16 **Abstract**

17 An online-coupled regional chemistry/aerosol-climate model (RIEMS-Chem) was developed
18 and utilized to investigate the mechanisms of haze formation and evolution and aerosol
19 radiative feedback during winter haze episodes in February-March 2014 over the Beijing-
20 Tianjin-Hebei (BTH) region in China. Model comparison against a variety of observations
21 demonstrated a good ability of RIEMS-Chem in reproducing meteorological variables, PBL
22 heights, PM_{2.5} and its chemical components, as well as aerosol optical properties. The model
23 performances were remarkably improved for both meteorology and chemistry by taking aerosol
24 radiative feedback into account. The domain average aerosol radiative effects (AREs) were
25 estimated to be -57 W m⁻² at the surface, 25 W m⁻² in the atmosphere and -32 W m⁻² at the top
26 of atmosphere (TOA), respectively, during a severe haze episode (20–26 February), with the
27 maximum hourly surface ARE reaching -384 W m⁻² in southern Hebei province. The average
28 feedback-induced changes in 2-m air temperature (T2), 10-m wind speed (WS10), 2-m relative
29 humidity (RH2) and planetary boundary layer (PBL) height over the BTH region during the
30 haze episode were -1.8 °C, -0.5 m s⁻¹, 10.0% and -184 m, respectively. The BTH average

31 changes in $PM_{2.5}$ concentration due to the feedback were estimated to be $20.0 \mu\text{g m}^{-3}$ (29%)
32 and $45.1 \mu\text{g m}^{-3}$ (39%) for the entire period and the severe haze episode, respectively, which
33 demonstrated a significant impact of aerosol radiative feedback on haze formation. The relative
34 changes in secondary aerosols were larger than those in primary aerosols due to enhanced
35 chemical reactions by aerosol feedback. The feedback-induced absolute change in $PM_{2.5}$
36 concentrations was largest in haze persistence stage, followed by those in growth stage and
37 dissipating stage. Process analyses on haze events in Beijing revealed that local emission,
38 chemical reaction and regional transport mainly contributed to haze formation in the growth
39 stage, whereas vertical processes (diffusion, advection and dry deposition) were major
40 processes for $PM_{2.5}$ removals. Chemical processes and local emissions dominated the increase
41 in $PM_{2.5}$ concentrations during the severe haze episode, whereas horizontal advection
42 contributed to the $PM_{2.5}$ increase with a similar magnitude to local emissions and chemical
43 processes during a moderate haze episode on 1–4 March. The contributions from physical and
44 chemical processes to the feedback-induced changes in $PM_{2.5}$ and its major components were
45 explored and quantified through process analyses. For the severe haze episode, the increase in
46 the change rate of $PM_{2.5}$ ($9.5 \mu\text{g m}^{-3} \text{h}^{-1}$) induced by the feedback in the growth stage was
47 attributed to the larger contribution from chemical processes ($7.3 \mu\text{g m}^{-3} \text{h}^{-1}$) than that from
48 physical processes ($2.2 \mu\text{g m}^{-3} \text{h}^{-1}$), whereas, during the moderate haze episode, the increase in
49 the $PM_{2.5}$ change rate ($2.4 \mu\text{g m}^{-3} \text{h}^{-1}$) in the growth stage was contributed more significantly
50 by physical processes ($1.4 \mu\text{g m}^{-3} \text{h}^{-1}$) than by chemical processes ($1.0 \mu\text{g m}^{-3} \text{h}^{-1}$). In general,
51 the aerosol-radiation feedback increased the accumulation rate of aerosols in the growth stage
52 through weakening vertical diffusion, promoting chemical reactions, and/or enhancing
53 horizontal advection. It enhanced the removal rate through increasing vertical diffusion and
54 vertical advection in the dissipation stage, and had little effect on the change rate of $PM_{2.5}$ in
55 the persistence stage.

