10 **Abstract.** Polycyclic aromatic hydrocarbons (PAHs) are not declining in Arctic air despite reductions in their global emissions. In Svalbard, the Longyearbyen coal-fired power plant is considered to be one of the major local source of PAHs. Power plant stack emissions and ambient air samples, collected simultaneously 1 km (UNIS) and 6 km (Adventdalen) transect distance, were analyzed (gaseous and particulate phases separately) for 22 nitro-PAHs, 9 oxy-PAHs and 16 parent PAHs by GC/ECNI/MS and GC-MS/MS. Results confirm low level of PAH emissions ( $\Sigma 16$  PAHs = 1.5  $\mu\text{g kg}^{-1}$  coal) from  
15 the power plant. Phenathrene, 9,10-anthraquinone, 9-fluorenone, fluorene, fluoranthene, and pyrene accounted for 85% of the plant emission (not including naphthalene). A dilution effect was observed for the transect ambient air samples,  $1.26 \pm 0.16$  and  $0.63 \pm 0.14$  ng m<sup>-3</sup> sum all 47 PAH derivatives for UNIS and Adventdalen, respectively. The PAH profile was homogeneous for these recipient stations with phenathrene and 9-fluorenone being most abundant. Principal component analysis, in combination with PAH diagnostic ratios and literature data on different source-specific markers, confirmed coal  
20 combustion, gasoline, and diesel traffic as the predominant sources of PAHs. Secondary atmospheric formation of 9-nitroanthracene and 2+3-nitrofluoranthene was evaluated and concluded. Results also indicate that ambient PAH concentrations were affected by precipitation events, and specific humidity is an essential parameter influencing PAH scavenging from the air. The present study contributes important data which can be utilized to eliminate uncertainties in model predictions that aim to assess the extent and impacts of Arctic atmospheric contaminants.

### 25 1 Introduction

Traditionally, Arctic regions are considered to be pristine and remote from the majority of potential large-scale emission sources in industrialized middle latitude countries (Armitage et al., 2011; Macdonal et al., 2000; Barrie et al., 1992). Atmospheric transport is the most efficient way for polycyclic aromatic hydrocarbons (PAHs), released in the lower latitudes, to reach the Arctic (Friedman et al., 2014). Long range atmospheric transport (LRAT) to Arctic regions has strong  
30 seasonality with an increased tendency during winter and spring (Willis et al., 2018). This is driven by a different mean circulation direction across the Arctic in winter compared to summer, the extension and significantly increased permeability of the Arctic front in winter, and the absence of wet removal of particles during transport (Willis et al., 2018). These factors explain observed maximum near-surface pollutant concentrations during winter and minimum levels during summer (Klonecki, 2003). Fossil fuel sources dominate total aerosol organic carbon in Arctic winter air, with a predominance of  
35 alkanes, PAHs, and phthalates (Fu et al., 2009). During the past decades, the background monitoring of atmospheric pollutants in Ny-Ålesund, Svalbard, and Alert, Canada, have been an important data repository for information on occurrence and LRAT of anthropogenic contaminants including persistent organic pollutants and PAHs in the Arctic regions. The data demonstrates ubiquitous distribution of PAHs on a global scale, including the Arctic. “Confirmed occurrence of a pollutant in a polar environment” is an important criterion considered by conventions, including the United Nations  
40 Economic Commission for Europe (UNECE), Stockholm, Basel, and Rotterdam (Fiedler et al., 2019). UNECE has

incorporated PAHs in the Convention on Long-range Transboundary Air Pollution (UNECE, 1998). PAHs are regulated in many countries, eg. US, Canada, Holland, Sweden, Switzerland, and Denmark (Bandowe and Meusel, 2017). PAHs are also included in the list of target chemicals of the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR). PAH concentrations are not declining in the Arctic despite global emission reductions (Yu et al., 2019),  
45 and PAHs are listed as “chemicals of emerging concern in the Arctic” (Balmer and Muir, 2017).

PAHs are byproducts of different incomplete combustion processes, mainly fossil fuels and biomass burning. Their toxic and carcinogenic effects on both human health and ecosystems are well documented (Kim et al., 2013; Reynaud and Deschaux, 2006; Macdonald et al., 2010). Under unique Arctic weather conditions, with extreme temperatures, wind, and light seasonality, atmospheric PAHs may behave differently compared to in temperate climatic conditions. Low temperatures  
50 favor partitioning of semi-volatile PAHs from gas phase to particulate phase, which makes them more persistent in the Arctic environment (Lammel, 2015). Due to extended winter darkness in the Arctic, photodegradation of PAHs is limited for several months. The transition from dark polar winter to the light spring and summer brings large increase in the amount of available solar radiation and oxidants in the Arctic troposphere (Willis et al., 2018). PAHs react with a number of atmospheric oxidants, most notably the hydroxyl radical, ozone, the nitrate radical, and nitrogen dioxide (Keyte et al., 2013).  
55 This leads to their transformation into more toxic oxygenated and nitrated PAH derivatives (oxy-PAHs and nitro-PAHs). Oxy- and nitro-PAHs are also constituents of raw coal and can be emitted with PAHs following the same combustion processes (Huang et al., 2014b). Oxy- and nitro-PAHs have high toxicity (Onduka et al., 2012); they can act as direct mutagens, carcinogens, and oxidative stressors in biota (Durant et al., 1996). The biological effects of nitro- and oxy-PAHs can be greater than those of the parent PAHs (Kielhorn et al., 2003). In remote locations they are found at concentrations  
60 near detection limits and thus are mostly not included in monitoring programs, and the level of nitro- and oxy-PAHs in the Arctic atmosphere is unknown (Balmer and Muir, 2017).

The Arctic is warming at a higher rate than the global average and visible changes happen rapidly here. Thus, it is a key area for modeling studies on climate effects on contaminants with a main focus on LRAT from lower latitudes. As a consequence, local Arctic sources are usually disregarded, and lack of information on local emission sources is a source of  
65 uncertainty in model predictions that often deviate significantly from observations (Schmale et al., 2018). Local emission sources may be of high importance in winter, when strong temperature atmospheric inversions can be frequent in Arctic region (Bradley et al., 1992). These episodes inhibit the mass and heat fluxes from the surface to the atmosphere, and consequently the dilution of surface emissions (Janhall et al., 2006; Li et al., 2019). This trapping of emissions results in poor air quality and can be potentially harmful to local people. Climate change introduces additional sources of PAHs to the  
70 Arctic region. In the past decade, human activities such as resource exploration, research, tourism, fisheries, and maritime traffic have increased substantially due to warming and corresponding reduction of sea ice, opening up new shipping routes (Jörundsdóttir et al., 2014). Warming may also enhance volatilization of low molecular weight (LMW) PAHs from ground surfaces (Friedman et al., 2014) and melting sea ice (Yu et al., 2019). Reactivity of PAHs in the gas phase is significantly greater than when associated with particles (Keyte et al., 2013), therefore increasing air temperatures can be expected to lead  
75 to increased levels of toxic nitro- and oxy-PAHs.

