and IWP. It has to be
566 noted here that to obtain a better estimate of the cloud water content, the CloudSat
567 observations were constrained with MODIS observations which resulted in a lack of data
568 during the months with darkness (Oct-Mar) over the Arctic (see Section 2.4.3). Hence, we
569 present the results for the polar summer months only. As seen in Figure 5, all simulations
570 overestimated the climatological (2007-2014) mean Polar summer LWP by up to almost
571 75%. The smallest bias (14%) is calculated for the nudged atmosphere-only
572 (Eclipse_OnlyAtm_NCEP), while the coupled simulations had biases of 70% or more.
573 Observations show a gradual increase in the LWP, peaking in July, whereas the model
574 simulates a more constant amount for the nudged simulation and a slightly decreasing
575 tendency for the other configurations. All model simulations overestimate LWP during the
576 spring months. The atmosphere-only nudged simulations tend to better simulate the observed
577 LWP during the summer months (June through September). The coupled simulations,
578 irrespective of the emission dataset used, are closer to observations only during the months of
579 July and August.

580

581 The climatological (2007-2014) mean Polar summer IWP is slightly better simulated
582 compared to the LWP, with biases within -60% with the exception of the nudged Eclipse
583 (Eclipse_AMIP_NCEP) simulation ($NMB=-74\%$). All simulations simulated the monthly
584 variation well, with r values of 0.95 and more. In the Arctic, the net cloud forcing at the
585 surface changes sign from positive to negative during the polar summer (Kay and L'Ecuyer,
586 2013). This change typically occurs in May driven mainly by shortwave cooling at the
587 surface. Since the model simulates the magnitude of the LWP reasonably, particularly in
588 summer, the negative cloud forcing can also be expected to be realistic in the model (e.g.
589 Gryspeerdt et al. 2019). Furthermore, the aerosol and pollution transport into the Arctic
590 typically occurs in the lowermost troposphere where liquid water clouds are prevalent during
591 late spring and summer seasons (Stohl, 2006; Law et al., 2014; Thomas et al., 2019). The
592 interaction of ice clouds with aerosols is, however, more complex, as ice clouds could have
593 varying optical thicknesses, with mainly thin cirrus in the upper troposphere and relatively
594 thicker clouds in the layers below. Without the knowledge on the vertical distribution of
595 optical thickness, it is difficult to infer the potential impact of the underestimation of IWP on
596 total cloud forcing and their implications.

597

598 3.2. Arctic burdens and radiative forcing due to aerosol-radiation interactions (RF_{ARI})

599

600 The recent past and future Arctic column burdens for BC, OA and SO_4^{2-} for the different
601 scenarios and emissions are provided in Figure 6. In addition, Table 4 shows the calculated
602 trends in the burdens for BC, OA and SO_4^{2-} for the different scenarios, while Table 5
603 provides the 1990-2010 and 2030-2050 mean burdens of the aerosol components. The BC
604 and SO_4^{2-} burdens started decreasing from the 1990s, while OA burden remains relatively
605 constant, although there is large year-to-year variability in all simulations. All figures show a
606 decrease in burdens after 2015, except for the SSP3-7.0 scenario, where the burdens remain
607 close to the 2015 levels. The high variability in BC and OA burdens over the 2000's is due to
608 the biomass burning emissions from GFED, which have not been harmonized with the no-

609 satellite era. It should also be noted that these burdens can be underestimated considering the
610 negative biases calculated for the surface concentrations and in particular for the AODs
611 reported in Table 2 and Tables S2-6.

612

613 In addition to the burdens of these aerosol species, the TOA radiative forcing due to aerosol-
614 radiation interaction (RF_{ARI}) over the Arctic are simulated by the GISS-E2.1 ensemble. RF_{ARI}
615 is calculated as the sum of shortwave and longwave forcing from the individual aerosol
616 species between 1850 and 2050 are presented in Figure 7. It is important to note that the
617 present study uses the instantaneous forcing diagnostics from the model, which are calculated
618 with a double call to the model's radiation code, with and without aerosols, as described in
619 Bauer et al. (2020) and Miller et al. (2021), and not the effective radiative forcing. The
620 transient cloud radiative effect in GISS-E.2.1 follows Ghan (2013), which calculates the
621 difference in cloud radiative forcing with aerosol scattering and absorption omitted (Bauer et
622 al., 2020). However, the present study only focuses on the RF_{ARI} . The model outputs separate
623 forcing diagnostics for anthropogenic and biomass burning BC and OC, as well as biogenic
624 SOA, making it possible to attribute the forcing to individual aerosol species. The negative
625 RF_{ARI} has increased significantly since 1850 until the 1970's due to an increase in aerosol
626 concentrations. Due to the efforts of mitigating air pollution and thus a decrease in emissions,
627 the forcing became less negative after the 1970's until 2015. Figure 7 also shows a visible
628 difference in the anthropogenic RF_{ARI} simulated by the NINT (prescribed aerosols) and OMA
629 (interactive aerosols) simulations in the CMIP6 ensemble, where the anthropogenic RF_{ARI} by
630 NINT simulation is less negative (by almost 30%) compared to the OMA simulation (Figure
631 7b). On the other hand, no such difference is seen in the net RF_{ARI} time series (Figure 7a).
632 This compensation is largely driven by the 50% more positive dust and 10% less negative
633 sea-salt RF_{ARI} in the OMA simulation.

634

635 3.2.1. Black carbon

636 All simulations show a statistically significant (as calculated by Mann-Kendall trend
637 analyses) decrease in the Arctic BC burdens (Table 4) between 1990-2014, except for the
638 CMIP6_Cpl_Hist, which shows a slight non-significant increase that can be attributed to the
639 large increase in global anthropogenic BC emissions in CMIP6 after year 2000 (Figure 1).
640 From 2015 onwards, all future simulations show a statistically significant decrease in the
641 Arctic BC burden (Table 4). The Eclipse CLE ensemble shows a 1.1 kTon (31%) decrease in
642 the 2030-2050 mean Arctic BC burden compared to the 1990-2010 mean, while the decrease
643 in 2030-2050 mean Arctic BC burden is larger in the MFR ensemble (2.3 kTon: 62%). In the
644 CMIP6 simulations, the 2030-2050 mean Arctic BC burdens decrease by 0.70 to 1.59 kTon,
645 being largest in SSP1-2.6 and lowest in SSP3-7.0-lowNTCF, while the SSP3-7.0 simulation
646 leads to an increase of 0.43 kTon (12%) in 2030-2050 mean Arctic BC burdens. It is
647 important to note that the changes in burden simulated by the Eclipse CLE ensemble (-1.1
648 kTon) is comparable with the change of -1 kTon in the SSP2-4.5 scenario, consistent with the
649 projected emission changes in the two scenarios (Figure 1).

650

651 As seen in Table 6, the GISS-E2.1 ensemble calculated a BC RF_{ARI} of up to 0.23 W m^{-2} over
652 the Arctic, with both CMIP6 and Eclipse coupled simulations estimating the highest forcing

653 of 0.23 W m^{-2} for the 1990-2010 mean (Table 6a). This agrees with previous estimates of the
654 BC RF_{ARI} over the Arctic (e.g. Schacht et al., 2019). In the future, the positive BC RF_{ARI} is
655 generally decreasing (Figure 6) due to lower BC emissions and therefore burdens, except for
656 the SSP3-7.0 scenario, where the BC forcing becomes more positive by 0.05 W m^{-2} due to
657 increasing BC emissions and burdens. The changes in the Arctic RF_{ARI} in Table 6a follows
658 the Arctic burdens presented in Table 5, and emission projections presented in Figure 1,
659 leading to largest reductions in BC RF_{ARI} simulated in SSP1-2.6 (-0.10 W m^{-2}). Similar to the
660 burdens, the Eclipse CLE and CMIP6 SSP2-4.5 scenarios simulate a very close decrease in
661 the 2030-2050 mean BC RF_{ARI} of -0.06 W m^{-2} and -0.06 W m^{-2} , respectively.