56

57 **1 Introduction**

58 Aerosols affect radiation transfer by scattering or absorbing solar and infrared radiation,
59 by acting as cloud condensation nuclei (CCN) to modify cloud properties, and by heating the

60 atmosphere to alter cloud formation, termed as the aerosol direct radiative effect, indirect effect,
61 and semi-direct effect (Twomey, 1974; Albrecht, 1989; Ramanathan et al., 2001), respectively.
62 In addition, there exists a set of interactions between chemistry, radiation and meteorology
63 (Dawson et al., 2007; Zhang, 2008; Isaksen et al., 2009; Baklanov et al., 2014; Cai et al., 2017),
64 which is highly complex and nonlinear and is currently one of the least understood mechanisms
65 in atmospheric science community. The above interactions are traditionally not included or
66 simplified in meteorological or chemical models, but have now been considered and treated
67 with different degrees of complexity in a few online coupled models along with the advances
68 in our knowledge and computer power, and the coupling of meteorology and chemistry and its
69 feedbacks remains one of the most challenging issues in air quality and climate change (Zhang,
70 2008; Baklanov et al., 2014).

71 Rapid and continuous growth of economy and energy consumption in the past decades has
72 greatly elevated aerosol levels in China (Chan and Yao, 2008; Zhang et al., 2012; Li et al.,
73 2017a), resulting in serious air pollution problem and potentially significant influence on
74 radiation and climate at multi-scales. Although emission control strategies have been gradually
75 implemented in recent years, haze events still often occur in east China, especially in the BTH
76 region in wintertime due to both higher anthropogenic emissions and poorer meteorological
77 conditions. The haze issue has attracted wide attentions from public, government and scientific
78 community in China and a lot of monitoring and modeling studies have been carried out to
79 explore the sources, characteristics, formation and evolution mechanisms of haze events at both
80 urban and regional scales (Chan and Yao, 2008; Zhang et al., 2012; Che et al., 2014; Guo et al.,
81 2014; Huang et al., 2014; Sun et al., 2014; Zheng et al., 2015; Cheng et al., 2016; Ding et al.,
82 2016; Li and Han, 2016a; Cai et al., 2017; Fu and Chen, 2017; Li et al., 2017b; Wang et al.,
83 2017; Huang et al., 2018; Zhang et al., 2018a; Zhong et al., 2018a; Zhong et al., 2018b; An et
84 al., 2019; Li et al., 2019a), through which our understanding on haze issue has been promoted.
85 However, there is still a large gap in our knowledge about haze formation mechanism, in
86 particular the role of aerosol-radiation-meteorology feedback in haze formation and evolution
87 (Fu and Chen, 2017; Zhong et al., 2018a; An et al., 2019).

88 The aerosol radiative feedbacks on air quality and meteorology have ever been studied in
89 American and Europe with regional online coupled meteorology-chemistry models, such as

90 WRF-Chem (Zhang et al., 2010; Forkel et al., 2012), which demonstrates an important role of
91 the feedback in both air quality and meteorology. Carslaw et al. (2010) also pointed out the
92 complexity and significance of natural aerosol interactions and feedbacks within the Earth
93 system.

94 In east Asia, Han et al. (2013) revealed a significant feedback of mineral dust on dust
95 deflation and transport, atmospheric dynamics, cloud and precipitation in spring and an
96 improvement of model prediction for PM (particulate matter) concentration and surface
97 meteorology by the inclusion of the feedback effect into an online coupled chemistry-aerosol-
98 climate model. In recent years, given the increasing concerns on severe PM pollution during
99 haze days, some modeling studies have been conducted to investigate the effect of aerosol
100 radiative feedback on meteorology and near surface PM_{2.5} concentration, with focus on winter
101 haze events in north China (Wang et al., 2014a; Wang et al., 2014b; Zhang et al., 2015; Gao et
102 al., 2015; Gao et al., 2016; Qiu et al., 2017; Zhao et al., 2017; Zhang et al., 2018b; Chen et al.,
103 2019; Wu et al., 2019). Most of the model results exhibited a positive feedback which tended
104 to increase PM_{2.5} level, but the magnitude of such feedback differs largely, with the mean
105 fractional change in PM_{2.5} concentration varying from just a few percentage (Kajino et al., 2017;
106 Wu et al., 2019) to around 30% (Wang et al., 2014a). Some studies even show a negative
107 feedback on PM_{2.5} in Beijing (Zhang et al., 2015; Gao et al., 2016). Recently, Gao et al. (2020)
108 reported that the aerosol–radiation feedback-induced daytime changes in PM_{2.5} concentrations
109 were less than 6% during haze days in the BTH region in January 2010 from six applications
110 of different online coupled meteorology-chemistry models under the international framework
111 of the MICS-Asia (Model Inter Comparison Study for Asia) Phase III. There existed some
112 differences in the above modeling studies in terms of study period and haze level, although
113 they were all for winter haze events in the BTH region. Zhong et al. (2018a) reported that over
114 70% of PM_{2.5} increase during cumulative explosive stage of haze event in Beijing in winter
115 can be attributed to the feedback effect based on integrated analysis of observations. The above
116 studies highlight the importance and large uncertainties in the aerosol radiative feedback, which
117 require further model development and investigation.