The need for a comprehensive assessment of local contaminant sources in Svalbard was acknowledged and initiated in the international Arctic Monitoring and Assessment Programme (AMAP); with the major focus on persistent organic pollutants (Pedersen et al., 2011), there is a scarcity of data on local sources of PAHs in Svalbard. A back-trajectory analysis of twenty years data for three representative PAHs (Phe, Pyr, and BaPyr; see Table 1 for full names) suggested that Svalbard is  
80 impacted by air masses coming from eastern Russia, northern Europe, and northwest Russia during winter (Yu et al., 2019). Overall, combined European and Russian emissions accounted for more than 80% of episodic high-concentration events in Svalbard in 2007 (Balmer and Muir, 2017; Friedman and Selin, 2012). However, observed concentrations of Phe and Pyr from the Zeppelin station, Svalbard, were higher than model simulations, indicating important contributions of local sources

of PAHs to the Arctic atmosphere, too (Yu et al. (2019)). This study focused on the main settlement in Svalbard,  
85 Longyearbyen, with a population of approximately 2300 inhabitants and a high level of (partially seasonal) human activities  
(transport, coal mining, industry, tourism, and research). The local coal-fired power plant (PP) was hypothesized to be the  
major local source of PAHs, and the overall objectives of this study were to: (1) evaluate PAH emissions from the local  
power plant, (2) examine concentrations and profile changes with distance from the PP, (3) quantify concentrations of PAHs  
and nitro- and oxy-PAHs, in both gaseous and particulate phases, and (4) determine other potential local sources of PAHs,  
90 and nitro- and oxy-PAHs.

## 2 Material and methods

### 2.1 Sampling site

Svalbard is an archipelago located between latitudes 77° and 81°N in the Western Barents Sea. Longyearbyen, being the  
largest populated settlement, was chosen as the study area. The local PP was installed in Longyearbyen in the 1980s and  
95 provides the community with sufficient electricity (45 000 MW) and central heating supply (70 000 MW) throughout the  
year (Bøckman, 2019). The PP is fueled by coal produced in a nearby mine at Breinosa (mine No. 7). This coal has a distinct  
quality (brown, high volatile bituminous coal with vitrinite reflectance  $R_o=0.78\%$  (Marshall et al., 2015)) and is well suited  
for energy production. Coal consumption is about 25-30 thousand ton per year. The PP has two boilers, 32 MW each. The  
coal burning temperature is about 1000 °C (Bøckman, 2019). Since December 2015, the flue gas purification system consists  
100 of a selective non-catalytic reduction (SNCR) system, an electrostatic precipitator (ESP), and a wet flue-gas desulfurization  
(WFGD) scrubber. After SNCR the  $\text{NO}_x$  content in the flue gas is reduced by 50% by spraying urea solution as a reduction  
agent into the boiler. Further, in the ESP step, dust is electrically charged and deflected toward the collection electrodes. In  
the WFGD scrubber, the flue gas is cooled and desulfurized by sea water.

For PP emission analysis, stack emission air samples were collected at source (PP), and two locations at transect distance:  
105 the roof of the University Centre in Svalbard (UNIS, urban location, 1 km from PP) and the former northern lights  
observatory in Adventdalen (Adventdalen, rural location, 6 km from PP, 7 km to the active coal mine No. 7) (Fig. 1).  
Sampling at UNIS and Adventdalen was performed simultaneously.

### 2.2 Sample collection

#### 2.2.1 Power plant

110 A total of 6 low volume ( $1.3\text{-}3.0\text{ m}^3$ ) samples of the PP stack emission were collected (Table S1) under normal operating  
conditions, collected on 27<sup>th</sup> September (PP1-PP3) and 2<sup>nd</sup> October (PP4-PP6) 2018. Sampling was performed downstream  
the scrubber, after all flue gas cleaning steps. The sampling probe (inner  $\varnothing = 11\text{ mm}$ ) was situated to face the direction of the  
flue gas. A custom-made low volume, battery powered, air sampler (Digitel, Switzerland) was used to pump the flue gas  
through the sampling material placed in a stainless steel cartridge (16249, Sartorius Stedim Biotech GmbH, Germany). The  
115 particulate phase was collected on quartz fiber filter (QFF, pre-burned at 450°C for 6 h;  $\varnothing = 47\text{ mm}$ , Pallflex, USA), and the  
gaseous phase on polyurethane foam (PUF, pre-cleaned in toluene for 24 h followed by 24 h acetone wash;  $\varnothing = 50\text{ mm}$ , L =  
75 mm, Klaus Ziemer GmbH, Germany). Although, the pump was operated at the maximum speed ( $35\text{ L min}^{-1}$ , which  
corresponds to  $6.1\text{ m s}^{-1}$  probe intake flow speed), an isokinetic sampling regime was not achieved. The flue gas parameters  
(temperature  $8.9\pm 0.5^\circ\text{C}$ , moisture  $28\pm 2\%$ , flow speed  $18.1\pm 0.8\text{ m s}^{-1}$ , and density  $1.24\pm 0.2\text{ kg m}^{-3}$ ) were measured during the  
120 sampling by FKT3DP1A multi meter equipped with S-type Pitote probe (FlowKinetics LLC, USA).

### 2.2.2 UNIS and Adventdalen

The prevailing wind direction in Longyearbyen and Adventdalen is from the southeast. In summer, when the soil surface in Adventdalen becomes warmer than water surface in Adventfjrd, the wind direction can temporary change to northwesterly. To focus on PP emission and avoid the peak marine traffic in the summer, simultaneous sampling at UNIS and Adventdalen was carried out from 28<sup>th</sup> August to 28<sup>th</sup> of September 2018 (Table S1), on days with predicted northwesterly wind direction, using high volume air samplers (TISCH-1000-BLXZ, TISCH Environmental Inc., USA) equipped with dual chamber sampling module (particle filter, stainless screen and vapor filter, glass cartridge). About 370 m<sup>3</sup> of ambient air was collected over 24 h per sample (Table S1). For each station, 6 high volume air samples were collected for particulate (QFF, pre-burned at 450°C for 6 h; Ø = 103 mm, Munktell/Ahlstrom, Finland) and gaseous (PUF, pre-cleaned in toluene for 24 h followed by 24 h acetone wash; Ø = 65 mm, L = 100 mm, Klaus Ziemer GmbH, Germany) phases. Weather parameters including ambient temperature, relative humidity, UV radiation, wind direction, and precipitation were recorded (Table S2). All samples were kept intact inside the sampling unit after collection. In order to reduce the risk of post-collection contamination, the unit was sealed in two plastic bags for transportation to the lab, where samples were removed from the unit, sealed with layers of aluminum foil, and stored airtight in two plastic bags. Samples were kept frozen at -20°C until analyzed. A total of 18 samples (18 QFFs and 18 PUFs) and 8 field blanks (4 for PP and 4 for UNIS and Adventdalen) were collected.