662

663 3.2.2. Organic aerosols

664 The Eclipse historical ensemble simulate a positive OA burden trend between 1990 and 2014,
665 however this trend is not significant at the 95% confidence level (Table 4). The
666 CMIP6_Cpl_Hist simulation gives a larger trend, due to a large increase in global
667 anthropogenic OC emissions in CMIP6 (Figure 1). The nudged AMIP Eclipse simulation
668 calculates the largest 1990-2010 mean OA burden (57 kTon), while the coupled simulation
669 shows a slightly lower 1990-2010 mean burden (55 kTon). This largest OA burden in the
670 Eclipse_AMIP_NCEP simulation is attributed to the largest biogenic SOA burden calculated
671 in this scenario, as well as a better-simulated transport from source regions due to the nudged
672 winds (Figure S1). The anthropogenic and biogenic contributions to SOA burdens in the
673 coupled Eclipse and CMIP6 recent past simulations imply that the differences in the burdens
674 between the two ensembles can be attributed to the different anthropogenic emissions
675 datasets used in the Eclipse and CMIP6 simulations (Figure S1), as well as the differences in
676 SOA contributions due to simulated increases in the biogenic emissions (Figure S5). The
677 AMIP-type Eclipse run simulates a lower 1990-2010 mean OA burden (50 kTon), attributed
678 to the smallest biogenic SOA burden in this scenario. The Eclipse CLE ensemble shows a
679 decrease of 6.6 kTon (12%) in 2030-2050 mean OA burden compared to the 1990-2010
680 mean, while the MFR ensemble shows a larger decrease in the same period (15.2 kTon:
681 27%). The CMIP6 simulations show a much larger decrease of 2030-2050 mean Arctic OA
682 burdens, with a decrease of 8.1 kTon (SSP2-4.5) to 17 kTon (SSP1-2.6), while the SSP3-7.0
683 simulation shows an increase in OA burdens in the same period by 1.3 kTon (2%). Similar to
684 BC burdens, Eclipse CLE and CMIP6 SSP2-4.5 scenarios project similar changes in 2030-
685 2050 mean OA burden (6.6 kTon and 8.1 kTon, respectively).

686

687 As shown in Table 6a, the Eclipse ensemble calculated an OA RF_{ARI} of -0.05 to -0.08 W m^{-2}
688 for the 1990-2010 mean, where the nudged AMIP-type simulation shows the largest RF_{ARI} ,
689 due to the largest Arctic OA burden calculated for this period (Table 5). For the future, both
690 Eclipse CLE and MFR ensembles show an increase in the negative 2030-2050 mean RF_{ARI}
691 by -0.02 W m^{-2} , which is very close to the increase in the negative forcing calculated for the
692 various CMIP6 simulations (-0.01 to -0.03 W m^{-2}). Following the burdens, the largest increase
693 in the 2030-2050 mean OA RF_{ARI} is calculated for the SSP3-7.0 (-0.03 W m^{-2}), and the lowest
694 for SSP1-2.6 and 3-7.0-lowNTCF (-0.01 W m^{-2}).

695

696 3.2.3. Sulfate

697 Regarding SO_4^{2-} burdens, all simulations show a statistically significant negative trend both
698 in 1990-2014 and in 2015-2050, as seen in Figure 6 and Table 5. Both the nudged AMIP-type
699 and coupled Eclipse simulations showed a 1990-2010 mean SO_4^{2-} burden of 93 kTon, while
700 the AMIP-type simulation showed a slightly larger SO_4^{2-} burden of 95 kTon, attributed to the
701 larger cloud fraction simulated in this model version (Table 2). For the 2015-2050 period, the
702 Eclipse ensemble simulates a mean Arctic SO_4^{2-} burden decrease of 30-40 kTon (32-42%),
703 compared to the 1990-2010 mean, while CMIP6 ensemble simulates a reduction of 16-45
704 kTon (16-45%). The SSP2-4.5 and Eclipse CLE scenarios simulate a very similar decrease
705 (30 kTon) in 2030-2050 mean Arctic SO_4^{2-} burdens, while the MFR and SSP1-2.6 scenarios
706 also simulate comparable reductions in the burdens (Table 5). Following the emission
707 projections, the SSP1-2.6 scenario gives the largest decrease (45 kTon: 45%), and the SSP3-
708 7.0 scenario gives the smallest reduction (16 kTons: 16%) in Arctic 2030-2050 mean SO_4^{2-}
709 burdens.

710
711 The SO_4^{2-} RF_{ARI} is decreasing (Figure 6) following the decreasing emissions (Figure 1) and
712 burdens (Figure 5). Both Eclipse and CMIP6 ensembles simulate a decrease in SO_4^{2-} RF_{ARI}
713 by 0.06-0.18 Wm^{-2} . The 2030-2050 mean SO_4^{2-} RF_{ARI} follows the burdens (Table 6), with
714 CLE and SSP2-4.5 giving similar decreases in the negative SO_4^{2-} RF_{ARI} of 0.11 Wm^{-2} , while
715 the Eclipse MFR and SSP1-2.6 simulates a very similar decrease in the 2030-2050 mean
716 SO_4^{2-} RF_{ARI} (0.16 and 0.18 Wm^{-2} , respectively).

717 718 *3.2.4. Net aerosol radiative forcing*

719 The coupled simulations in both Eclipse and CMIP6 ensemble show an Arctic RF_{ARI} of -0.32
720 to -0.35 Wm^{-2} for the 1990-2010 mean, slightly lower than recent estimates (e.g. -0.4 W m^{-2}
721 by Markowicz et al., 2021). In the Eclipse ensemble, $-0.22 \pm 0.01 \text{ Wm}^{-2}$ is calculated to be
722 originated by the anthropogenic aerosols, while in the CMIP6 near-past simulations show a
723 contribution of -0.19 to -0.26 Wm^{-2} from anthropogenic aerosols (Table 6b). The AMIP-type
724 Eclipse simulations calculated a much larger RF_{ARI} of -0.47 W m^{-2} for the same period,
725 which can be mainly due to the increase in the positive forcing of the BC aerosols in the
726 coupled simulations due to larger burdens. This effect is amplified due to the larger sea-ice
727 concentration simulated with the coupled model, leading to brighter surfaces compared to the
728 AMIP simulations. For the 2030-2050 period, the Eclipse ensemble simulated an increase in
729 the negative in RF_{ARI} by -0.07 W m^{-2} , while the negative anthropogenic in RF_{ARI} increased
730 by only -0.02 W m^{-2} , suggesting that the contribution from natural aerosols become more
731 important in the future. The results show that the positive dust forcing is decreased by 0.03
732 Wm^{-2} (from 0.12 Wm^{-2} to 0.09 Wm^{-2}), while the negative sea-salt forcing becomes more
733 negative by -0.03 Wm^{-2} due to the increase of ice-free ocean fraction due to melting of sea-
734 ice (see Section 3.3). For the same period, the CMIP6 future ensemble simulated an increase
735 of the negative RF_{ARI} by -0.01 Wm^{-2} to -0.06 Wm^{-2} , the largest change being in SSP1-2.6 and
736 SSP2-4.5, mainly driven by the change in BC forcing (Table 6a). Table 6 also shows that the
737 SSP1-1.6 simulates no change in the anthropogenic forcing, while SSP2-4.5 shows a similar
738 increase of -0.01 Wm^{-2} in the Eclipse ensemble. In contrary, the SSP3-7.0 and SSP3-7.0-
739 lowNTCF simulates a large decrease in the anthropogenic negative RF_{ARI} by 0.05 Wm^{-2} and
740 0.02 Wm^{-2} , respectively.

741
742 The different behavior in the two ensembles is further investigated by looking at the aerosol-
743 radiation forcing calculated for the individual aerosol species of BC, OA, SO_4^{2-} and NO_3^-
744 presented in Figure 8 that shows the box-whisker plots using the similar scenarios in the
745 Eclipse (CLE and MFR) and CMIP6 (SSP2-4.5 and SSP1-2.6) ensembles. The increase in
746 cooling effect of aerosols calculated by the Eclipse ensemble is attributed mainly to the
747 decrease in BC as opposed to other aerosol species (Figure 8). More negative forcing is
748 calculated for the OA and NO_3^- , while the SO_4^{2-} forcing is becoming less negative due to
749 large reductions in SO_2 emissions (Figure 1). The net aerosol forcing is therefore slightly
750 more negative. In the CMIP6 ensemble, the BC forcing does not change as much compared
751 to the Eclipse ensemble to counteract the change in impact from SO_4^{2-} , giving a more
752 negative net aerosol forcing, slightly smaller compared to the Eclipse ensemble. The CMIP6
753 ensemble also simulates a larger increase in the negative NO_3^- forcing compared to the
754 Eclipse ensemble (Shindell et al., 2013). Overall, the changes in the different aerosol species
755 leads to a more negative aerosol forcing by mid-century (2030-2050) compared to the 1990-
756 2010 period.