118 The diversity in the feedback effect among models could be associated with the differences
119 in the predictions of aerosol chemical components and aerosol optical properties, the

120 assumption of mixing state and hygroscopic growth scheme, as well as meteorological fields,
121 all of which determine the direction and magnitude of the feedback effect. Majority of previous
122 model studies underpredicted PM concentrations in the north China Plain, especially for
123 aerosol components, such as sulfate, nitrate and SOA concentrations, mainly due to incomplete
124 understanding and unrealistic treatment of secondary aerosol formation through multi-phase
125 chemical processes. Gao et al., (2018) reported that most of the participating models (including
126 WRF-Chem) in the MICS-Asia (Model Inter Comparison Study for Asia) project
127 underpredicted inorganic and organic aerosol concentrations by up to a factor of three. Besides
128 aerosol mass concentration, the unrealistic representation of aerosol properties, such as
129 composition, size distribution, mixing state, hygroscopic growth would also lead to model
130 biases in aerosol optical properties and direct radiative effects. The low biases in the predicted
131 aerosol compositions may lead to underpredictions of aerosol optical depth (AOD) and
132 consequently of aerosol radiative effects and feedback. Che et al. (2014) reported a reduction
133 of solar radiation by aerosols exceeding 200 W m^{-2} during a severe haze event in the north
134 China Plain, much stronger than the estimations from models (around -100 W m^{-2}). Therefore,
135 a realistic treatment and an accurate representation of aerosol processes and properties are
136 crucial to the estimation of aerosol radiative effects and feedback.

137 It has been well recognized that high aerosol loadings can apparently reduce incoming
138 solar radiation at the surface, leading to surface cooling and inversion associated with reduced
139 wind speed and vertical diffusivity, and consequently increase in surface aerosol concentrations.
140 However, while we have gained considerable knowledge on the overall feedback effect of
141 aerosols, the detailed processes involved in the feedback mechanism are still poorly understood
142 and barely quantified, for example, how does the aerosol radiative effect modify meteorological
143 variables? how do the radiative and meteorological changes affect physical and chemical
144 processes and in turn affect the magnitude and distribution of aerosol components? how to
145 quantify the relative contributions from various physical and chemical processes to the
146 feedback effect?

147 In this study, an online coupled regional climate-chemistry-aerosol model (RIEMS-Chem)
148 was developed and applied to explore the formation and evolution of haze events during
149 February-March 2014, in which a week-long haze episode with the daily maximum $\text{PM}_{2.5}$

150 concentration up to $400 \mu\text{g m}^{-3}$ (hourly mean up to $483 \mu\text{g m}^{-3}$) was observed. A wide variety
151 of field measurements of aerosol chemical components, optical properties, as well as
152 meteorological variables were conducted and applied to develop, constrain and validate the
153 model. The mechanisms of haze formation and evolution, aerosol radiative effects and
154 feedback on meteorology and chemistry were investigated and assessed. The overall aerosol
155 feedback on $\text{PM}_{2.5}$ and its aerosol compositions and the individual contributions to the feedback
156 from physical and chemical processes (advection, diffusion, deposition, chemistry, etc.) during
157 haze events were interpreted and quantified by a process analysis approach incorporated in the
158 model. The results from this study are expected to provide new insights into the mechanism of
159 aerosol-radiation-meteorology feedback, which is currently the source of one of the largest
160 uncertainties in haze formation and evolution.

161

162 **2 Model and Data**

163 2.1 Model description

164 An online-coupled regional atmospheric chemistry/aerosol-climate model RIEMS-Chem
165 was used in this study, which was developed based on the Regional Integrated Environmental
166 Model System (RIEMS) (Fu et al., 2005; Wang et al., 2015). A series of modules and
167 parameterizations were adopted to represent major physical processes, including a modified
168 Biosphere-Atmosphere Transfer Scheme (BATS; Dickinson et al., 1993) to simulate land
169 surface process, the Medium-Range Forecasts scheme (MRF) to represent the planetary
170 boundary layer process (Hong and Pan, 1996), the cumulus convective parameterization
171 scheme from Grell (1993), and a modified radiation package of the NCAR Community Climate
172 Model, version CCM3 (Kiehl et al., 1996) to represent radiation transfer process including
173 aerosol effect. RIEMS had been applied to investigate East Asian monsoon climate and the
174 interactions among physical, biological and chemical processes (Xiong et al., 2009; Zhao, 2013;
175 Wang et al., 2015). RIEMS had participated in the Regional Climate Model Intercomparison
176 Project (RMIP) for Asia and it was one of the best models in predicting air temperature and
177 precipitation over east Asia (Fu et al., 2005).

