24 **Abstract**

25
26 Sulphuric acid has been shown to be a key driver for new particle formation and subsequent growth
27 in various environments mainly due to its low volatility. However, direct measurements of gas-phase
28 sulphuric acid are oftentimes not available, and the current sulphuric acid proxies cannot predict for
29 example its nighttime concentrations or result in significant discrepancies with measured values.
30 Here, we define the sources and sinks of sulphuric acid in different environments and derive a new
31 physical proxy for sulphuric acid to be utilized in locations and during periods when it is not
32 measured. We used H₂SO₄ measurements from four different locations: Hyttiälä, Finland; Agia
33 Marina, Cyprus; Budapest, Hungary; and Beijing, China, representing semi-pristine boreal forest,
34 rural environment in the Mediterranean area, urban environment and heavily polluted megacity,
35 respectively. The new proxy takes into account the formation of sulphuric acid from SO₂ via OH
36 oxidation and other oxidation pathways, specifically that via stabilized Criegee Intermediates. The
37 sulphuric acid sinks included in the proxy are its condensation sink (CS) and atmospheric clustering
38 starting from H₂SO₄ dimer formation. Indeed, we found that the observed sulphuric acid
39 concentration can be explained by the proposed sources and sinks with similar coefficients in the four
40 contrasting environments where we have tested it. Thus, the new proxy is a more flexible and an
41 important improvement of previous proxies. Following the recommendations in the manuscript, a
42 proxy for a specific location can be derived.

43
44 Keywords: sulphuric acid, proxy, boreal, rural, urban, megacity

45

46 1. Introduction

47
48 Atmospheric New Particle formation (NPF) events and their subsequent growth have been observed
49 to take place almost everywhere in the world (Kulmala et al., 2004; Kerminen et al., 2018; Chu et al.,
50 2019). Many of these observations are based on continuous measurements and some include more
51 than a year of measurement data (Nieminen et al., 2018). The importance of NPF events on the global
52 aerosol budget and cloud condensation nuclei formation has been well established (Spracklen et al.,
53 2008; Merikanto et al., 2009; Spracklen et al., 2010; Kerminen et al., 2012; Gordon et al., 2017).
54 Recently, the contribution of NPF to haze formation, which was still controversial, is being
55 investigated in an increasing number of studies from Chinese megacities (Guo et al., 2014; Zamora
56 et al., 2019).

57
58 Sulphuric acid (H_2SO_4), which has a very low saturation vapor pressure, has been found to be the
59 major precursor of atmospheric NPF (Weber et al., 1996; Kulmala et al., 2004; Sihto et al., 2006;
60 Sipilä et al., 2010; Erupe et al., 2011; Lehtipalo et al., 2018; Ma et al., 2019). However, atmospheric
61 measurements of gas-phase sulphuric acid are rare, mainly due to its low concentration (10^6 –
62 10^7 molecules cm^{-3} or below) that can only be measured using state-of-the art instruments (Mikkonen
63 et al., 2011) such as the Chemical Ionization atmospheric pressure interface time of flight
64 spectrometer (CI-API-ToF) (Eisele and Tanner, 1993; Jokinen et al., 2012). Therefore, a physically
65 and chemically sound proxy is needed to estimate H_2SO_4 concentrations in various environments
66 where NPF events are observed but H_2SO_4 concentrations are not continuously measured.

67
68 Due to its important participation in clustering and thus in the NPF process, several studies have tried
69 to produce proxies for H_2SO_4 in order to fill gaps in data. For example, Petäjä et al. (2009) developed
70 an approximation of gas-phase H_2SO_4 concentration in Hyytiälä, southern Finland, using its source
71 from reactions between SO_2 and OH radicals, and its loss by condensation onto pre-existing particles
72 (condensation sink, CS). Later, Mikkonen et al. (2011) developed H_2SO_4 proxies based on
73 measurements at six urban, rural and forest areas in European and North American sites. Proxies
74 developed by Mikkonen et al. (2011) suggested that the sulphuric acid concentration depends mostly
75 on the available radiation and SO_2 concentration, with little influence by CS. However, Lu et al.
76 (2019), who developed a daytime proxy based on measurement in Beijing China, proved the need of
77 taking into account the CS when approximating gaseous H_2SO_4 , especially in areas where the
78 condensational sink can be relatively high. The proxy developed by Lu et al. (2019) takes into
79 consideration the formation pathways of H_2SO_4 via OH radicals from both the conventional
80 photolysis of O_3 and from the photolysis of HONO, as well as, the loss of H_2SO_4 via CS.