757
758 The spatial distributions of the statistically significant change in the Arctic RF_{ARI} in 2030-
759 2050 mean with respect to the 1990-2010 mean in the different ensemble members are
760 presented in Figure 9. Results show a decrease of the negative RF_{ARI} over Europe, and partly
761 over North America, and an increase over northern Pacific in all ensemble members.
762 Globally, larger changes are simulated over the East and South Asia (Figure S2), where
763 largest anthropogenic emission reductions take place. The global net RF_{ARI} is dominated by
764 the sea-salt particles, accounting for about 60% of the 1990-2010 mean forcing of -2 to -2.3
765 Wm^{-2} in and 2030-2050 mean forcing of -1.9 to 2.1 Wm^{-2} .

766 767 3.3. Climate change

768 769 3.3.1. Surface air and sea surface temperatures

770 The surface air temperature and sea-ice extent are calculated in the different simulations for
771 the 1990-2050 period. As seen in Figure 10, the Arctic surface air temperatures increase in all
772 scenarios. Between 1990 and 2014, the surface air temperatures over the Arctic increased
773 statistically significant by $0.5 \text{ }^\circ\text{C decade}^{-1}$ (Eclipse_CplHist) to $1 \text{ }^\circ\text{C decade}^{-1}$
774 (CMIP6_Cpl_Hist), with CMIP6 showing larger increases compared to the Eclipse ensemble
775 (Table 7). On the other hand, the observed surface air temperature during 1990-2014 shows a
776 smaller and statistically non-significant increase of $0.2 \text{ }^\circ\text{C decade}^{-1}$. From 2015 onwards,
777 surface air temperatures continue to increase significantly by 0.3 to $0.6 \text{ }^\circ\text{C decade}^{-1}$, with
778 larger increases in the Eclipse ensemble, due to larger reductions in the emissions and
779 therefore in the burdens and associated RF_{ARI} .

780
781 The 2030-2050 mean surface air temperatures are projected to increase by $2.1 \text{ }^\circ\text{C}$ and $2.3 \text{ }^\circ\text{C}$
782 compared to the 1990-2010 mean temperature (Table 8, Figure 10) according to the Eclipse
783 CLE and MFR ensembles, respectively, while the CMIP6 simulation calculated an increase
784 of $1.9 \text{ }^\circ\text{C}$ (SSP1-2.6) to $2.2 \text{ }^\circ\text{C}$ (SSP3-7.0). Changes in both ensembles are statistically

785 significant on a 95% level. These warmings are smaller compared to the 4.5 - 5 °C warmer
786 2040 temperatures compared to the 1950-1980 average in the CMIP6 SSP1-2.6, SSP2-4.5
787 and SSP3-7.0 scenarios, reported by Davy and Outen (2020). It should however be noted that
788 due to the different baselines used in the present study (1990-2010) and the 1950-1980
789 baseline used in Davy and Outen (2020), it is not possible to directly compare these datasets.
790 Figure 11 shows the spatial distributions of the statistically significant (as calculated by
791 student t-test) Arctic surface air temperature change between the 1990-2010 mean and the
792 2030-2050 mean for the individual Eclipse and CMIP6 future scenarios. All scenarios
793 calculate a warming in the surface air temperatures over the central Arctic, while there are
794 differences over the land areas. The Eclipse CLE and MFR ensembles show similar warming
795 mainly over the Arctic ocean as well as North America and North East Asia and cooling over
796 the Greenland Sea. The latter is a well-known feature of observations and future projections,
797 linked, i.e., to the deep mixed layer in the area and declines in the Atlantic Meridional
798 Circulation (e.g. IPCC, 2014; Menary and Wood, 2018; Keil et al., 2020). There are also
799 differences between the Eclipse and the CMIP6 ensembles as seen in Figure 11. All CMIP6
800 scenarios show a warming over the central Arctic and a limited cooling over northern
801 Scandinavia, following the changes in RF_{ARI} shown in Figure 9, except for the SSP3-7.0
802 scenario that shows no cooling in the region. The SSP3-7.0-lowNTCF scenario shows an
803 additional cooling over Siberia. These warmings are comparable with earlier studies, such as
804 Samset et al. (2017) estimating a warming of 2.8 °C, attributed to aerosols.

805 806 3.3.2. *Sea-ice*

807 The Arctic sea-ice extent is found to decrease significantly in all simulations (Figure 10 and
808 Table 7). Similar to the near-surface temperatures, during the 1990-2014 period, the CMIP6
809 ensemble simulated a large decrease of sea-ice extent compared to the Eclipse ensemble. On
810 the other hand, the CMIP6_Cpl_Hist largely overestimated the observed decrease of 30 000
811 km² yr⁻¹. This overestimation has also been reported for some of the CMIP5 and CMIP6
812 models (Davy and Outten, 2020). After 2015, the Eclipse CLE ensemble projected larger
813 decreases in the sea-ice extent compared to the CMIP6 ensemble (Table 7), in agreement
814 with the changes in the near-surface temperatures. The evolutions of March and September
815 sea-ice extents, representing the Arctic annual maximum and minimum extents, respectively,
816 are also analyzed. The Eclipse ensemble projects a decrease of $23\,000 \pm 11\,000$ km² yr⁻¹ in
817 March sea-ice extent during the 2015-2050 period, while the CMIP6 ensemble projects a
818 decrease of $10\,000 \pm 6000$ km² yr⁻¹ for the same period, both statistically significant. In
819 September, much larger decreases are projected by both ensembles. The Eclipse ensemble
820 simulates a decrease of $64\,000 \pm 10\,000$ km² yr⁻¹ in the 2015-2050 period while the CMIP6
821 ensemble predicts a decrease of $50\,000 \pm 20\,000$ km² yr⁻¹.

822
823 The 2030-2050 annual mean sea-ice extent (Table 8) is projected to be 1.5 and 1.7 million
824 km² lower compared to the 1990-2010 mean in the Eclipse CLE and MFR scenarios,
825 respectively, both statistically significant on a 95% level. The CMIP6 simulations predict a
826 lower decrease of sea-ice extent by 1.2 - 1.5 million km², however these changes are not
827 statistically significant. These results are comparable with the results from the CMIP6 models
828 (Davy and Outten, 2020). In the 2030-2050 March mean the sea-ice extent is projected to be

829 925 000 km² lower in the Eclipse ensemble (statistically significant), while the CMIP6
830 ensemble projects a decrease of 991 000 km² (not statistically significant) A much larger
831 decrease is projected for the 2030-2050 September mean, being 2.6 million km² and 2.3
832 million km² in Eclipse and CMIP6 ensembles, respectively. As seen in Figure 12, the Eclipse
833 ensemble predicts an up to 90% lower September sea-ice fraction in a band marking the
834 maximum retreat of the sea ice line at the end of the summer, while the changes simulated by
835 the CMIP6 ensemble are not statistically significant on 95% level (therefore not shown in
836 Figure 11), which can be attributed to the single ensemble member per scenario in the CMIP6
837 ensemble, as well as the not significant changes in the near-surface temperatures (not shown).
838 In March (Figure S3), the Eclipse ensemble simulated a decrease in maximum sea-ice extent
839 at the end of winter over the northern Pacific, while the CMIP6 ensemble did not show any
840 statistically significant changes in sea-ice. In addition, the Eclipse ensemble shows a decrease
841 over the north Atlantic close to Greenland. All simulations show a similar and statistically
842 significant decrease in annual mean sea-ice extent (Figure S4 over the central Arctic, with the
843 CMIP6 ensemble showing also some increase in the sea-ice extent over the Canadian Arctic,
844 that is largest in SSP3-7.0.

845
846 The retreat in sea-ice extent also led to an increase of oceanic emissions of DMS and sea-salt
847 (Figure S5); however, the increases are not significant on a 95% significance level. The
848 simulated increase, in particular for the DMS emissions, is slightly larger in the Eclipse
849 ensemble compared to the CMIP6 ensemble, due to a larger decrease of sea-ice extent in the
850 Eclipse ensemble. Also note that GISS-E2.1 is using prescribed and fixed maps of DMS
851 concentration in the ocean. When ocean locations that are year-round under sea-ice at present
852 get exposed, the DMS that would exist in that sea water is not included in the simulations,
853 likely underestimating the increased flux of DMS into the atmosphere as the sea ice retreats.

854

855 4. Summary and Conclusions

856

857 The GISS-E2.1 earth system model has been used to simulate the recent past (1990-2014)
858 and future (2015-2050) aerosol burdens and their climate impacts over the Arctic. An
859 ensemble of seventeen simulations has been conducted, using historical and future
860 anthropogenic emissions and projections from CMIP6 and ECLIPSE V6b, the latter
861 supporting the ongoing Arctic Monitoring and Assessment Programme.