178 The online-coupled model RIEMS-Chem has been developed in recent years by

179 incorporating major atmospheric chemistry/aerosol processes into the host model. Transport of
180 pollutants are driven by meteorological fields from RIEMS and changes of pollutants exert
181 feedbacks on the existing dynamic and physical modules (Han, 2010; Han et al., 2012). Major
182 atmospheric processes including emission, advection, diffusion, multi-phase chemistry, dry
183 deposition and wet scavenging of pollutants are considered. The advection and diffusion for
184 pollutants are treated with the same scheme for substances (such as moisture). Gas phase
185 chemistry is represented by an updated Carbon-bond mechanism (CB-IV; Gery et al., 1989).
186 The aerosol effect on photolysis rate is considered by using the Tropospheric Ultraviolet-
187 Visible (TUV) radiation model (Lee-Taylor and Madronich, 2007). Thermodynamic processes
188 are calculated by the ISORROPIA II model (Fountoukis and Nenes, 2007). Dry deposition
189 velocity of aerosol is calculated by a size-dependent scheme which is expressed as the inverse
190 of the sum of resistance plus a gravitational settling term, while below-cloud wet scavenging
191 of aerosol is parameterized as a function of precipitation rate and collision efficiency of particle
192 by hydrometeor (Han et al., 2004). Heterogeneous reactions between gases and mineral dust
193 and sea salt aerosols have also been incorporated into RIEMS-Chem (Li and Han, 2010; Li et
194 al., 2018a). SOA formation is parameterized by a two-product model (Odum et al., 1997).

195 Current atmospheric chemistry models generally tend to underpredict sulfate
196 concentrations, especially in source regions during wintertime, such as north China, which
197 could be due to uncertainties in the treatment of chemical formation mechanism. Recent model
198 studies suggested that heterogeneous reactions could be an important pathway in sulfate
199 formation during winter haze episodes in north China (Li et al., 2017c; Li et al., 2018b).
200 Therefore, heterogeneous reactions concerning the conversion of SO₂ to sulfate on pre-existed
201 hydrated aerosols were incorporated in RIEMS-Chem. The method of Li et al. (2018b) was
202 adopted, in which the uptake coefficient (γ_{SO_2}) was a stepwise function determined by the
203 aerosol liquid water content (ALWC) which was predicted by the ISORROPIA II model.
204 Accordingly, the upper bound of ALWC was set to 300 $\mu\text{g m}^{-3}$ ($\gamma_{\text{SO}_2}=1\times 10^{-4}$) while the lower
205 bound was 30 $\mu\text{g m}^{-3}$ ($\gamma_{\text{SO}_2}=1\times 10^{-6}$). γ_{SO_2} was linearly interpolated between the upper and lower
206 bounds in terms of ALWC.

207 RIEMS-Chem treats 9 aerosol types including sulfate, nitrate, ammonium, black carbon
208 (BC), primary organic aerosol (POA), secondary organic aerosol (SOA), anthropogenic

209 primary PMs (PM_{2.5} and PM₁₀), dust and sea salt. The size distribution of the different types of
 210 aerosols is previously prescribed based on the OPAC database (Optical Properties of Aerosols
 211 and Clouds) (Hess et al., 1998). In this study, measurements in Beijing are used to represent
 212 aerosol size distribution more realistically and to constrain the model. During the study period,
 213 a scanning mobility particle sizer (SMPS; TSI, Inc., Shoreview, MN, USA) was used to
 214 measure aerosol size distribution (Ma et al., 2017) and the geometric mean radius of inorganic,
 215 black carbon and organic carbon aerosols were estimated to be 0.1 μm, 0.05 μm and 0.1 μm,
 216 with standard deviations of 1.65, 1.6, 1.65, respectively. The above aerosol size information
 217 was incorporated into RIEMS-Chem. The deflation of mineral dust is represented by the
 218 scheme of Han et al. (2004) with 5 size bins (0.1–1.0, 1.0–2.0, 2.0–4.0, 4.0–8.0, 8.0–20.0 μm).
 219 Primary PMs from anthropogenic are also assigned to the 5 size bins.