81
82 Here, we derive a new proxy which takes into account the production of gaseous sulphuric acid from
83 SO_2 with oxidation by OH and stabilized Criegee Intermediates (Mauldin et al., 2012) reactions, and
84 its losses onto pre-existing aerosol particles (condensation sink) and due to molecular cluster
85 formation. In order to evaluate the accuracy of the our hypothesized sources and sinks and the
86 goodness of our new proxy, we utilize measurements from four different locations: (1) Hyytiälä,
87 Finland, (2) Agia Marina, Cyprus, (3) Budapest, Hungary and (4) Beijing, China, representing a semi-
88 pristine boreal forest environment, rural environment in the Mediterranean area, urban environment
89 and heavily polluted megacity, respectively. We further compare the coefficients of production and
90 losses in each environment in order to understand the prevailing mechanism of the H_2SO_4 budget in
91 each of the studied environments. As a result of this investigation, a well-defined sulphuric acid

92 concentration can be derived for multiple areas around the world and even extended in time during
93 times when it was not measured (such as: gap filling, forecast, prediction, estimation, etc.).

94

95 **2. Measurement locations, observations and instrumentation**

96

97 **2.1. Locations**

98 **Semi-pristine boreal forest environment: Hyytiälä, Finland**

99

100 Measurements were conducted at the SMEAR II-station, located in Hyytiälä (61.1° N, 24.17°E, 181
101 m a.s.l. (Hari and Kulmala, 2005)), southern Finland. Here we used measurements from August 18,
102 2016 to April 16, 2017 and from March 8, 2018 to February 28, 2019. The measurements were
103 performed at a tower 35 m above the ground level. A summary for all locations and instrumentation
104 is given in Table S1.

105

106 **Rural background site: Agia Marina, Cyprus**

107

108 Measurements were conducted at the Cyprus Atmospheric Observatory (CAO) (35.03° N, 33.05° E;
109 532 m a.s.l.), a rural background site located close to Agia Marina Xyliatou village, between February
110 22 and March 3, 2018. For more details, see for example Pikridas et al. (2018).

111

112 **Urban location: Budapest, Hungary**

113

114 The measurements took place at the Budapest platform for Aerosol Research Training (BpART)
115 Research Laboratory (N 47° 28' 30", E 19° 03' 45", 115 m a.s.l.) of the Eötvös University situated on
116 the bank of the Danube between March 21 and May 2, 2018. The site represents a well-mixed average
117 atmosphere of the city centre Salma et al. (2016).

118

119 **Polluted megacity: Beijing, China**

120

121 Here the observations were performed during December 1, 2018 to January 31, 2019, at the west
122 campus of Beijing University of Chemical Technology (39.94° N, 116.30° E). The sampling took
123 place from outside the window at the 5th floor of a university building adjacent to a busy street. For
124 more details, see for example Lu et al. (2019); Zhou et al. (2020).

125

126 **2.2. Instrumentation**

127

128 **Trace Gases**

129

130 A summary for all locations and instrumentation is given in Table S1. In all four locations, the
131 sulphuric acid concentrations were measured using a Chemical Ionization atmospheric pressure
132 interface time of flight spectrometer (CI-API-ToF) (Eisele and Tanner, 1993; Jokinen et al., 2012)
133 with NO₃⁻ as a reagent ion and analyzed using a tofTools package based on MATLAB software
134 (Junninen et al., 2010). In Hyytiälä and Beijing, the SO₂ and O₃ concentrations were measured using
135 an SO₂ analyzer (Model 43i, Thermo, USA), with a detection limit of 0.1 ppbv, and O₃ analyzer
136 (Model 49i, Thermo, USA), respectively. In Cyprus, SO₂ and O₃ are monitored using Ecotech
137 Instruments (9850 and 9810, respectively). Concentrations of SO₂ in Budapest were measured by UV

138 fluorescence (Ysselbach 43C) with a time resolution of 1 h at a regular station of the National Air
139 Quality Network located in 1.7 km in the upwind prevailing direction from the BpART site. It was
140 shown earlier that the hourly average SO₂ concentrations (See Figure S1) in central Budapest are
141 ordinarily distributed without larger spatial gradients (Salma and Németh, 2019).