862

863 The evaluation of the recent past simulations shows underestimates of Arctic surface aerosol
864 levels by up to 50%, with the smallest biases calculated for the simulations where winds are
865 nudged, and sea-surface temperature and sea-ice are prescribed (AMIP-type: atmosphere-
866 only). An exception is SO₄²⁻, where the nudged Eclipse AMIP simulation had the highest
867 bias, due to the high cloud bias that leads to more in-cloud sulfate production from SO₂. The
868 model skill analyses indicate slightly better performance of the CMIP6 version of the GISS-
869 E2.1 model in simulating both the aerosol levels and climate parameters compared to the
870 Eclipse version. In addition, the underestimations in summer time cloud fraction suggests
871 missing sources of aerosols, in particular the local marine sources. GISS-E2.1 does not
872 include marine VOC emissions except for DMS, which are suggested to be important for the

873 summer time cloud properties over the Arctic (Ornella et al., 2011; Karl et al., 2013; Schmale
874 et al., 2021). Results also suggest that the underestimation of both absorbing and scattering
875 aerosol levels can partly cancel out their impacts on RF_{ARI} and near-surface temperatures as
876 the temperatures are very well reproduced by the model.

877

878 From 2015 onwards, all simulations, except for the worst case CMIP6 scenario SSP3-7.0,
879 show a statistically significant decrease in the Arctic BC, OA and SO_4^{2-} burdens, with the
880 CMIP6 ensemble simulating larger aerosol burdens Eclipse, while the Eclipse ensemble
881 shows larger reductions (10-60%) in Arctic aerosol burdens compared to the reduction
882 simulated by the CMIP6 ensemble (10-45%). The largest burden reductions are calculated by
883 the highly ambitious emission reductions in the two ensembles; i.e. the Eclipse MFR (25-
884 60%) and the CMIP6 SSP1-2.6 (25-45%).

885

886 The present-day (1990-2010 mean) CMIP6 and Eclipse simulations calculated an aerosol
887 radiative forcing due to aerosol-radiation interactions (RF_{ARI}) of -0.32 to -0.35 $W m^{-2}$. For
888 the same period, the atmosphere only (AMIP) Eclipse simulations calculated a much larger
889 negative RF_{ARI} of -0.47 $W m^{-2}$. This smaller RF_{ARI} by the coupled simulations is mainly due
890 to larger BC burdens in the coupled simulations, leading to more positive forcing, which is
891 amplified by the larger albedo effect due to larger sea-ice extent simulated in the coupled
892 simulations. In the 2030-2050 period, the Eclipse ensemble simulated a RF_{ARI} $-0.39 \pm 0.01 W$
893 m^{-2} , of which $-0.24 \pm 0.01 W m^{-2}$ are attributed to the anthropogenic aerosols (BC, OA, SO_4^{2-}
894 and NO_3^-). For the same period, the worst case CMIP6 scenario (SSP3-7.0) simulated a
895 similar RF_{ARI} ($-0.35 W m^{-2}$) compared to the 1990-2010 mean, while large emission
896 reductions led to a more negative RF_{ARI} ($-0.40 W m^{-2}$), mainly due to decrease in the positive
897 forcing of the BC aerosols. Overall, the Eclipse ensemble simulated slightly larger changes in
898 the RF_{ARI} over the 2015-2050 period, relative to the 1990-2010 mean, compared to the
899 CMIP6 ensemble, which can be attributed to the larger reductions in burdens in the Eclipse
900 ensemble. The differences between the two ensembles are further attributed to differences in
901 the BC and SO_4^{2-} forcings. The results suggest that the different anthropogenic emission
902 projections lead to only small differences in how the RF_{ARI} will evolve in the future over the
903 Arctic.

904

905 The future scenarios with the largest aerosol reductions, i.e. MFR in the Eclipse and SSP1-
906 2.6 in the CMIP6 ensemble projects a largest warming and sea-ice retreat. The Eclipse
907 ensemble shows a slightly larger warming of 2030-2050 mean surface air temperatures
908 compared to the 1990-2010 mean warming (2.1 to 2.5 $^{\circ}C$) compared to that from the CMIP6
909 ensemble (1.9 $^{\circ}C$ to 2-2 $^{\circ}C$). Larger warming in the Eclipse ensemble also resulted in a
910 slightly larger reduction in sea-ice extent (-1.5 to -1.7 million km^2 in CLE and MFR,
911 respectively) in 2030-2050 mean compared to the reduction in the CMIP6 scenario (-1.3 to -
912 1.6 million km^2 in SSP1.2-6 and SSP3-7.0, respectively). However, the changes simulated
913 by the two ensembles are within one standard deviation of each other.

914

915 The overall results showed that the aerosol burdens will substantially decrease in the short- to
916 mid-term future, implying improvements in impacts on human health and ecosystems.

917 However, the impacts of aerosols on the radiative forcing can be amplified by the sea-ice
918 extent. Results also show that even the scenarios with largest emission reductions, i.e. Eclipse
919 MFR and CMIP6 SSP1-2.6, lead to similar impact on the future Arctic surface air
920 temperatures and sea-ice loss compared to scenarios with very little mitigation such as the
921 CMIP6 SSP3-7.0, exacerbating the dominant role played by well-mixed greenhouse gases
922 and underlining the importance of continued greenhouse gas reductions.

923
924 *Author contributions.* UI coordinated the study, conducted the model simulations, as well as
925 model evaluation and analyses of the simulations, and wrote the manuscript. KT and GF
926 supported the model simulations and processing of the Eclipse V6b emissions for the GISS-
927 E2.1 model. JPF contributed to the plotting of the spatial distributions by further developing
928 the autoimage R package (French, 2017). RM prepared and provided the AOD
929 measurements, as well as the surface air temperature, sea surface temperature and sea-ice
930 data. MAT prepared the cloud observation data. CHW prepared the Arctic surface aerosol
931 measurement data. KvS coordinated the experimental setup for the Eclipse simulations in the
932 framework of the ongoing AMAP assessment. ZG prepared and provided the Eclipse V6b
933 anthropogenic emissions. HS and DCT prepared the Villum Research Station aerosol data. JB
934 and PL contributed to analyses of aerosols and climate parameters, respectively, and
935 manuscript writing. All authors contributed to the analyses and interpretation of the results, as
936 well as contributing to the writing of the manuscript.

937 *Competing Interests.* The authors declare that they have no conflict of interest.

938 *Special issue statement.* This article is part of the special issue “Arctic climate, air quality,
939 and health impacts from short-lived climate forcers (SLCFs): contributions from the AMAP
940 Expert Group”.

941 *Acknowledgements.* This paper was developed as part of the Arctic Monitoring Assessment
942 Programme (AMAP), AMAP 2021 Assessment: Arctic climate, air quality, and health
943 impacts from short-lived climate forcers (SLCFs). HadISST data were obtained from

947 UDel_AirT_Precip data provided by the NOAA/OAR/ESRL PSL, Boulder, Colorado, USA,
948 from their Web site at <https://psl.noaa.gov/>. Alert sulfate data are from Sangeeta and EC &
949 OA data from Lin Huang, respectively, as part of Canadian Aerosol Baseline Measurement
950 (CABM) program at ECCC and would like to thank operators & technicians for collection of
951 filters, calibration and analysis and Canadian Forces Services Alert for the operation of the
952 military base. These datasets are also available on Global Atmospheric Watch program,
953 World Data Center for aerosols, EBAS database (<http://ebas.nilu.no/default.aspx>). Aside from
954 Alert, Canada’s surface air quality data are from the National Atmospheric Pollutant
955 Surveillance network (NAPS: <https://open.canada.ca/data/en/dataset/1b36a356-defd-4813-acea-47bc3abd859b>).
956
957

958 Fairbanks aerosol measurements are from William Simpson and KC Nattinger. Aside from
959 Fairbanks, Alaskan measurements are from the IMPROVE network. IMPROVE is a
960 collaborative association of state, tribal, and federal agencies, and international partners. The
961 US Environmental Protection Agency is the primary funding source, with contracting and
962 research support from the National Park Service. The Air Quality Group at the University of
963 California, Davis is the central analytical laboratory, with ion analysis provided by Research
964 Triangle Institute, and carbon analysis provided by Desert Research Institute.
965 European measurements are from the EMEP network, and obtained from the EBAS database
966 (<http://ebas.nilu.no>). Other European data include the Gruebadet measurements, for which
967 we acknowledge Mauro Mazzola (mauro.mazzola@cnr.it), Stefania Gilardoni
968 (stefania.gilardoni@cnr.it), and Angelo Lupi (angelo.lupi@cnr.it) from the Institute of Polar
969 Sciences fo Gruvabadet eBC measurements; and Rita Traversi (rita.traversi@unifi.it), Mirko
970 Severi (mirko.severi@unifi.it), and Silvia Becagli (silvia.becagli@unifi.it) from University
971 of Florence [http://www.isac.cnr.it/~radiclim/CCTower/ ?Data:Aerosol](http://www.isac.cnr.it/~radiclim/CCTower/?Data:Aerosol); the Zeppelin datasets,
972 for which we acknowledge Vito Vitale and Angelo Lupi (also available on
973 <http://ebas.nilu.no>); and the Villum Station datasets (www.villumresearchstation.dk) from
974 Henrik Skov (hsk@envs.au.dk; also available in <http://ebas.nilu.no>). The AERONET AOD
975 measurements were obtained from NASA's Goddard Space Flight Center
976 (https://aeronet.gsfc.nasa.gov/new_web/index.html). The authors acknowledge Dr. L.
977 Sogacheva and AEROSAT team for satellite based merged AOD data.