### 2.3 Analytical procedure

16 PAHs, 8 oxy- and 21 nitro-PAHs (Table S3) were quantified using GC-EI-MS/MS and GC-ECNI-MS, respectively. Full details on analytical methods, including equipment and procedures, are outlined in the SI (Text S1, Tables S4 and S5). In brief, all QFFs (particulate phase) and PUFs (gaseous phase) samples were extracted separately by two different methods, followed by the same clean-up procedure. Several <sup>2</sup>H-labelled PAH (dPAH) surrogates (16 dPAHs, 3 dOxy-PAHs, and 6 dNitro-PAHs), were added to samples prior to extraction. QFF samples were extracted with dichloromethane using QuEChERS-like procedure developed previously for the analysis of particulate bound PAHs (Albinet et al., 2013; Albinet et al., 2014). PUF samples were Soxhlet extracted with dichloromethane for 24 h. The extracts were concentrated and cleaned up first with neutral alumina Al<sub>2</sub>O<sub>3</sub>, and then with neutral silica SiO<sub>2</sub>. Elutes were dried under gentle nitrogen stream and redissolved in approximately 100 µL *n*-hexane. The purified samples were spiked with three labelled standards to evaluate the surrogate recoveries.

### 2.4 Quality assurance

Detailed information on method validation and quality control is provided in SI (Text S2). Field (n=4 for PP, n=4 for UNIS and Adventdalen combined) and laboratory (n=3 for PP, n=3 for UNIS and Adventdalen combined) blanks were analysed in order to evaluate possible contamination during sample transport and analysis. The method detection limit (MDL) was determined based on blank values for each sampling material type (Table S6). High contamination of PUF blank samples by 9,10-PheQ (for UNIS and Adventdalen), and 2-NFlu (for PP) was found; these compounds were excluded from the final results. No blank correction was performed for the concentration calculations. Samples with PAH concentrations below instrumental limit of quantification (LOQ) were replaced by LOQ/2 for statistical analysis. The method efficiency was tested using QFF (n=4) and PUF (n=4) spiked samples (Table S7). Acceptable recoveries ranged between 63-109% for dPAHs, 56-68% for dOxy-PAHs, and 44-89% for dNitro-PAHs (Table S8).

### 2.5 Statistical analysis

Statistical analyses of compound concentrations were performed with Minitab 18 Statistical Software (Minitab LLC, Pennsylvania, USA). Normality and homogeneity of variances were tested with Shapiro-Wilk and Levene's tests,

respectively. Mann–Whitney U test was performed to test significant differences between sampling locations (UNIS and Adventdalen). Spearman's correlation was used to investigate relationships between different variables. The statistical significance was set at  $p < 0.05$ , unless stated.

165 Principle component analysis (PCA) was performed for PAH source apportionment. A  $6 \times 29$  matrix (sample number  $\times$  29 detected compounds, including 14 PAHs and 15 nitro- and oxy-PAHs) dataset was used to assess the source contribution to PAHs for each location, and  $12 \times 29$  matrix dataset to investigate PAH profile differences between UNIS and Adventdalen. Total PAH concentrations (gaseous and particulate, G+P), were used to minimize the influence of partitioning, ageing, and photochemical degradation (Kim et al., 2009). PCA was based on a correlation matrix to standardize scales and weight all variables equally (Holmes et al., 2017). PCA was first applied on the concentrations matrix only, and then weather parameters were carefully included in order to explain the observed sample groupings.

### 3 Results and discussion

#### 3.1 Longyearbyen power plant PAH emission profile

175 Individual concentrations and phase distribution (percentage on particulate matter, %PM) of target PAH are summarized in Table 1. The sum of total (G+P) concentration of the 16 priority PAHs ( $\Sigma 16$  PAHs; U.S. Environmental Protection Agency) in the purified flue gases emitted from the PP is  $0.106 \mu\text{g m}^{-3}$ , which corresponds to  $1.5 \mu\text{g kg}^{-1}$  coal. Currently, there is no PAH emissions standard for coal-fired power plants in Norway. However, compared to the Canadian emission limits of PAHs for municipal solid waste incinerators of  $5 \mu\text{g m}^{-3}$  (Li et al., 2016), the Longyearbyen PP emissions is a factor of 3 lower. About 94% of 16 PAHs were emitted in a gas phase, in agreement with earlier studies (Li et al., 2016; Wang et al., 2015; Yang et al., 1998). The emission profile of the Longyearbyen PP is dominated by LMW PAHs (2 and 3 rings), which represents 89% of  $\Sigma 16$  PAHs emission; high molecular weight (HMW) PAHs (5-7 rings) were not detected, likely due to their low vapor pressure and thus association to particles. A combination of ESP and WFGD has a removal efficiency of PM up to 99.9% (Wang et al., 2019). Fine cooling of the PP flue gas ( $8.9 \pm 0.5$  °C) by cold sea water facilitates high PM collection efficiency as well (Noda and Makino, 2010; Wang et al., 2019). As a result, PP dust emissions are below the ultra-low standard of  $5 \text{ mg m}^{-3}$  (Zhao et al., 2017) at  $1.5 \pm 0.2 \text{ mg m}^{-3}$  (Lundgjerdingen, 2017). The PAH emissions profile

180 was dominated by Nap and Phe, accounting for 53 % and 27 % of  $\Sigma 16$  PAHs, followed by Flu, Flt and Pyr. Nap and Phe are often reported as major emitted compounds from power plants equipped with analogous exhaust cleaning systems and/or burning the same type of coal (Hsu et al., 2016; Li et al., 2016; Wang et al., 2015). A similar PAH emissions profile was reported by Hsu et al. (2016) for the power plant in central Taiwan (Table S12). A higher flue gas dust concentration and different coal sources resulted in 40% emissions of four ringed PAHs compared to 11% for Longyearbyen PP. Operation conditions and boiler type can have significant effects on emitted PAH profiles and concentrations (Wang et al., 2015), as well as combustion temperature (Peng et al., 2016), and geological maturity (Huang et al., 2014b).

Nitro- and oxy-PAHs are constituents of raw coal and can also be produced from parent PAH compounds during high temperature coal combustion (Huang et al., 2014b). The yields of individual nitro-PAHs from the PP was 1 - 2 orders of magnitude lower than those of their corresponding parent PAHs, and individual concentrations were at or below  $1.7 \text{ ng m}^{-3}$ ;

195 1-NNap was the most abundant nitro-PAH. Huang et al. (2014b) investigated the same type of coal (bituminous,  $R_0 = 0.77$  %), burned at lower temperatures in a honeycomb briquette stove; nitro-PAHs were absent in the raw coal and calculated nitro-PAH/PAH ratios were  $>1$  confirming formation of nitro-PAH compounds during coal combustion. In contrast, in the present work, the same daughter to parent PAH ratios were  $< 1$  (Table 2), indicating an absence of nitro-PAH formation during coal combustion or possible thermal degradation of nitro-PAH at 1000 °C.