220 Recent observational analyses of aerosol mixing state in Beijing (Ma et al., 2012; Wu et
 221 al., 2016) indicated that more than 80% aerosols were internally mixed with BC during haze
 222 days, whereas about 70% of aerosols were externally mixed with BC in clean days, so an
 223 internal mixing assumption was adopted for model simulation because this study focuses on
 224 haze events. Recent measurements also exhibited that the geometric mean radius of dry aerosol
 225 internal mixture during haze evolution from light-moderate to severe pollution stages just
 226 increased slightly from 0.10 μm to 0.12 μm (Ma et al., 2017), so an average of 0.11 μm is
 227 chosen for the geometric mean radius of internal mixture, with standard deviation of 1.65.

228 Aerosol optical parameters including extinction coefficient, single scattering albedo and
 229 asymmetry factor were calculated by a Mie-theory based method developed by Ghan and
 230 Zaveri (2007). In this method, the optical properties of different types of aerosols are pre-
 231 calculated by Mie theory and fitted by Chebyshev polynomials, which are functions of aerosol
 232 geometric mean diameter and refractive index:

$$233 \quad Q = \exp \left[\sum_{k=1}^{10} A_k T_k(x) \right], \quad (1)$$

$$234 \quad x = \frac{2 \log(D_p) - \log(D_{\min}) - \log(D_{\max})}{\log(D_{\max}) - \log(D_{\min})}, \quad (2)$$

235 where Q represents the aerosol optical properties (such as scattering efficiency). T_k(x) are the
 236 Chebyshev polynomial of order k, which is related to particle size, A_k are the Chebyshev

237 coefficients which is related to refractive index, D_p is the geometric mean diameter, D_{\min} and
 238 D_{\max} are the minimum and maximum D_p for obtaining the Chebyshev polynomials, with values
 239 of 0.001 μm and 10 μm , respectively. It has been proved that 40 groups of D_p in the range from
 240 D_{\min} and D_{\max} are sufficient to control errors below 10% compared with classical Mie code
 241 calculation.

242 The effect of water uptake is treated by the κ -Köhler parameterization (Petters and
 243 Kreidenweis, 2007), which calculates aerosol wet diameter due to hygroscopic growth under
 244 different relative humidity. The bulk κ for internal mixture of aerosols is derived by the
 245 volume-weighted average of κ of each aerosol component, while the κ values for inorganic
 246 aerosols, BC, POA, SOA, dust and sea salt were set to 0.65, 0, 0.1, 0.2, 0.01 and 0.98,
 247 respectively, according to previous observational and modeling studies (Riemer et al., 2010;
 248 Liu et al., 2010a; Westervelt et al., 2012):

$$249 \quad \kappa = \sum_j \frac{V_j}{V_a} \kappa_j, \quad (3)$$

250 where V_a is the total volume of dry aerosols, V_j is the volume of each aerosol component j .

251 The refractive index of internally mixed aerosols is calculated using the Maxwell-Garnett
 252 mixing rule:

$$253 \quad R_w^2 = R_s^2 \left[\frac{R_i^2 + 2R_s^2 + 2f_i(R_i^2 - R_s^2)}{R_i^2 + 2R_s^2 - f_i(R_i^2 - R_s^2)} \right], \quad (4)$$

$$254 \quad f_i = \frac{V_i}{V}, \quad (5)$$

255 where R_w is the refractive index of the internal mixture, R_i and R_s are the refractive index
 256 of insoluble components (BC and POA) and soluble components (inorganic aerosols, SOA and
 257 water), respectively. V_i represents the volume of insoluble components, V represents the total
 258 volume of wetted aerosols.

259 After obtaining the wet diameter (D_p) and refractive index of the internally mixed aerosols
 260 (R_w), the aerosol optical properties (Q) can be derived from formula (1) with the Chebyshev
 261 fitting coefficients table. Then, aerosol optical parameters, such as extinction coefficient can
 262 be obtained through multiplying Q by aerosol mass concentration from chemical module. The
 263 advantage of this optical module is the computational speed is much faster than that from the

264 traditional Mie calculation, with a similar level of accuracy. This module has been successfully
265 used in estimations of aerosol optical properties and direct radiative effects over East Asia (Han
266 et al., 2011a; Li and Han, 2016b; Li et al., 2019b).