978
979 *Financial support.* This research has been supported by the Aarhus University
980 Interdisciplinary Centre for Climate Change (iClimate) OH fund (no. 2020-0162731), the
981 FREYA project, funded by the Nordic Council of Ministers (grant agreement no. MST-227-
982 00036 and MFVM-2019-13476), and the EVAM-SLCF funded by the Danish Environmental
983 Agency (grant agreement no. MST-112-00298). KT and GF thank the NASA Modeling,
984 Analysis and Prediction program (MAP) for support. ZK was financially supported by the
985 EU-funded Action on Black Carbon in the Arctic (EUA-BCA) under the EU Partnership
986 Instrument. JPF was partially supported by NSF award 1915277.

Figures

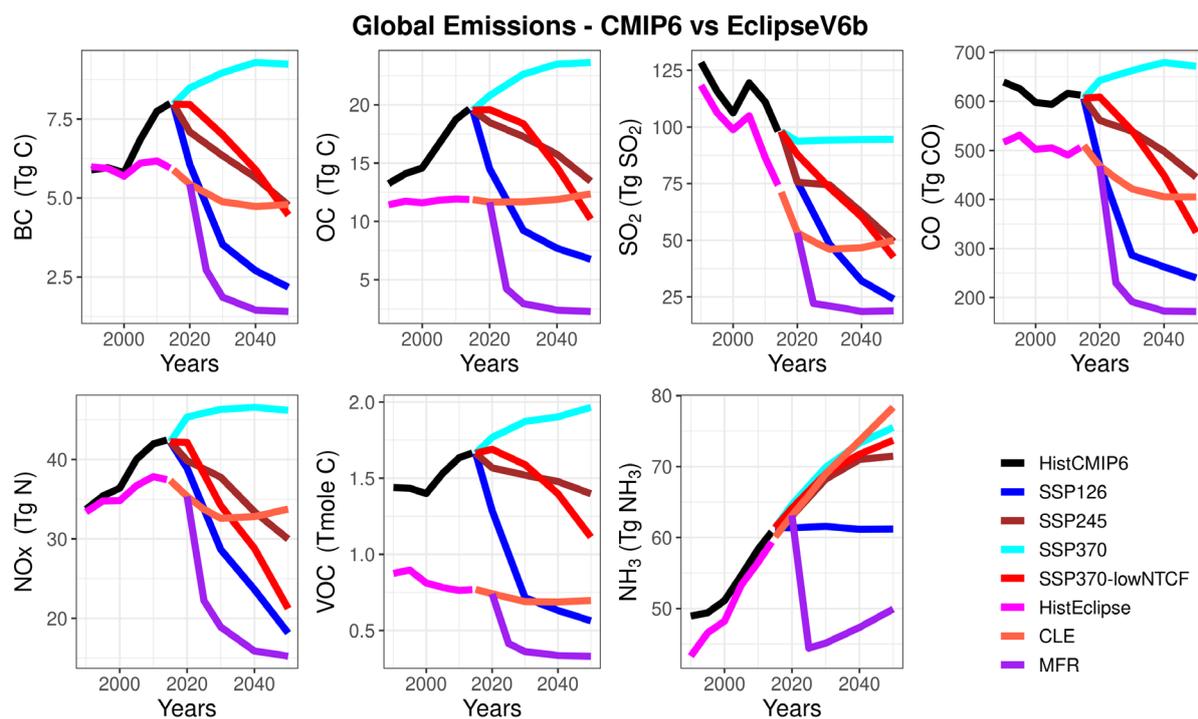

Figure 1. Global recent past and future CMIP6 and Eclipse V6b anthropogenic emissions for different pollutants and scenarios.

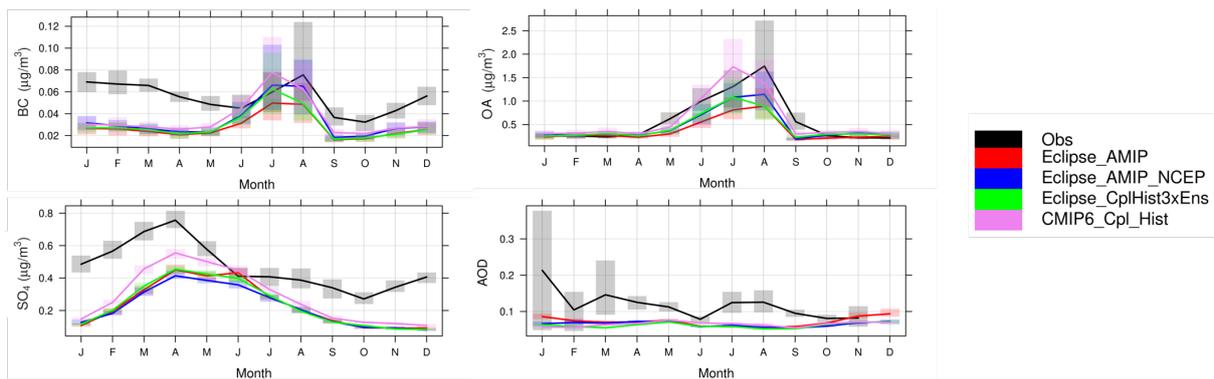

Figure 2. Observed and simulated Arctic climatological (1995-2014) monthly BC, OA, SO_4^{2-} , and AERONET AOD at 550nm (2008/09-14), along with the interannual variation shown in bars. The data presents monthly accumulated timeseries for all stations that are merged together.