200 The yields of oxy-PAHs were orders of magnitude higher than nitro-PAHs because oxy-PAHs can be produced by reaction of PAH with O $\cdot$  or  $\cdot$ OH radicals generated continuously by radical chain reactions during combustion (Huang et al., 2014b).

9-Flu and 9,10-AntQ were the most abundant among the oxy-PAHs (12.4 and 15.6 ng m<sup>-3</sup>, respectively), and concentration of 9,10-PheQ was a factor of six lower. The calculated ratios of oxy-PAH to corresponding parent PAH were lowest for 9,10-PheQ/Phe and highest for 9,10-AntQ/Ant (Table 2). This can be due to a higher content of Phe in coal, as well as different reaction rates of Phe, Ant, and Flu with O<sup>•</sup> or <sup>•</sup>OH radicals. Difference between the reaction rates of Flu and Ant can possibly be explained by different reaction pathways; Flu undergoes H atom abstraction at the 9-position to form 9-Flu, while Ant requires <sup>•</sup>OH attack on the aromatic ring (Brubaker and Hites, 1998). Ant and Phe have essentially the same 3-ring structure, only differing by the relative position of their aromatic rings. However, Ant appears to be significantly more reactive, due to the sterically unhindered molecular structure of Ant (Keyte et al., 2013). Formation of specific PAHs is also a temperature dependent process (Peng et al., 2016).

Ant, BaAnt, and Chry are often used as tracers of coal combustions (Zheng et al., 2019; Wu et al., 2014; Wang et al., 2009), however, their concentrations in the flue gas of the Longyearbyen PP were negligible. This demonstrates the strong importance of determining indicative PAH profiles for individual combustion sources for correct source identification. PAH emissions from different coal plants are hard to compare because they are affected by many factors including coal type, boiler load, combustion mode (Wang et al., 2015), and flue gas cleaning systems. Nap was the most abundant PAH emitted from the Longyearbyen PP. Nap is not a common tracer due to its ubiquitous presence and often high blank sampling material contamination; thus, Nap was not considered as potential marker. Further, Phe, Flu, Flt, Pyr, 9-Flu, and 9,10-AntQ were the main PAHs detected in the Longyearbyen PP flue gas (Fig. 2), therefore the presence and diagnostic ratios (Table 3) of these compounds were used as markers of the PP source in the present work. In Yu et al. (2019), coal combustion was identified as the main source (68% contribution) of PAHs, at the Zeppelin monitoring station at Ny-Ålesund, Svalbard, and Phe, Flu, Flt, and Pyr were the main contributors, most likely attributable to the Longyearbyen PP located 115 km southeast of Ny-Ålesund. Overall, total flue gas emissions were 960 000 Nm<sup>3</sup> day<sup>-1</sup> (Lundgjerdingen, 2017), and a daily emissions of Σ16 PAHs and sum of the nitro- and oxy-PAHs are approximately 98.7 g of and 35.6 g, respectively.

### 3.2 UNIS and Adventdalen

#### 3.2.1 Ambient concentrations and PAH profiles

The concentrations of PAHs measured at UNIS was a factor of 2 higher than at Adventdalen, while the PAH profiles were similar. Σ16 PAHs was 749.2±72.6 and 369.1±66.7 pg m<sup>-3</sup> at UNIS and Adventdalen, respectively (Table 1). ΣOxy-PAHs were approximately a factor of 2 lower, with average values of 471.0±150.8 (UNIS) and 233.1±68.3 pg m<sup>-3</sup> (Adventdalen); Σnitro-PAHs were an order of magnitude lower than both parent PAHs and oxy-PAHs, with average values of 36.8±6.2 (UNIS) and 27.2±11.1 pg m<sup>-3</sup> (Adventdalen). Among the parent PAHs, Phe (ranged from 191.7 to 470.0 pg m<sup>-3</sup>) and Flu (ranged from 38.5 to 236.0 pg m<sup>-3</sup>) were the most abundant at both sites. The PAH concentrations measured at Longyearbyen (UNIS and Adventdalen) were two orders of magnitude higher than those detected at the Zeppelin station and the same order of magnitude as in Birkenes (southern mainland Norway) (NILU, 2019) (Table S13) for the same period (autumn 2018). Phe and Flu also dominated the PAH profile at Zeppelin station, which may indicate similar sources of contamination.

Concentrations of 9-Flu and 9,10-AntQ were the highest among measured oxy-PAHs in the present study. The 9-Flu level (270.3±146.9 pg m<sup>-3</sup> at UNIS and 139.4±24.9 pg m<sup>-3</sup> in Adventdalen) was the same order of magnitude as reported for the background monitoring stations in the north of Finland (Pallas) and in the south of Sweden (Råö) (Brorström-Lundén et al., 2010), while 9,10-AntQ (163.5±57.4 pg m<sup>-3</sup> at UNIS and 71.7±39.2 pg m<sup>-3</sup> in Adventdalen) was an order of magnitude higher in Longyearbyen. The nitro-PAH levels in our study were overall lower than other reported background sites. 1-NNap and 2+3-NFlt were the most abundant nitro-PAHs detected at UNIS and Adventdalen air samples; the level of 2+3-NFlt (9.5±1.6 pg m<sup>-3</sup> at UNIS and 12.3±7.7 pg m<sup>-3</sup> in Adventdalen) was an order of magnitude higher than that at Råö and Pallas stations; 1-NNap average detected concentrations were 17.0±3.0 pg m<sup>-3</sup> at UNIS and 5.0±3.2 pg m<sup>-3</sup> in Adventdalen.

### 3.2.2 Gas/particle partitioning

245 Gas/particle partitioning is an important process that controls transport, degradation, and distribution patterns of  
contaminants in and between environmental compartments (Huang et al., 2014a). The sampling campaign in the present  
study was conducted from late Arctic summer until early autumn and during this period the temperature varied from 6.8 °C  
in August to -4.4°C in September and several precipitation events (snow and rain) occurred. In general, LMW PAHs were  
found in the gas phase, while HMW PAHs were present in the particulate phase (Table 1), which is in accordance to their  
250 physico-chemical parameters, such as octanol-air partition coefficient (Table S3). Repartitioning between phases (Fig. 3)  
mainly impacted semi-volatile compounds with three and four aromatic rings (Flt, Pyr, BaAnt, Chry; 2-NFlu, 9-Flu, cPphe-  
4, 9,10-AntQ, 9-NAnt, and 2+3-NFlt) as a response to changing meteorological conditions (Hu et al., 2019). Strong negative  
correlations (Spearman coefficient > 0.65) of percentage of PAH determined in particulate phase (%PM) with ambient  
temperature and specific humidity were determined for Chry, 1-NNap, 2-NNap, cPphe-4, and 2+3-NFlt, although they were  
255 not statistically significant (Table S14). Likely, it was confounded by diurnal variations in the rate of PAH emissions from  
different local sources. Specific humidity played an essential role in PAH wet scavenging as it is further discussed in Section  
4.1.