267 An empirical method from Hegg (1994) is applied to link cloud droplet number
268 concentration N_c to mass concentration of hydrophilic aerosols (sulfate, nitrate, hydrophilic BC
269 and OC) to represent the first indirect effect, while the parameterization of Beheng (1994) is
270 used to represent the second indirect effect, in which the autoconversion rate converting from
271 cloud water to rain water depends on N_c and cloud liquid water content W_L . The cloud effective
272 radius r_e is calculated based on N_c , W_L and the cube of the ratio of the mean volume radius and
273 the effective radius of the cloud-droplet spectrum following Martin et al. (1994). The effect of
274 aerosols on ice nuclei and convective cloud is not treated yet in this model because of the
275 complexity and limitation in knowledge.

276 The aerosol optical parameters and N_c due to aerosol activation calculated above are
277 transferred into radiation module to account for the perturbation of radiation and atmospheric
278 heating rate due to aerosol direct and indirect effects. The subsequently called land surface
279 module and boundary layer module calculate the changes in land-air fluxes of heat and
280 moisture, turbulent diffusion coefficients and meteorological variables in the boundary layer in
281 response to the radiation change, and then air temperature tendency is calculated in terms of
282 the altered atmospheric heating rate and radiation, which further leads to changes in
283 meteorological variables, and in turn affect physical and chemical processes and concentrations
284 of aerosols and their precursors represented in the chemical module. All the physical modules
285 are called every 2.5 minutes and the transfer of variables between chemical module and
286 radiation/meteorological modules is made every 30 minutes.

287 RIEMS-Chem has been successfully applied in previous modeling studies of
288 anthropogenic aerosols, mineral dust and marine aerosols regarding spatial-temporal
289 distributions, physical and chemical evolutions, radiative and climatic effects over east Asia
290 (Han et al., 2011b; 2012; 2013; 2019; Li et al., 2014; Li and Han, 2016b; 2016c; Li et al.,
291 2019b). RIEMS-Chem has been participating in the international model comparison project
292 Model Inter Comparison Study for Asia phase III (MICS-Asia III) and shows a good ability in
293 predicting $PM_{2.5}$ concentration and AOD over East Asia (Gao et al., 2018).

294

295 2.2 Process analysis

296 In RIEMS-Chem, a time-splitting scheme based on continuity equation is applied to predict
297 species concentrations; therefore, the species concentrations are the net results of successive
298 changes in emissions, dynamic transport, physical and chemical processes and the changes in
299 species concentration by each process can be recorded, allowing the quantification of
300 individual contribution of each process to species variation. In this study, a process analysis
301 (PA) scheme, which calculates the Integrated Process Rates (IPR) at each time step and each
302 grid, was embedded in RIEMS-Chem to identify the contributions of physical and chemical
303 processes to aerosol evolution. At each time step, the IPR for a certain process was calculated
304 by subtracting the species concentrations at the beginning of this process from the ones after
305 the process. The IPR method has ever been applied to study the formation and fate of particulate
306 and gaseous pollutants in North America and China (e.g. Yu et al., 2008; Zhang et al., 2009;
307 Liu et al., 2010b). The processes involved in aerosol evolution include emissions of primary
308 species, advections (horizontal and vertical), diffusions (horizontal and vertical), dry deposition,
309 chemical processes (gas-phase chemistry, aqueous chemistry, thermodynamic equilibrium and
310 heterogeneous reactions), cloud processes and wet deposition. Here cloud process represents
311 the effects of cloud attenuation of photolysis rate, aqueous-phase chemistry and in-cloud
312 mixing. In this study, PA is applied not only to quantify the contributions of individual physical
313 and chemical processes to haze evolution, but also to help interpret the processes involved in
314 aerosol radiative feedback. In addition, different from the previous PA application, chemical
315 processes are further classified into gas phase, thermodynamic and heterogeneous reactions to
316 provide more details on chemical pathways of secondary aerosol formation. The mass balance
317 of IPR has been examined, assuring that the change in species concentration during one time
318 step is equal to the sum of IPRs by each of the processes.