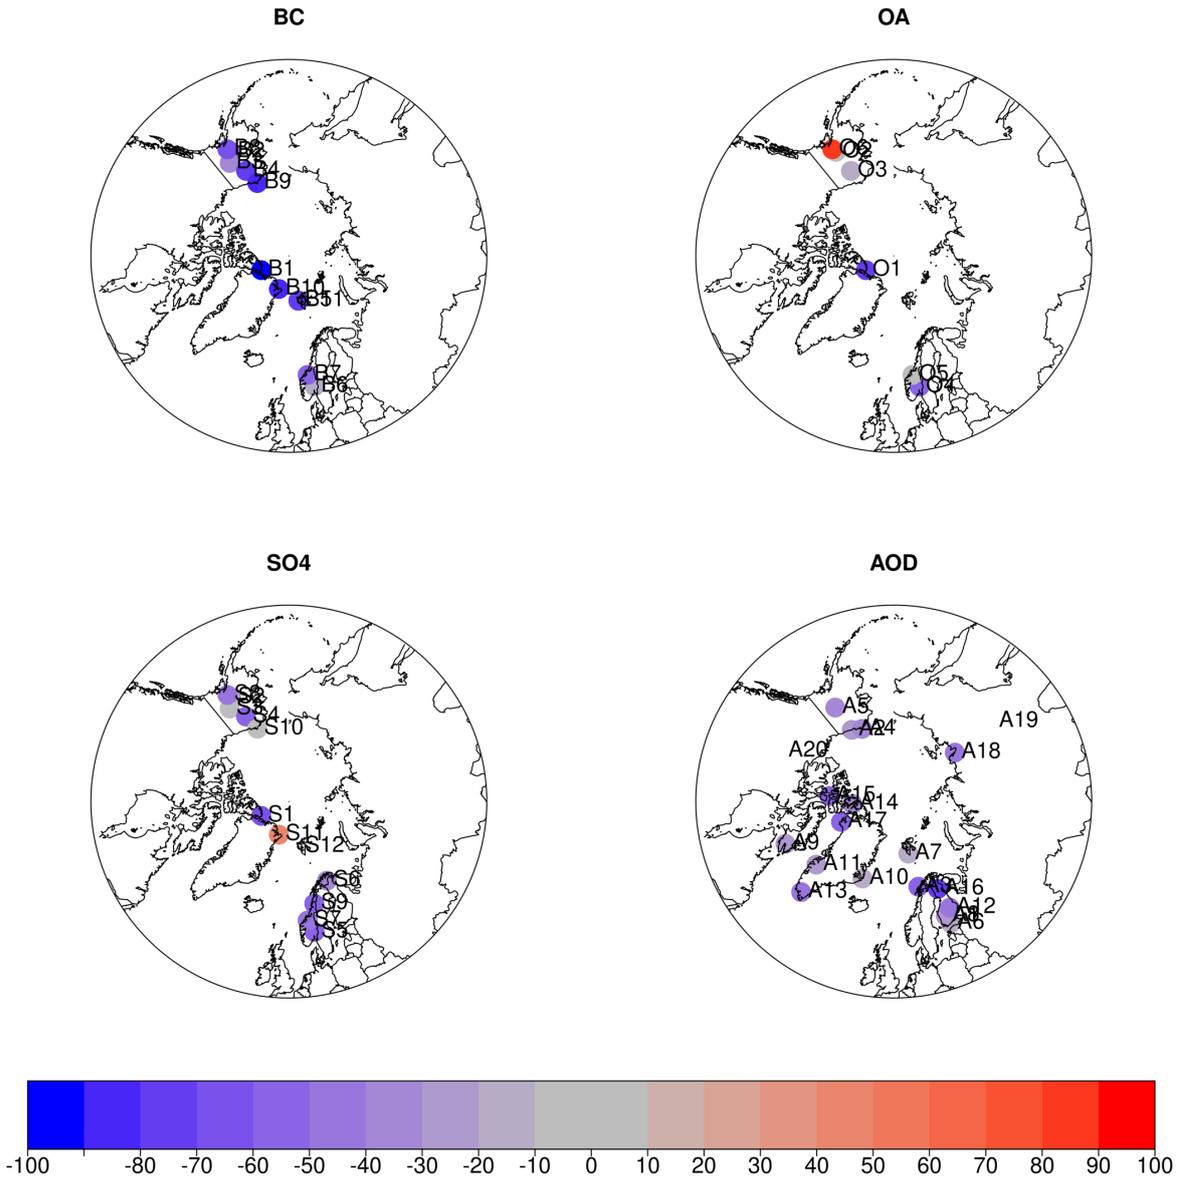

Figure 3. Spatial distribution of normalized mean bias (*NMB*, in %) for climatological mean (1995-2014) BC, OA, SO₄²⁻ and AOD at monitoring stations, calculated as the mean of all recent past simulations.

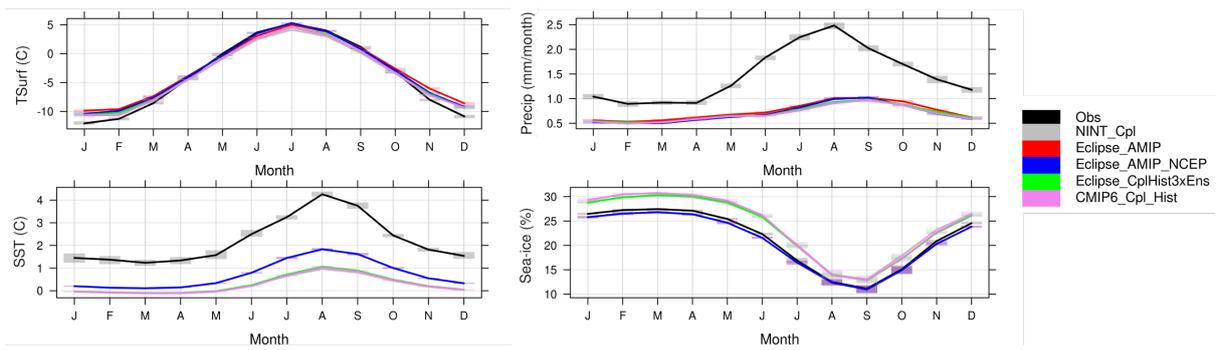

Figure 4. Observed and simulated Arctic climatological (1995-2014) surface air temperature, precipitation, sea surface temperature, and sea-ice, along with the interannual variation shown in bars. Obs denote UDel dataset for surface air temperature and precipitation, and HADISST for sea surface temperature and sea-ice extent. Note that the two AMIP runs (blue and red lines) for the SST and sea-ice are on top of each other as they use that data to run, as input.

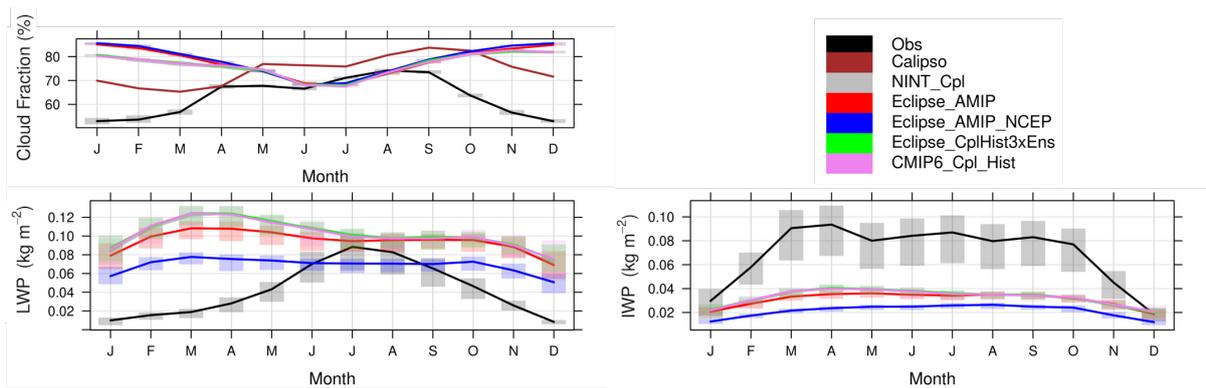

Figure 5. Observed and simulated Arctic climatological total cloud fraction (1995-2014 mean), liquid water path (2007-2014 mean), and ice water path (2007-2014 mean), along with the interannual variation shown in bars. Obs denote Clara-A2 for the cloud fractions and CloudSat for the LWP and IWP.

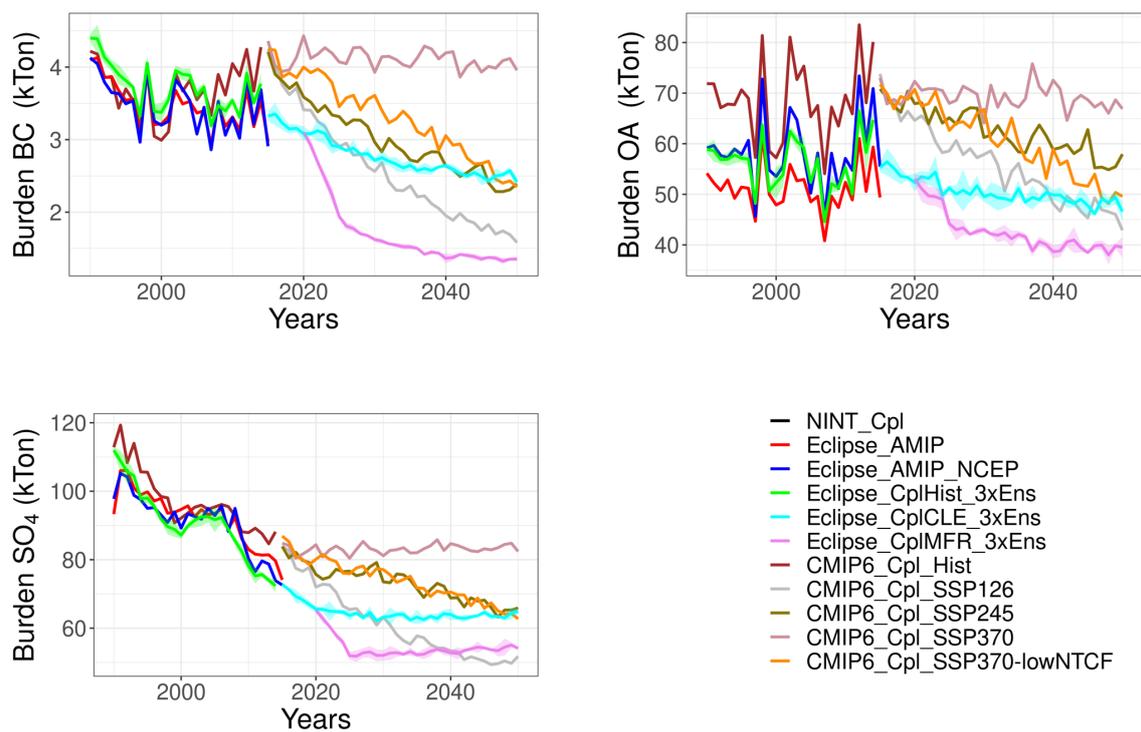

Figure 6. Arctic BC, OA and SO₄²⁻ burdens in 1990-2050 as calculated by the GISS-E2.1 ensemble.