Compared to Adventdalen, the urban UNIS location ensure a higher level of PAHs emitted from different nearby  
anthropogenic sources, including the PP. Low ambient temperature reinforces partitioning of freshly emitted gaseous PAHs  
260 to the particulate phase. As a result, %PM at UNIS was higher than in Adventdalen. Deposition (wet and dry) and chemical  
reactions with atmospheric oxidants are important removal processes of PAH from air (Keyte et al., 2013). On the local  
scale, within an hour of travel time from PP to Adventdalen, it is not expected that photolytically-initiated transformation of  
the freshly emitted PAHs has a strong influence on gas phase concentrations and consequently on %PM. Dry deposition  
rates vary depending on the type of adsorbing particle (mass, size, aerodynamic properties, shape, and chemical  
265 composition) and the atmospheric conditions (Weinbruch et al., 2018). The influence of wet deposition was indicated by a  
significant negative correlation between concentrations of several HMW PAHs (Pyr, Chry, BbkFlt, IPyr, BPer, BaFlu-11,  
and BaAnt-7,12) and precipitation (Spearman correlation,  $p < 0.05$ , Table S15), resulting in a lower amount of particle-bound  
PAHs transported from the town, and thus lower %PM in Adventdalen.

## 4 Source identification

270 PCA was the main tool applied on Adventdalen (n=6) and UNIS (n=6) samples to determine possible PAH sources at each  
location, as well as on all the analyzed ambient samples together (n=12) to identify the difference between the two transect  
locations. Total PAH (G+P) concentrations were used to minimize the influence of partitioning, aging, and photochemical  
degradation. PAH diagnostic ratios (Table 4) were utilized as an additional supportive tool taking into account their possible  
shift due to large scale mixing of PAHs in the atmosphere, different emission rates of PAH from the same source, influence  
275 of changing environmental conditions (Katsoyiannis and Breivik, 2014), and atmospheric processing (Alam et al., 2013).  
Transport of PAHs over short distances from a source can be enough to cause a change in interpretation and identification of  
the source (Katsoyiannis and Breivik, 2014). Different PAHs have diverse reactivity with other atmospheric species and  
half-lives in the atmosphere (Ravindra et al., 2008; Tobiszewski and Namieśnik, 2012). Due to high atmospheric reactivity  
of Ant and BaAnt, utilization as source apportionment should be avoided, while HMW PAH diagnostic ratios may be  
280 exploited with greater confidence owing to their increased stability (Alam et al., 2013). Although, based on similarities in  
characteristic travel distances among pairs of PAHs, Katsoyiannis and Breivik (2014) named BaAnt/(BaAnt+Chry) ratio as  
the most robust for air concentrations. Conclusions on the chosen diagnostic ratios are incorporated in the PCA findings  
discussion. Two principal components (PCs) for Adventdalen (79%) and three PCs for UNIS (80%) were studied in details.

#### 4.1 Adventdalen

285 Two PCs explain 79% of the total variance (Table S16) of Adventdalen data. PC1 (55%) revealed a distinct profile  
dependence on ambient conditions (temperature, specific humidity, and UV radiation). Two groups, “humid samples” (A1,  
A2, A3) and “dry samples” (A4, A5, A7), were identified (Fig. 4). The first group corresponds to the sampling days with  
higher values of temperature, specific humidity, and UV radiation (Table S2). Most of the target compounds in the “humid  
samples” were at lower concentrations compared to the “dry samples”. The majority of PAHs were negatively correlated  
290 with specific humidity, temperature, UV radiation, and precipitation (Fig. 4). Samples A2 and A5, corresponding to two days  
with heavy precipitation events (raining at +5 °C and snowing at -3 °C, respectively), were not grouped together but sharply  
separated by the PC1. This indicates that the mass of water vapor in the air (specific humidity), in contrast to relative  
humidity, is an essential parameter for removal from the atmosphere. In the present study, many compounds were negatively  
correlated with humid conditions, particularly the intense rainfall episode (sample A2, Fig. 4). Heavier molecular weight  
295 compounds of this group (Chry, 9,10-AntQ, cPPhe-4, 9-NPhe, BaFlu-11, and BaAnt-7,12), which have lower vapor pressure  
and thus volatility, were full or partly bound to particles, 38-100% PM (Table 1). Therefore, they were readily scavenged by  
precipitation (rainfall). For those which are lighter and more volatile, water solubility (for Ace, Acy, Flu, Phe, 1- and 2-  
NNap, 9-Flu, and 9,10-AntQ) and polarity (for nitro- and oxy-PAHs) play an additional role in wet scavenging processes  
(Shahpoury et al., 2018). The gas phase removal from the atmosphere is due to substance dissolution in water droplets  
300 (Shahpoury et al., 2018), which enhances the scavenging effect at higher humidity. A strong negative correlation with  
humidity was determined for all quantified LMW PAHs, significant for Acy, Pyr, 1-NNap, and 9-Flu (Spearman correlation,  
 $p < 0.05$ ; Table S17). Presence of Ant and Flt (gas-phase PAHs with low polarity and water solubility) in the group is likely  
due to the same source of origin.

Based on the tracers and their loadings (Table S16), PC1 can be assigned to local PP coal burning (Flu, Phe, Flt, Pyr, 9-Flu,  
305 9,10-AntQ) and vehicular emissions (Pyr, Chry, 1-NNap, cPPhe-4, BaFlu-11, BaAnt-7,12). The diagnostic ratios  
IPyr/(IPyr+BPer) and IPyr/BPer indicated mainly contribution from diesel emissions (Table 4) and several of these  
compounds (cPPhe-4, 1-NNap, and BaAnt-7,12) were reported to be emitted after diesel burning as well (Rogge et al., 1993;  
Albinet et al., 2007; Zhao et al., 2018).