319

320 2.3 Emission inventories

321 Monthly mean anthropogenic emissions of sulfur dioxide (SO₂), nitrogen (NO_x), ammonia
322 (NH₃), non-methane volatile organic compounds (NMVOC), carbon monoxide (CO), black
323 carbon (BC), primary organic carbon (POA), other anthropogenic primary PM_{2.5} and primary

324 PM₁₀ in China for the year 2014 were obtained from the MEIC inventory (Multi-resolution
325 Emission Inventory for China) which was developed by Tsinghua University
326 (<http://meicmodel.org>). Anthropogenic emissions outside China were taken from the MIX
327 inventory which was developed to support the Model Inter-Comparison Study for Asia phase
328 III (MICS-Asia III) and the Hemispheric Transport of Air Pollution (HTAP) projects (Li et al.,
329 2017a). Both inventories of MEIC and MIX have the horizontal resolution of 0.25 degree.
330 Biomass burning emissions of aerosols and gas precursors for the year 2014 with a horizontal
331 resolution of 0.25 degree were derived from the fourth version of the Global Fire Emissions
332 Database (GFED4) (Giglio et al., 2013). Monthly mean biogenic emissions of isoprene and
333 monoterpene were derived from Global Emissions Inventory Activity (GEIA,
334 <http://www.geiacenter.org/>). The above emission data were bilinearly interpolated to the
335 lambert projection of RIEMS-Chem.

336

337 2.4 Model configuration and numerical experiments

338 RIEMS-Chem was configured on a lambert conformal projection with horizontal
339 resolution of 60 km, covering most areas of China, the Korean Peninsula, Japan and part of the
340 Indo-China Peninsula (Figure 1). 16 vertical layers distributed vertically and unevenly in the
341 terrain-following sigma coordinate, with the lowest 8 layers within the boundary layer. This
342 study focused on the Beijing-Tianjin-Hebei (BTH) region with more attentions to the Beijing
343 metropolitan. The study period was from 10 February to 12 March, 2014, encountering several
344 haze episodes. The first 7 days were taken as model spin-up and the results from 17 February
345 to 12 March were used for analysis.

346 Initial and boundary conditions for meteorological variables were provided by the final
347 reanalysis data (FNL) with 1°×1° resolution and 6-hourly interval from the National Centers
348 for Environmental Prediction (NOAA/NCEP, 2000). Lateral boundary conditions of chemical
349 species at 6-hourly interval were derived from the simulations of the global chemical model
350 MOZART-4 (Model for Ozone and Related chemical Tracers, version 4; Emmons et al., 2010).

351 To investigate the aerosol radiative effects and its potential feedback on solar radiation,
352 meteorological variables, planetary boundary layer (PBL) and aerosol concentrations in the
353 study domain, two simulations were designed. The FULL simulation (with aerosols)

354 considered all aerosol direct and indirect effects and feedbacks, and the NoAFB simulation
355 shuts off aerosol direct radiative effects and removes anthropogenic aerosols in aerosol indirect
356 effects. In both simulations, the driving meteorological data, emissions and model settings were
357 exactly the same.

358

359 2.5 Observational data

360 Several observational datasets for meteorological variables, aerosol concentrations and
361 aerosol optical parameters were obtained and used for model comparison and analysis.

362 In-situ 3-hourly observations of temperature at 2 meter (T2), wind speed at 10 meter
363 (WS10) and relative humidity at 2 meter (RH2) from three meteorological monitoring sites
364 around Beijing (Figure 1) were collected from the China Meteorological Data Service Center
365 (CMDS) (<http://data.cma.cn/>).

366 To evaluate the model ability in reproducing evolution of planetary boundary layer (PBL),
367 high-frequency sounding data measured around 14:00 LST at the Xianghe station (39°45'N,
368 116°58'E; approximately 63 km southeast of Beijing downtown) were collected, from which
369 the PBL height can be determined based on the vertical gradients of virtual potential
370 temperature and water mixing ratio according to the method from Heo et al. (2003). This
371 sounding dataset provided a good indicator of mixing layer height because the sounding was
372 launched at 14:00 LST and lasts for about one hour. The meteorological sounding was launched
373 in Xianghe once a week (every Tuesday) and totally four soundings were available during the
374 study period (18 and 25 February, 4 and 11 March). Fortunately, the four soundings
375 encountered one severe haze episode, one moderate haze episode, and two clean days,
376 providing robust evidences on day-to-day variation of mixing layer height under various
377 atmospheric conditions. Hourly downward shortwave radiation flux (SWDOWN) at the
378 surface was measured simultaneously at the Xianghe station by a pyranometer with sun shield
379 and was used in this study.