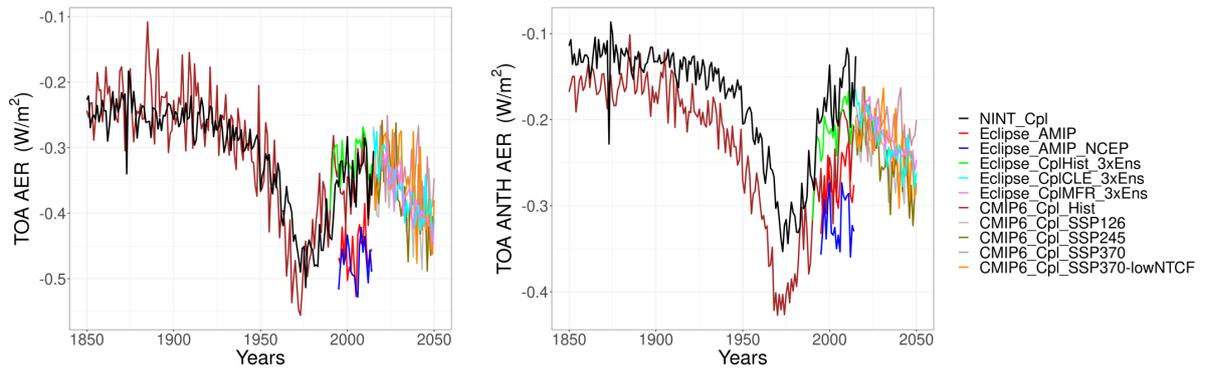

Figure 7. Arctic RF_{ARI} from anthropogenic and natural aerosols ($BC+OA+SO_4^{2-}+NO_3^-+Dust+SSA$), and only anthropogenic aerosols ($BC+OA+SO_4^{2-}+NO_3^-$) in 1850-2050 as calculated by the full GISS-E2.1 ensemble.

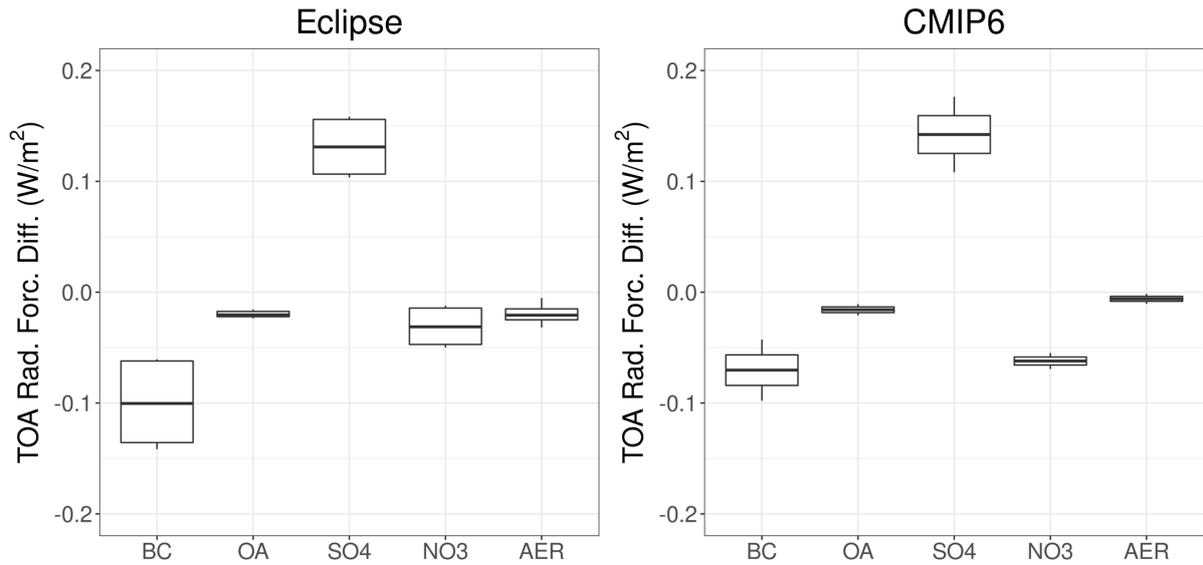

Figure 8. Box-Whisker plot showing the differences between 1990-2010 mean and 2030-2050 mean RF_{ARI} for the anthropogenic aerosol components (BC, OA, SO_4^{2-} and NO_3^-) and their sum (AER) in the Eclipse ensemble (CLE and MFR: left panel) and the CMIP6 (SSP2-4.5 and SSP1-2.6: right panel) ensembles. The boxes show the median, the 25th and 75th percentiles. The upper whisker is located at the *smaller* of the maximum value and $Q_3 + 1.5$ IQR, whereas the lower whisker is located at the *larger* of the smallest x value and $Q_1 - 1.5$ IQR, where IQR (interquartile range) is the box height (75th percentile - 25th percentile).

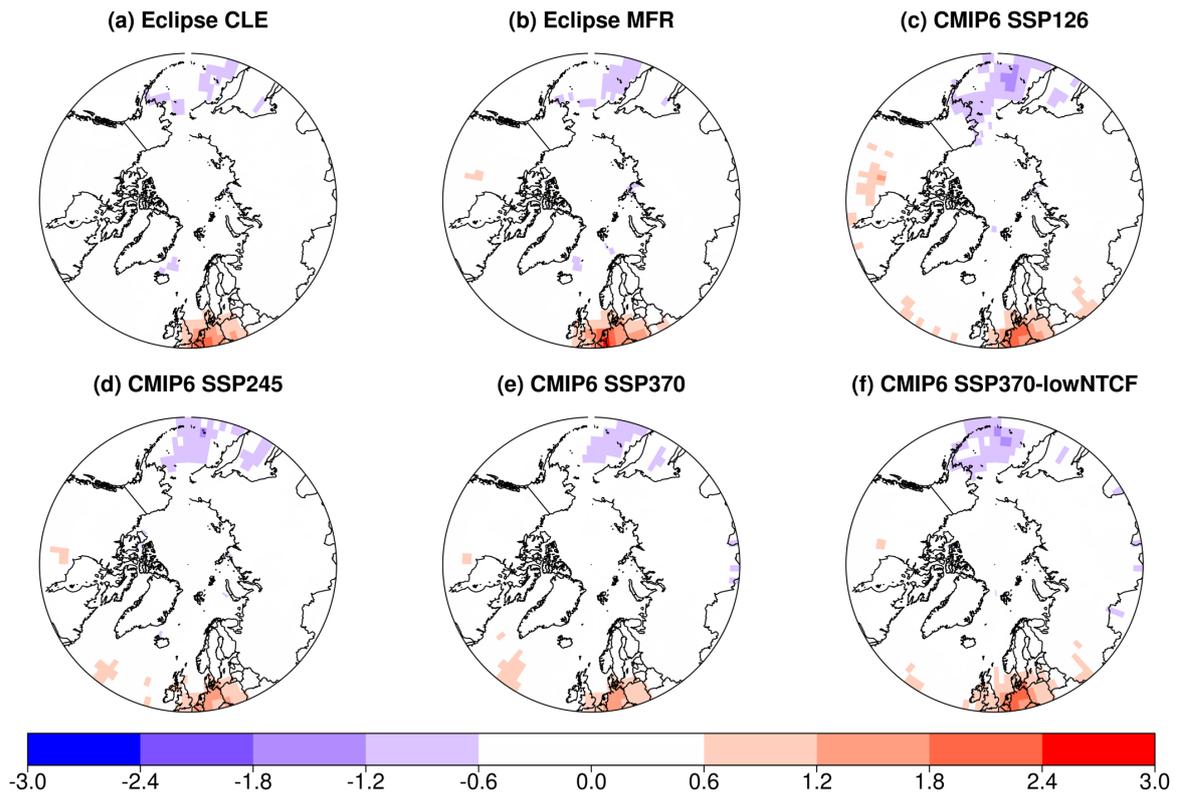

Figure 9. Spatial distribution of the statistically significant annual mean Arctic RF_{ARI} (W m^{-2}) changes between the 1990-2010 mean and the 2030-2050 mean as calculated by the GISS-E2.1 ensemble.