142

143 **Particle number Size Distribution**

144

145 The condensation sink (CS) was calculated using the method proposed by Kulmala et al. (2012) from
146 number size distribution measurements. In Hyytiälä, the particle number size distribution was
147 measured using a twin differential mobility particle sizer (DMPS) (Aalto et al., 2001). Hygroscopic
148 growth correction (Laakso et al., 2004) was included when calculating the CS in Hyytiälä (Figure
149 S2). In Agia Marina, the particle number size distribution between 2 and 800 nm was reconstructed
150 from two instruments: an Airel NAIS (Neutral cluster and Air Ion Spectrometer, 2-20 nm) and TSI
151 SMPS (Scanning Mobility Particle Sizer, 20-800 nm). In Budapest, the particle number size
152 distributions were measured by a flow-switching type DMPS in a diameter range from 6 to 1000 nm
153 in the dry state of particles (RH<30%) in 30 channels with a time resolution of 8 min (Salma et al.,
154 2016b). In Beijing, the particle number size distribution between 3 nm and 850 nm was measured
155 using a Particle Size Distribution System (PSD, (Liu et al., 2016)).

156

157 **Radiation**

158

159 In Hyytiälä, Global radiation (GlobRad) was measured using a SK08 solar pyranometer until August
160 24, 2017 and after that using a EQ08-S solar pyranometer. The measurements were relocated from
161 18-m height to 37-m height on February 14, 2017. Global Radiation from the Agia Marina is
162 monitored using a weather station (Campbell Scientific Europe). In Budapest, global radiation was
163 measured by an SMP3 pyranometer (Kipp and Zonnen, The Netherlands) on the roof of the building
164 complex with a time resolution of 1 min. Its operation was checked by comparing the measured data
165 with those obtained from regular radiation measurements performed by a CMP11 pyranometer (Kipp
166 and Zonnen, The Netherlands) at the Hungarian Meteorological Service (HMS) in a distance of 10
167 km. The annual mean GlobRad ratio and SD of the 1-h values for the BpART and HMS stations were
168 1.03 ± 0.23 for GlobRad > 100 W m⁻², which changed to 1.01 ± 0.05 when considering additionally
169 clear sky conditions. In Beijing, GlobRad intensity was measured at the rooftop of the 5-floor building
170 using a Vaisala Weather station data acquisition system (AWS310, PWD22, CL51), Metcon.

171

172 **Alkenes**

173

174 Volatile organic compounds (VOCs) were measured with a proton transfer reaction quadrupole mass
175 spectrometer (PTR-MS, Ionicon Analytik GmbH) in Hyytiälä. Ambient mixing ratios are measured
176 every third hour from several different measurement heights. In this study, we use data from 16.8 m
177 height. The instrument is calibrated regularly with standard gas (Apel-Riemer Environmental, Inc.)
178 (Taipale et al., 2008).

179 In Beijing, VOCs were measured using single photon ionization time-of-flight mass spectrometer
180 (SPI-MS 3000R, Hexin Mass Spectrometry) with unit mass resolution (UMR) (Gao et al., 2013) from
181 September 27, 2018 and May 28, 2019. The alkenes included here are propylene, butylene, butadiene,
182 isoprene, pentene and hexene. As the instrument cannot distinguish conformers, the pentene and

183 hexene could also be cyclopentene and cyclohexene. Correlation coefficients between the different
184 variables used in our study in all four locations are shown in Figures S3-S7.

185

186 3. Derivation of the new proxy

187

188 We applied the following equation to describe the time-evolution of gas-phase sulphuric acid
189 concentration:

190

$$191 \frac{d[H_2SO_4]}{dt} = k_0[OH][SO_2] + k_2[O_3][Alkene][SO_2] - CS[H_2SO_4] - k_3[H_2SO_4]^2 \quad (1)$$