Besides, PC1 emphasized positive correlation of 2+3-NFlt and 9-NAnt with temperature, humidity, and UV radiation, as  
310 well as negative correlation with a group of primary PAHs (Fig. 4, Table S17), suggestive of a secondary source of origin.  
The daughter to parent PAH ratios, 9-NAnt/Ant and 2+3-NFlt/Flt (Table S18), showed statistically significant correlations  
with temperature, humidity, and UV radiation (Spearman correlation,  $p < 0.10$ ; Table S19). Moreover, 2+3-NFlt and 9-NAnt  
had a strong positive correlation with each other and negatively correlated with their parent compounds (Spearman  
correlation, Table S20), by reason of assumed chemical transformation. It should be noted that 9-NAnt and 2+3-NFlt were  
315 detected in the PP flue gas at low levels ( $0.08 \text{ ng/m}^3$  and  $0.5 \text{ ng/m}^3$ , respectively), and further statistical analysis (Spearman  
correlation, Table S20, Fig. 4) showed no correlation with established PP tracers (Phe, 9,10-AntQ, 9-Flu), suggesting a  
different source of origin. These results indicate atmospheric formation as an additional source of 9-NAnt and 2+3-NFlt, in  
agreement with other studies (Lin et al., 2015b; Hayakawa et al., 2000; Shahpoury et al., 2018). Sampling close to a major  
source of  $\text{NO}_x$  emission, such as the local power plant, can result in concentrations of  $\text{NO}_3$  and  $\text{NO}_2$  at high enough level for  
320 atmospheric transformation of PAHs to occur. Relative contribution of primary and secondary sources of nitro-PAHs could  
be tested by applying a 2-NFlt/1-NPyr ratio (Zielinska et al., 1989), but 1-NPyr was not detected in our study. We conclude  
that PC1 (55%) is associated with local PP coal burning, atmospheric transformation, and traffic emission (mainly diesel  
exhaust) sources.

PC2 did not reveal additional PAH sources and confirmed inputs from the PP coal burning (Phe, Flu, and 9-Flu) and diesel  
325 exhaust (4-NBip, 1- and 2-NNap, 2+3-NFlt, Hu et al., 2013; Keyte et al., 2013; Alam et al., 2015). Moreover, PC2 revealed a  
negative correlation of LMW PAHs, namely 4-NBip, 2-NNap, Phe, Flu, 1-NNap, 9-Flu, and Acy (in loading order) with

precipitation, mainly snow on day five (sample A5, Fig. 4). These PAHs were detected in the gas-phase. Commonly, wet scavenging of PAHs is considered to be ineffective, unless the substance is particle-associated (Škrdlíková et al., 2011). However, studies by Wania et al. (1999) report that snow scavenging may be an important, and sometimes a dominating scavenging process for lighter PAHs, mediated via a process of adsorption to the air-ice (Wania et al., 1999).  
330 The two PCs explain 79% of the total variance. Traffic emission (mainly diesel exhaust) and the Longyearbyen coal-burning PP were the main local sources of PAHs and nitro- and oxy-PAHs in Adventdalen, and atmospheric transformation of PAHs is an additional source of nitro-PAHs. The statistical analysis has also emphasized the importance of weather conditions on the spatial distribution and concentrations of PAHs. LMW PAHs were scavenged by snow, while the level of humidity was  
335 an essential parameter for total PAH removal from the atmosphere.

#### 4.2 UNIS

The UNIS sampling location is only 1 km away from the local coal-fired PP and the PAH profile is therefore influenced by local activities in and around the town. Three PCs explain 80.3% of the total variance (Table S21). PC1 (41%) was equally loaded with Flt, Pyr, BaAnt, Chry, BbkFlt, BaPyr, IPyr, BPer, 2-NNap, BaAnt-7,12, BaFlu-11, and BZT, which are  
340 commonly found in traffic emissions. The diagnostic ratios IPyr/(IPyr+BPer) and IPyr/BPer mainly indicated contribution from gasoline emissions (Table 4) and several of these compounds (BPer, IPyr, and BaFlu-11) were reported to be emitted after gasoline burning as well (Zielinska et al., 2004; Albinet et al., 2007). Absence of 1-NPyr and 2-NFlu, the principal compounds of diesel exhaust (Albinet et al., 2007), supported gasoline combustion as more dominant source as well. Precipitation data was included in PCA as variables to explain sample groupings. On the PC1 biplot (Fig. 5) samples U1, U2,  
345 and U5, collected on days with substantial precipitation (snow and rain; Table S2), are grouped together. All PC1 contributors showed negative correlations with precipitation. For Pyr, Chry, BbkFlt, BPer, and BaAnt-7,12 the negative correlation with precipitation was statistically significant (Spearman correlation,  $p < 0.10$ ; Table S15). The majority of these PAH derivatives were found mainly in the particulate fraction (Table 1), and lighter compounds were less affected by precipitation. This is in agreement with particle scavenging dominant during wet deposition (Škrdlíková et al., 2011). Zhang et al. (2015) reported that scavenging of particulate-phase PAHs is about 20 times more efficient than scavenging of gas-phase PAHs.  
350

PC2 (25%) was highly loaded by wind direction (Fig. 5, Table S21), and samples were split between two groups depending on prevailing wind direction during sampling. The first group was characterized by the presence of 9,10-AntQ, Phe, and Flu, attributable to the PP emission source. Diagnostic ratios of Flu/(Flu+Pyr) and BaAnt/(BaAnt+Chry) (Table 4) also indicated  
355 that the PP is a source of PAHs and nitro- and oxy-PAHs at UNIS. 9-Flu, a tracer for the PP, may have other possible sources, including diesel and gasoline vehicle exhaust, coal powder, road dust particles (Keyte et al., 2013), and may be locally produced, transported from longer range, or secondarily formed in the atmosphere (Kojima et al., 2010). 9-Flu is associated with the second sample grouping (U2, U6, U7), collected during conditions of wind blowing from the west and west southwest (Fig. S1), and they are characterized by the presence of 4-NBip, 1,5-DNNap, 2+3-NFlt, and 2-NFlu, known markers for diesel emissions (Hu et al., 2013; Keyte et al., 2013; Helmig et al., 1992). This can be explained by coal transportation by trucks, mining work, geotechnical drilling, and boat traffic in the fjord. Therefore, PC2 was attributed to coal burning emissions from the PP and diesel emissions.  
360

PC3 (15%) was loaded mainly with 9-NAnt, cPPhe-4, 9-Flu, and 2+3-NFlt (Table S21). These compounds may originate from combustion processes, often from vehicle emissions. However, on the PC3 score and loading plots (Fig. S2) it can be interpreted that these compounds were negatively correlated with other traffic emission tracers such as 1-NNap, 2-NNap, BZT, 2- and 4-NBip, and BaFlu, suggesting different sources of origin. Several studies have shown that 9-NAnt, cPPhe-4, 9-Flu, and 2+3-NFlt can be secondarily formed via chemical reactions in the atmosphere (Singh et al., 2017; Lin et al., 2015a; Zhao et al., 2018). The compounds were also associated with the sample U2, collected on the warmest day with high UV  
365

radiation and humidity levels. Thus, a secondary origin of 9-NAnT and 2+3-NFlt at UNIS was concluded, in agreement with  
370 source apportionment in Adventdalen, and PC3 was attributed to atmospheric transformation of PAHs.

The three PCs explain 79.7% of the total variance of the UNIS samples. PP coal burning, gasoline and diesel emissions, and  
atmospheric transformations were determined as the main sources of PAHs and nitro- and oxy-PAHs at UNIS.