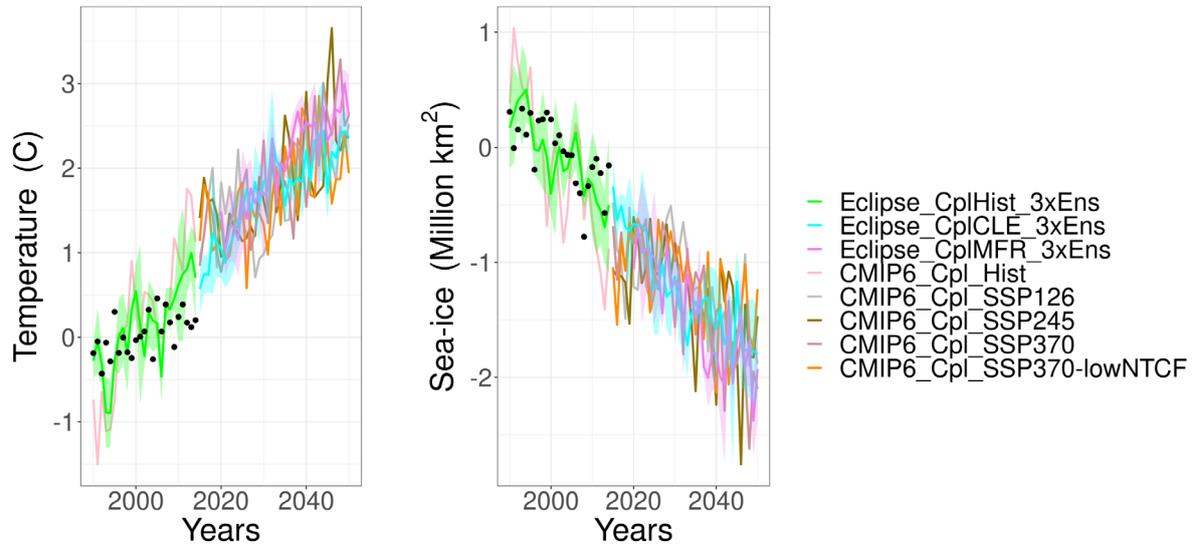

Figure 10. Arctic annual mean surface air temperature and sea-ice extent anomalies in 2015-2050 based on the 1990-2010 mean as calculated by the GISS-E2.1 ensemble.

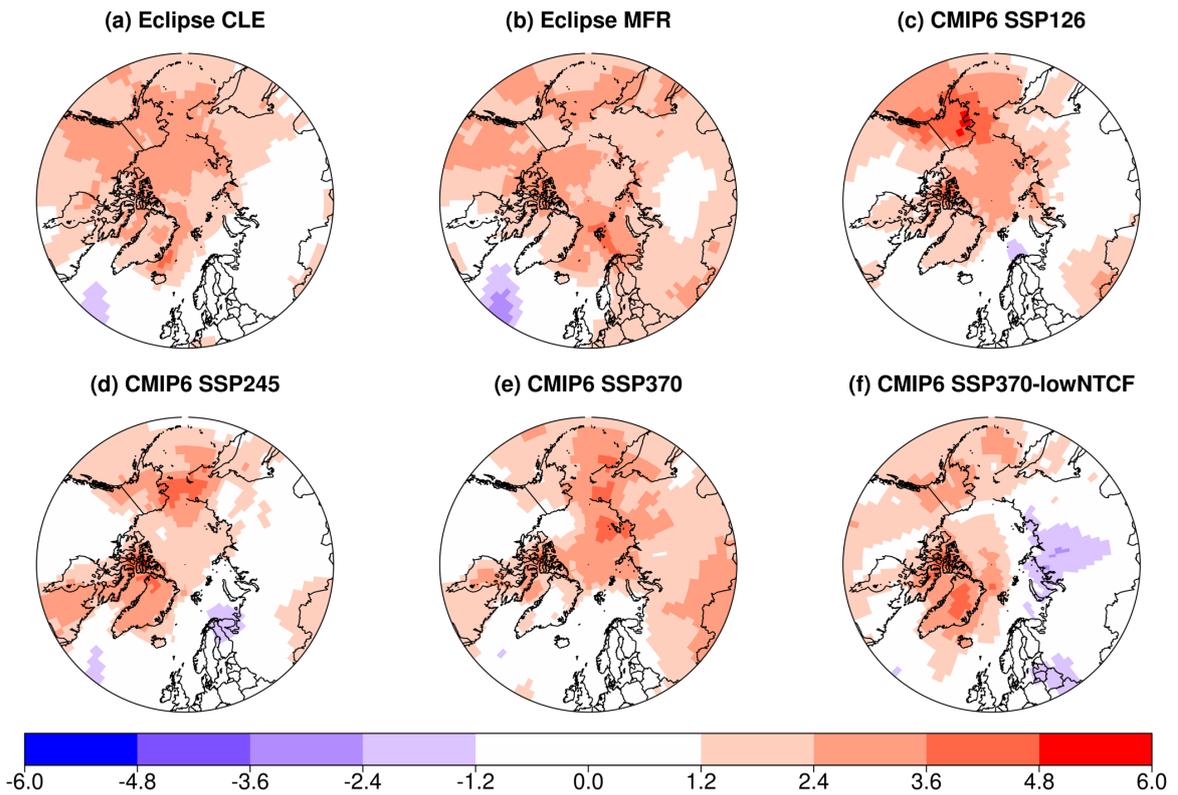

Figure 11. Spatial distribution of the statistically significant annual mean Arctic surface air temperature ($^{\circ}\text{C}$) changes between the 1990-2010 mean and the 2030-2050 mean as calculated by the GISS-E2.1 ensemble.

(a) Eclipse CLE

(b) Eclipse MFR

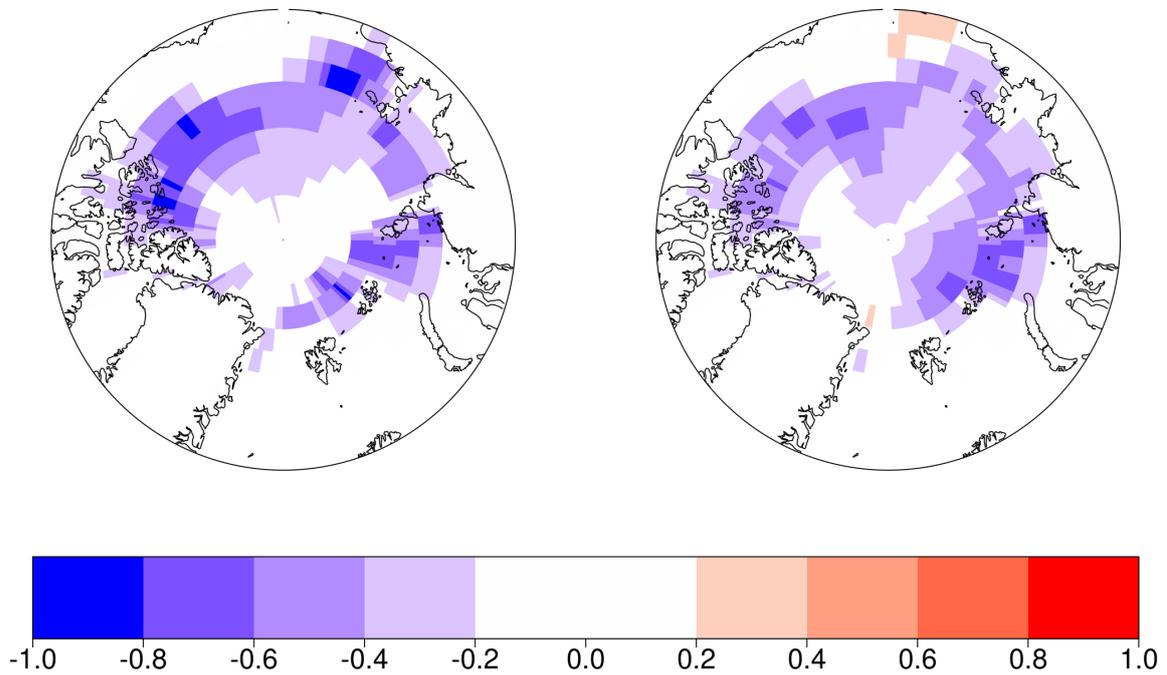

Figure 12. Spatial distribution of the statistically significant September Arctic sea-ice fraction change between the 1990-2010 mean and the 2030-2050 mean as calculated by the GISS-E2.1 Eclipse ensemble (CMIP6 ensemble is not shown due to statistically insignificant changes calculated by the student t-test).