192

193 Here, k_0 represents the coefficient of H_2SO_4 production term due to the well-known SO_2 - OH reaction
194 (Petäjä et al., 2009) and k_2 is the coefficient of H_2SO_4 production via stabilized Criegee Intermediates
195 (sCI) produced by the ozonolysis of alkenes (Mauldin et al., 2012). Here we use available
196 monoterpene concentration (MT) as a proxy for alkenes in Hyytiälä as they are the dominating species
197 in the boreal forest environment (Hakola et al., 2012; Hellén et al., 2018; Rinne et al., 2005). For
198 Beijing, we use urban dominating aromatic alkenes. As no VOC measurements are performed in
199 neither Agia Marina nor Budapest, we evaluate the proxy without the stabilized Criegee Intermediate
200 source term. It is important to note here that the coefficient for sCI is a “bulk” term, and it varies from
201 place to place due to the differences in sCI structures and different production efficiency from
202 different alkene species (Novelli et al., 2017; Sipilä et al., 2014). The third term in Equation 1
203 represents the loss of H_2SO_4 to pre-existing aerosol particles, known as condensation sink (CS). The
204 fourth term in Equation 1 takes into account the additional loss of H_2SO_4 due to cluster formation not
205 included in the term containing CS. This is necessary because CS is only inferred from size-
206 distribution measurements at maximum down to 1.5 nm, i.e. not containing any cluster concentrations
207 and hence losses onto these clusters. This term is written in the form of sulphuric acid dimer
208 production, which seems to be the first step of cluster formation once stabilized by bases (Kulmala et
209 al., 2013; Almeida et al., 2013; Yao et al., 2018).

210

211 Since measuring the OH concentration is challenging, we first replaced it with the UVB radiation
212 intensity, which has been shown to be a good proxy for the OH concentration (Berresheim et al.,
213 2002; Lu et al., 2019; Rohrer and Berresheim, 2006). Unfortunately, UVB was not measured in all
214 the field studies considered here. Alternatively, GlobRad, a commonly measured quantity, tends to
215 correlate well with UVB and can generally replace it, as used previously by Petäjä et al. (2009). We
216 confirmed the strong correlation between UVB radiation and Global radiation in two locations,
217 Hyytiälä and Beijing (Figure S8-S9). Accordingly, the coefficient k_1 here replaces the coefficient of
218 H_2SO_4 production k_0 terms (Equation 2). We proceed here using only GlobRad in the proxy to be
219 consistent with the two other locations where UVB was not measured (Agia Marina and Budapest).

220

221

$$222 \frac{d[H_2SO_4]}{dt} = k_1 GlobRad[SO_2] + k_2[O_3][Alkene][SO_2] - CS[H_2SO_4] - k_3[H_2SO_4]^2 \quad (2)$$

223

224

225 By assuming a steady state between H_2SO_4 production and loss, the H_2SO_4 concentration can be
226 solved directly from Equation (2):

227

$$228 \quad [H_2SO_4] = -\frac{CS}{2k_3} + \sqrt{\left(\frac{CS}{2k_3}\right)^2 + \frac{[SO_2]}{k_3}(k_1GlobRad + k_2[O_3][Alkene])} \quad (3)$$

229

230 In order to evaluate the importance of each of the source terms in determining the change in sulphuric
231 acid concentration, we refitted the data after excluding the stabilized Criegee intermediates source
232 pathway as shown in Equation 4.

233

$$234 \quad \frac{d[H_2SO_4]}{dt} = k_1GlobRad[SO_2] - CS[H_2SO_4] - k_3[H_2SO_4]^2 \quad (4)$$

235

236 In order to evaluate the importance of each of the sink terms in determining the sulphuric acid
237 concentration, we refitted the data after excluding the loss of sulphuric acid via the cluster formation
238 pathway using Equation 5.

239

$$240 \quad \frac{d[H_2SO_4]}{dt} = k_1GlobRad[SO_2] + k_2[O_3][Alkene][SO_2] - CS[H_2SO_4] \quad (5)$$

241

242 we also refitted the data using the simple proxy proposed by Petäjä et al. (2009) by excluding the
243 formation of sulphuric acid via stabilized Criegee intermediates source pathway and loss of sulphuric
244 acid via the cluster formation pathway using Equation 6 and evaluated it by comparing to the original
245 proxy.