#### 4.3 Transect ambient samples

PCA was performed to compare samples collected at UNIS and Adventdalen locations (n=12; Fig. 6). The same potential  
375 sources of PAHs and nitro- and oxy-PAHs for the Longyearbyen-Adventdalen vicinity were confirmed, which explains their  
similar profiles. Samples from UNIS and Adventdalen were clearly separated due to the higher concentrations of almost all  
the detected compounds at UNIS, originating from Longyearbyen activities: coal combustion in the PP, vehicle traffic, and  
marine traffic. LRAT input, including secondary formation of the derivatives, was more evident in Adventdalen where town  
emissions influence is reduced. In contrast to the study by Yu et al. (2019), no strong indication for LRAT biomass burning  
380 emissions was found for this set of air samples.

#### 5 Conclusion

Results provide insights into local sources of atmospheric PAHs and nitro- and oxy-PAHs in Svalbard. Source markers for  
the coal-burning PP in Longyearbyen were determined, and generally low emissions of PAHs confirmed an efficient exhaust  
cleaning system. However, PAHs are emitted daily from coal-burning, and due to a large volume of flue gas emissions, the  
385 PP remains an important local anthropogenic source of atmospheric contaminants. Ambient air concentrations of PAHs were  
substantially affected by rain and snow, and specific humidity plays an important role in PAH removal from the atmosphere.  
Overall, PAH concentrations were the same order of magnitude as detected at other background Scandinavian air sampling  
stations. The gas/particle partitioning of PAHs and nitro- and oxy-PAHs was dependent on air temperature and specific  
humidity, and mainly impacted semi-volatile compounds with three and four aromatic rings. Traffic emissions was another  
390 contributor to PAH emissions, with larger input from gasoline-driven cars at UNIS and diesel vehicles at the remote site due  
to mining and geotechnical work in Adventdalen. The results also revealed secondary atmospheric formation as an additional  
source of some nitro-PAHs. The present study contributes to understanding fate and distribution of PAHs in the Arctic, and  
it provides important information on the phase-separated concentrations of PAHs, and nitro- and oxy-PAHs in Arctic air, as  
well as markers of the Longyearbyen PP emissions. This data can eliminate uncertainties in model predictions that aim to  
395 assess the extent and impacts of Arctic atmospheric contaminants. Furthermore, the knowledge on the local emissions level  
can be important in case of temperature inversion in the lower atmosphere when vertical dilution is limited and contaminants  
are trapped near the ground, which may be adverse to public health.

*Data availability.* The dataset used in this paper is included in the Supplement, and further information is available from the  
400 corresponding author [tatiana.drotikova@unis.no](mailto:tatiana.drotikova@unis.no).

*Supplement.* The supplement related to this article is available online at: xxx.

*Author contribution.* RK, AKH, and HR designed the campaign. TD conducted the field and lab works. TD with support  
405 from AA and RK optimized, validated and performed GC analysis and further quantification. TD processed and interpreted  
PCA outcome. TD prepared the manuscript with contributions from all co-authors. TD, AA, and AKH prepared the  
Supplementary materials section.

645 n.d. not detected

**Table 2.** Ratios of individual oxy- and nitro-PAHs to their corresponding parent PAHs in Longyearbyen power plant (G+P; n=6).

Ratio	Mean	STD
Nitro-PAH/PAH		
2-NFlu/Flu	0.004	0.005
3-NPhe/Phe	0.028	0.028
2-NAnt/Ant	0.150	0.107
9-NAnt/Ant	0.040	0.028
2+3-NFlt/Flt	0.030	0.023
7-NBaAnt/BaAnt	5.37	3.87
Oxy-PAH/PAH		
9,10-PheQ/Phe	0.08	0.01
cPPhen-4/Pyr	0.31	0.10
BaFlu-11/Chry	0.65	0.34
9-Flu/Phe	0.47	0.13
9-Flu/Flu	1.67	0.29
9,10-AntQ/Ant	12.17	7.30

650

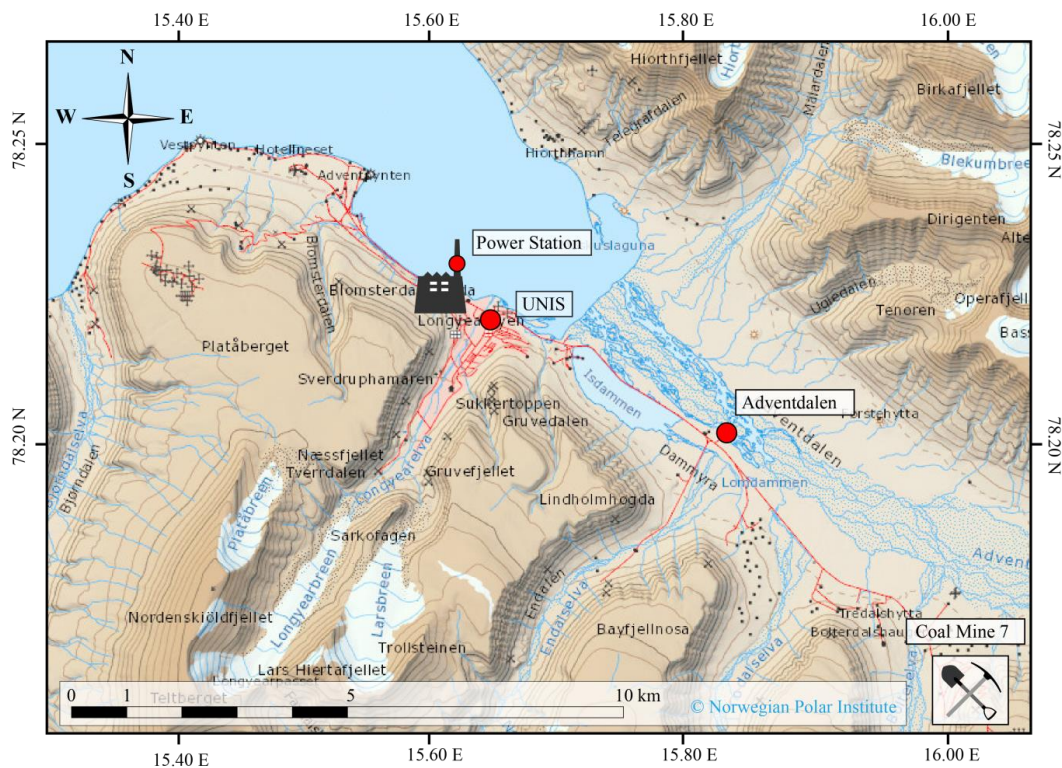

**Table 3.** PAHs diagnostic ratios for the Longyearbyen power plant (G+P; n=6).

Ratio	Mean	STD
Ant/(Ant+Phe)	0.044	0.002
Flt/(Flt+Pyr)	0.606	0.025
Flu/(Flu+Pyr)	0.638	0.110
BaAnt/(BaAnt+Chry)	0.332	0.027