246

$$247 \quad \frac{d[H_2SO_4]}{dt} = k_1GlobRad[SO_2] - CS[H_2SO_4] \quad (6)$$

248

$$249 \quad \frac{d[H_2SO_4]}{dt} = 1.4 \times 10^7 \times GlobRad^{-0.7}[SO_2] - CS[H_2SO_4] \quad (\text{See Petäjä et al. 2009}) \quad (7)$$

250

251 The fitting coefficients were obtained by minimizing the sum of the squared logarithm of the ratio
252 between the proxy values and measured sulphuric acid concentration using the method described by
253 Lagarias et al. (1998), a build-in function *fminsearch* of MATLAB, giving the optimal values for the
254 coefficients. The data was subject to boot strapping when getting the *k* values as a measure of accuracy
255 in terms of bias, variance, confidence intervals, or prediction error (Efron and Tibshirani, 1994). The
256 median, 25th percentile and 75th percentiles of the coefficients are shown in for all locations together
257 with the median *k* values in Table 1. Figures S3-S5 present the correlation matrix between the
258 different variables participating in H₂SO₄ formation and loss in all locations. In Beijing, the Alkenes
259 (AVOCs) have different patterns in day and night which forces us to have two separate equations for
260 daytime and nighttime. The goodness of the fit and the probability of overfitting or under-fitting was
261 evaluated using the Akaike information criterion (Figure S10), which also compares the proxies given
262 in equations 2, 4, 5 and 6. The criterion uses the sample size (number of points), the number of
263 parameters (terms in the equation) and the sum of squared estimate of errors (SSE: deviations
264 predicted from actual empirical values of data) to estimate the quality of each model, relative to each
265 of the other models and thus provides means for model selection (McElreath, 2018).

266

267

268 4. Results and Discussions

269

270 4.1. The sulphuric acid proxy for Hyytiälä SMEAR II station

271

272 Figure 1 shows the scatter plot between the observed H_2SO_4 concentrations and that derived by the
273 proxy using the full Equation 2. The correlation coefficient was 0.85 (2089 data points). The data
274 were related to 3-hour medians, as the monoterpene concentration was measured only every third
275 hour. In Figure 1B-D, the proxy is refitted after removing one of the source or sink terms (Equations
276 4-6), in order to evaluate the sensitivity of the proxy to each of the terms and to show the improvement
277 of the proxy using the additional source and sink (Figure 1A) in comparison to the simple proxy that
278 was used by Petäjä et al. (2009) (Figure 1D). Our results show that the integration of additional terms
279 of H_2SO_4 formation (i.e. the stabilized Criegee Intermediates) and loss (atmospheric cluster
280 formation) gives the new proxy the ability to accurately capture the diurnal variation of the H_2SO_4
281 concentration, demonstrating a clear improvement over the earlier physical proxy (Petäjä et al., 2009).
282 In Figure 1B the corresponding data are shown without the alkene term (Equation 4). The correlation
283 is significantly weaker (0.73) than with the full equation. Even more importantly, we cannot estimate
284 the contribution of the alkene term to the sulphuric acid concentration (Figure 2 – Fit 2) as the fit
285 results also in an unphysical coefficient for cluster formation (Kürten et al., 2015) and the fit fails to
286 capture the diurnal pattern during dark hours after 16:00 (Figure 2 – Fit 2). When fitting the data
287 without the cluster source term (Equation 5), the correlation coefficient is high (Figure 1C), yet the
288 goodness of the fit is not as good as when the cluster source term is taken into account (Figure S10).
289

290 The fit was able to reproduce the sulphuric acid concentration in such clean environment without the
291 cluster term (Figure 2 – Fit 3), perhaps due to low concentrations of bases participating in clustering
292 in Hyytiälä (Jen et al., 2014). Finally, the corresponding data without both the alkene source term and
293 cluster formation source term (Equation 6, Figure 1D) shows a weaker correlation between the
294 measured and modelled sulphuric acid concentration (0.73), but more importantly, it deviates far from
295 the 1:1 line during both daytime and nighttime (Figure 2 – Fit 4). It is important to note here that
296 when deriving the Petäjä proxy (Petäjä et al. 2009), the model relied on summer data between April
297 and June 2007 which could explain the misfit with the current data from Hyytiälä which spans the
298 whole year. In general, using all four terms in equation 2 shows improvement over all other
299 combinations (Equations 4-6) in terms of not only correlation coefficients and accurate diurnal cycle
300 between measured and calculated concentrations of sulphuric acid as shown in Figures 1 and 2, but
301 also show a better goodness of the fit as shown in Figure S10 when using the AIC statistical method.
302

302

303 4.2. Sulphuric Acid Proxy at a Rural Site: Agia Marina, Cyprus

304

305 Since there were no direct measurements of alkenes in Agia Marina, we had to exclude the formation
306 of H_2SO_4 in the oxidation by sCI from the proxy, and therefore we derived only the daytime H_2SO_4
307 proxy concentration. The correlation between the measured and proxy concentration of H_2SO_4 was
308 0.88 (96 data points) which proves the truthfulness of this proxy (Figure 3). However, the slope
309 deviates from the 1-to-1 line which could be attributed to the additional formation mechanisms that
310 we could not include with the current data. However, the addition of the cluster loss mechanism shows
311 a noticeable improvement over the simple proxy, in Figure 3B ($R = 0.80$). The cluster loss term starts
312 to become more important in this rural environment in comparison to the boreal forest, which could
313 be due to a higher concentration of stabilizing bases in Agia Marina compared with Hyytiälä.

314 Although both fits, Equation 4 and 6, show similar diurnal patterns (Figure 4, Fits 2 and 4), the loss
315 term due to H_2SO_4 cluster formation improved the precision of the new proxy (Figures 3). According
316 to the statistical AIC method, the goodness of the fit has improved from 161 to 71, with and without
317 the clustering term, respectively, as shown in Figure S10. Also, even without the alkene term, the new
318 coefficients derived improved the proxy in comparison to Petäjä et al. (2009) Figure 4.

319

320 4.3. Proxy for urban environment: Budapest, Hungary

321

322 Next we try to understand the mechanisms of sulphuric acid formation and losses in an even more
323 complex environment, such as urban Budapest (Figures 5 & 6). Since there were no direct
324 measurements of alkenes there, neither its proxies such as monoterpenes or anthropogenic volatile
325 organic compounds, we derived the sulphuric acid proxy excluding the formation due to stabilized
326 Criegee Intermediate pathway, as in Equation 4. In comparison to the simple proxy (Figure 5B; $R =$
327 0.49 ; 262 data points), the correlation between the measured and proxy concentration of H_2SO_4
328 improved with the addition of the loss term due to cluster formation, $R = 0.59$ (Figure 5A). The
329 correlation between measured and modelled values of sulphuric acid became weaker in Budapest in
330 comparison to Hyytiälä and Agia Marina, which could be attributed to a more complex environment,
331 and additional pathways of sulphuric acid formation and losses. Additionally, we observed a sudden
332 SO_2 concentration change in the middle of the campaign, possibly due to sudden change in local
333 meteorology and airmass transport, which could also explain the weaker correlation (See Figure S1).
334 The loss term due to H_2SO_4 dimerization improved the precision of the new proxy in comparison to
335 the simple model as well as the Petäjä et al. (2009) derivation, as shown in Figure 6. We think that
336 the overestimation in the Petäjä proxy is because of its dependence on the SO_2/CS ratio. The proxy is
337 originally derived in Hyytiälä and when we apply the same coefficients to Budapest it gives higher
338 estimated concentration compared to the measured since SO_2/CS ratio is smaller in Budapest (Figure
339 10). It is also visible from Figures 5 and 6, that the addition of the dimerization term was capable of
340 better capturing the lower H_2SO_4 concentrations in comparison to fitting the data without the
341 dimerization term. In comparison to both Hyytiälä and Agia Marina, the coefficient associated with
342 dimerization in Budapest is slightly higher, which can be attributed to the availability of a possibly
343 facilitated clustering due to higher abundance of stabilizing bases such as amines and ammonia
344 (discussed in the later section 4.5).

345

346 4.4. Proxy for Megacity: Beijing, China

347

348 In megacities, in our case Beijing, the sulphuric acid concentration is particularly high during
349 nighttime, which confirms the need for determining the contribution of sources other than OH
350 (radiation) to its formation. Our observations emphasize the contribution of the alkene pathway, as
351 without considering this route we would not replicate morning hours correctly. During daytime, there
352 is enhanced dimerization and cluster formation due to the abundance of stabilizing bases (Yao et al.,
353 2018). In addition, alkenes or volatile organic compounds during daytime are different from those
354 during nighttime, which could be attributed to a different fleet composition during those times (Yang
355 et al., 2019). For that purpose, we had to divide the data for Beijing into two groups: daytime
356 ($\text{GlobRad} \geq 50 \text{ W/m}^2$) and nighttime ($\text{GlobRad} < 50 \text{ W/m}^2$). Besides, in such a complex environment,
357 sulphuric acid might originate from sources other than the ones we accounted for in our calculation,
358 for example through the hydrolysis of SO_3 formed from non-photochemical processes (Yao et al.,

359 2020, In Prep.). As a result, we derived two separate sets of equations, as shown in Table 1. Results
360 of a combined equation are shown in Figures S11 and S12.