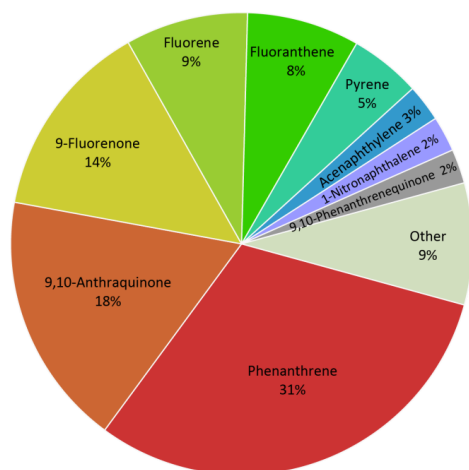

655 **Table 4.** Source identification based on diagnostic ratios derived from total (G+P) concentrations; average of individual ratio values (n=6) with standard deviation are presented

	Ratio	Potential sources	Reference
<b>IPyr/(IPyr+BPer)</b>			
Power plant	n.d.	-	
UNIS	0.32±0.01	<0.35 Gasoline	(Ravindra et al., 2008)
Adventdalen	0.45±0.05	0.35-0.70 Diesel	(Kavouras et al., 2001), (Ravindra et al., 2008)
<b>Flu/(Flu+Pyr)</b>			
Power plant	0.64±0.11	-	
UNIS	0.81±0.04	>0.5 coal combustion >0.5 Diesel	(Yunker et al., 2002), (Katsoyiannis and Breivik, 2014) (Ravindra et al., 2008)
Adventdalen	0.68±0.05	0.64 local power plant >0.5 coal combustion	This study (Table 3) (Yunker et al., 2002), (Katsoyiannis and Breivik, 2014)
<b>BaPyr/( BaPyr +Chry)</b>			
Power plant	n.d.	-	
UNIS	0.12±0.07	<0.2 Petrogenic source	(Wu et al., 2014)
Adventdalen	0.16±0.04	<0.2 Petrogenic source	(Wu et al., 2014)
<b>BaPyr/BPer</b>			
Power plant	n.d.	-	
UNIS	0.34±0.14	<0.6 Vehicular emissions	(Pandey et al., 1999)
Adventdalen	0.45±0.20	<0.6 Vehicular emissions	(Pandey et al., 1999)
<b>BaAnt/(BaAnt+ Chry)</b>			
Power plant	0.33±0.03	-	
UNIS	0.30±0.04	0.33 coal combustion 0.2-0.35 coal combustion	This study (Table 3) (Akyüz and Çabuk, 2010)
Adventdalen	n.d.	-	
<b>IcdP/BghiP</b>			
Power plant	n.d.	-	
UNIS	0.39±0.20	<0.4 Gasoline	(Ravindra et al., 2008)
Adventdalen	0.81±0.16	~1 Diesel	(Ravindra et al., 2008)

**Figure 1.** Air sampling transect locations in the vicinity of Longyearbyen.

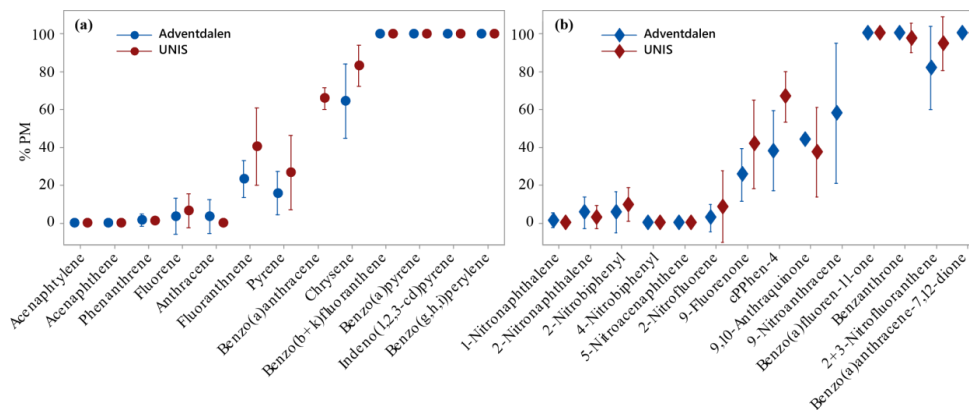

660

**Figure 2.** Proportion of PAH derivatives (G+P; excluding Nap) in the Longyearbyen power plant emission (n=6).

665

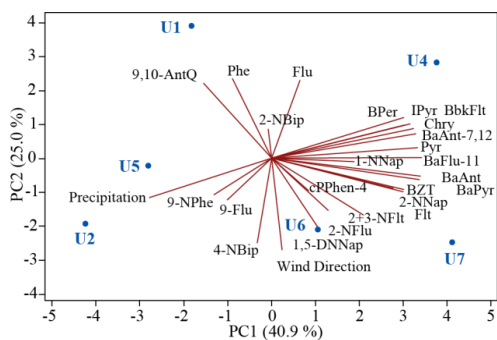

**Figure 3.** Percentage of (a) PAHs and (b) nitro- and oxy-PAHs determined in particulate phase (% PM) at UNIS (n=6) and Adventdalen (n=6); individual standard deviations are used to calculate the intervals.

670

**Figure 4.** Principal component analysis biplot of PC1 and PC2 for Adventdalen samples (G+P; n=6).

675

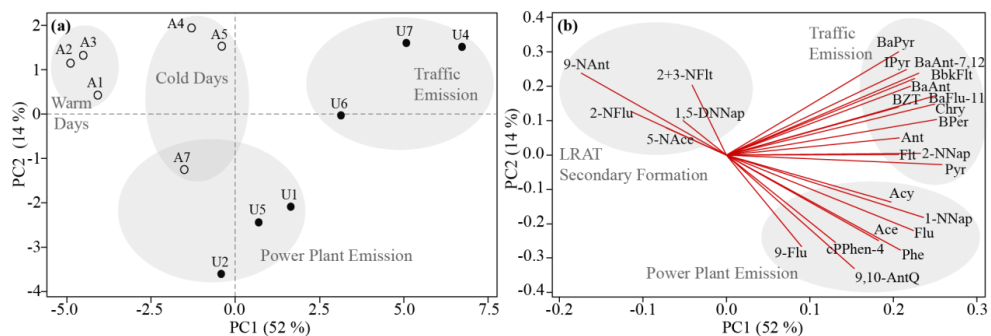

**Figure 5.** Principal component analysis biplot of PC1 and PC2 for UNIS samples (G+P; n=6).

680

**Figure 6.** Score (a) and loading (b) plots of PC1 and PC2 for Adventdalen (A) and UNIS (U) samples together (G+P; n=12).