361

362 In Figure 7, we see an improvement of the new proxy (Equation 2) in comparison to the simple proxy
363 (Equation 6) derived by Petäjä et al. (2009) as the former takes into the account the additional sources
364 and sinks of H_2SO_4 which were not considered in previous works (See also Figure S10). Introducing
365 the alkene production term improved the accuracy of the H_2SO_4 concentration slightly for daytime
366 and significantly during nighttime (Figures 7 and 8), which supports our assumption that H_2SO_4
367 formation during nighttime is driven by stabilized Criegee Intermediates. In Figure 7B we show the
368 proxy without the alkene term. Although the correlation improves, this is only because the nighttime
369 values are not captured. In Figure 9, we see the importance of all sources and sinks predicted for
370 sulphuric acid, as Fit 1 (Equation 2) predicts best the measured sulphuric acid concentration.
371 Additionally, according to the statistical AIC method, using the full equation has the least probability
372 of inaccuracy and error in estimating the sulphuric acid concentration (Figure S10). Moreover, it is
373 clear that the addition of the cluster sink term in Megacity environment is required due to its large
374 contribution as a sink for H_2SO_4 especially due to higher concentrations of stabilizing molecules, the
375 cluster mode (sub-3 nm) particle concentration, are the highest in Chinese Megacities (Zhou et al.,
376 2020).

377

378 4.5. Sensitivity of the proxy to the H_2SO_4 sources and sinks

379

380 The variations of coefficients related to Equation 3 can be used to get insights into the general
381 chemical behavior under current atmospheric conditions, as well as into the mechanisms of sulphuric
382 acid formation and losses in various environments. The contribution of different terms in different
383 locations seem to vary significantly. The new loss term taking into account clustering starting from
384 dimer formation needs to be taken into account in all the environments in daytime. On the other hand,
385 without alkene term it is in practice impossible to get nighttime concentrations right.

386

387 In Table 1 we have presented the fitted coefficients (Equation 3) for all our sites, whereas the
388 contributions of the different terms in the balance equation are given during daytime in Figure 9 and
389 Table 2. The variability of the coefficients (Table 1), as well as the relative contributions of each term
390 to the total sulphuric acid concentration (Table 2), could give valuable information on the mechanisms
391 resulting in sulphuric acid formation and losses. At steady state (Equation 2), the sources and sinks
392 are in balance with each other during both daytime and nighttime, but there were clear differences in
393 the individual contributions. For instance, a variation in k_1 could be due to variations in OH sources
394 and sinks. Although in urban locations OH sinks are expected to be higher and therefore k_1 to be
395 lower, additional sources of OH are available in such locations, for example HONO (Zhang et al.,
396 2019). The alkene/Criegee intermediate term was found to be an important H_2SO_4 source (Figures 1,
397 2, 7 and 8), as without it we are not able predict night or morning concentrations of H_2SO_4 properly.
398 The alkene source term contributed up to almost 100% of the H_2SO_4 sources during nighttime in
399 Beijing and up to 82% of the sources during nighttime in Hyytiälä (Table 2). The alkene term is,
400 however, not only important during nighttime but also during daytime, as it contributed to the sources
401 by a median of 41% during daytime in Beijing. It is important to note here that Criegee intermediates
402 vary between locations, they also form in different yield percentages from different alkenes (Novelli
403 et al., 2017; Sipilä et al., 2014). These stabilized Criegee intermediates also react differently under
404 different environmental conditions.

405

406 The CS term had the highest contribution to the total sink in Hyytiälä. Its contribution decreased when
407 moving towards more polluted environments (Figure 10), to become in Beijing, regardless of the
408 relatively high condensation sink in Megacities (Laakso et al., 2006; Monkkonen et al., 2005;
409 Monkkonen et al., 2004; Yao et al., 2018), smaller than that of the cluster sink term. This observation
410 might be attributed to decreased effectiveness of condensation sink in more polluted environments
411 (Kulmala et al., 2017), but also to increased contribution of the clustering sink term in such
412 environments where the concentration of stabilizing bases is highest, particularly in daytime (Yao et
413 al., 2018; Yan et al., 2018). It should be noted that measurements of ammonia and similar bases are
414 rare, so their exact contribution is difficult to estimate..

415

416 5. Conclusions and recommendations

417

418 Sulphuric acid is a key gas-phase compound linked to secondary aerosol production in the
419 atmosphere. The concentration of sulphuric acid in the gas phase is governed by source and sink
420 terms. In this paper we define the sources and sinks of H_2SO_4 and derived a physically and chemically
421 sound proxy for the sulphuric acid concentration using measurements at 4 different locations,
422 including boreal forest environment (Hyytiälä, Finland), a rural Mediterranean site (Cyprus), an urban
423 area (Budapest) and a megacity (Beijing). When describing the change in gas phase sulphuric acid
424 concentration, we took into account two source terms: 1) photochemical oxidation of sulfur dioxide
425 and 2) sulphuric acid originating from alkene and ozone reactions and associated stabilized Criegee
426 radical pathway. For the sink terms, we considered 3) the loss rate to the pre-existing aerosol described
427 by condensation sink, and 4) loss rate of sulphuric acid monomer due to clustering process.

428

429 In general, the variation in the environmental conditions and difference in concentrations of air
430 pollutants affects the coefficients derived and therefore it is important to derive location specific
431 coefficients. The derived coefficients give insights into the general chemical behavior and into the
432 mechanisms of sulphuric acid formation and losses in various environments. As improvements from
433 previously derived proxies, without the alkene H_2SO_4 formation pathway, it is in practice impossible
434 to get nighttime concentrations. On the other hand, the additional loss term taking into account
435 clustering starting from dimer formation needs to be taken into account in all the environments
436 especially those with higher cluster formation probabilities due to availability of stabilizing bases.

437

438 The coefficients derived do not differ substantially between the different locations. The proxy could
439 therefore be used at locations with no prior H_2SO_4 measurements, provided that the environmental
440 conditions are approximately similar to those in one of the four sites described here. More specifically,
441 the proxies could be utilized to derive long-term data sets for H_2SO_4 concentrations, which would be
442 essential in performing various kinds of trend analyses. In order to derive the long term sulphuric acid
443 concentrations, we recommend deriving in-house coefficients in case sulphuric acid concentrations
444 are directly measured rather than using the ones from already derived studies. The choice of equation
445 depends on the availability of the data on site. In case alkenes or their proxies are measured and
446 sulphuric acid is measured, derivation of the coefficients should be based on Equation 2. In case
447 neither alkenes nor their proxies are measured but sulphuric acid is measured, the coefficients and
448 therefore the proxy for daytime only can be derived, using Equation 4. In case, sulphuric acid is not
449 measured, one can calculate the sulphuric acid proxy using the Equation 2 or Equation 4, depending
450 on whether the alkene data is available or not, respectively, using the coefficients suggested in Table

451 1 which are relevant to the site of interest. In order to make the best choice for the coefficients, Figure
452 10 can be followed in order to decide which description fits the location of interest best. For instance,
453 in case the condensation sink is between 2×10^{-3} and $6 \times 10^{-3} \text{ s}^{-1}$, and the SO_2 concentration is lower
454 than $2 \times 10^9 \text{ molecules. cm}^{-3}$, coefficients of Hyytiälä or the boreal forest are to be used.

455

456 **Data availability**

457 The data used in the manuscript and the MATLAB code which provides the k values are available
458 from the first author at lubna.dada@helsinki.fi.

459

460 **Author contributions**

461 MK came up with the idea, LD, IY, CL, RB analyzed the data, YG, CD, RY, CY, LY, JJ, YL, BC
462 performed the measurements in Beijing and pre-processed the raw data, NS, TJ, MS, TP performed
463 the measurements in Hyytiälä and pre-processed the raw data, LD, TN, JK, KRD, DS, TH, PP, FB,
464 VMK, MK provided useful discussion and ideas, IS, TW, RB, TJ performed the measurements in
465 Budapest and pre-processed the raw data, MP, JS, RB, TJ performed the measurement in Agia Marina
466 and pre-processed the raw data. LD, VMK and MK wrote the manuscript. All co-authors contributed
467 to reviewing the manuscript and to the discussions related to it.