380 The measurements of mass concentrations of PM_{2.5} and its components and aerosol optical
381 parameters were carried out at the tower division of the Institute of Atmospheric Physics (IAP),
382 Chinese Academy of Sciences (CAS) in Beijing (39°58'N, 116°22'E) from 17 February to 12
383 March, 2014. Real-time hourly PM_{2.5} mass concentrations were online measured by a hybrid

384 beta attenuation particulate monitor (Model 5030 SHARP, Thermo Scientific, USA). PM_{2.5}
385 samples were collected in parallel by an R&P Partisol® Model 2025 dichotomous sequential
386 PM air sampler (Thermo, USA) and a MiniVol TAS PM sampler (Airmetrics, USA) between
387 24 February and 12 March, 2014. Samples were collected twice per day with one during the
388 daytime (from 7:00 to 19:00 LST) and the other at night (from 19:00 to 7:00 of the next day).
389 Totally 33 half-day samples were collected. Aerosol chemical compositions including sulfate
390 (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺), BC and OC were analyzed by ion chromatography
391 (Dionex ICS-90 for cations and ICS-1500 for anions) and a DRI-2100A carbonaceous aerosol
392 analyzer. Real-time hourly aerosol extinction coefficient and aerosol absorption coefficient at
393 dry condition (RH=10%) were synchronously measured by a nephelometer (Aurora3000) and
394 an aethalometer (AE-31), respectively. Detailed information about this experiment including
395 the sampling site, instruments, measurement procedures and sample analysis were well
396 documented in Ma et al. (2017). The mass concentration of SOC was estimated using a revised
397 EC tracer method (Zhao et al., 2013).

398 Measurements of AOD at the 4 sites (Nanjiao, Tianjin, Gucheng and Shangdianzi) in the
399 BTH region were obtained from the China Aerosol Remote Sensing Network (CARSNET)
400 (Che et al., 2014). Nanjiao is an urban site located in southern Beijing. Tianjin site is located
401 in the center of Tianjin city, about 120 km to the southeast of Beijing. Gucheng, a suburban site
402 in Hebei province, is about 130 km to the southwest of Beijing downtown. Shangdianzi is
403 located 150 km to the northeast of Beijing, which is a background station since it is far away
404 from anthropogenic sources. Daily mean AOD was derived by temporally averaging the raw
405 data measured by sunphotometer during daytime. To compare with the model output, AOD at
406 550 nm was used.

407

408 **3 Model validations**

409 3.1 Meteorological variables

410 Wind speed, temperature and relative humidity are key meteorological factors affecting
411 physical and chemical processes of atmospheric pollutants. The statistics for comparison
412 between in-situ observation and the FULL simulation for WS10, T2 and RH2 are presented in

413 Table 1. At the 3 sites (Beijing, Tianjin and Tanggu), the model performances were reasonably
414 good, although wind speeds were somewhat overpredicted. The overall correlation coefficient
415 (R) and normalized mean bias (NMB) at the 3 sites were 0.83 and -2% for T2, 0.61 and -1%
416 for RH2 and 0.47 and 31% for WS10. In all, RIEMS-Chem was able to reasonably reproduce
417 the meteorological variables during the study period. The statistics for NoAFB simulation are
418 also list in Table 1. It is noteworthy that the statistics for the FULL simulation are overall better
419 than those for NoAFB simulation, such as the warm bias in the simulated air temperature and
420 positive bias in wind speed are apparently reduced. This demonstrates the inclusion of aerosol
421 radiative effects does improve meteorological prediction in this study.

422 The observed hourly SWDOWN in Xianghe was compared with model simulation (Figure
423 2a). In general, the FULL case well reproduced SWDOWN in clean days and light-moderate
424 polluted days, but tended to underpredict observations in heavy haze days, such as the period
425 from 20 to 26 February. Underpredictions of cloud amount and PM concentrations could be
426 reasons for the low bias. For the entire study period, the observed and simulated (FULL) mean
427 SWDOWN were 136.0 W m^{-2} and 188.4 W m^{-2} , respectively, with R of 0.91 (Figure 2a). If
428 only days with low cloud covers were considered, the SWDOWNS were 183.3 W m^{-2} and 213.7
429 W m^{-2} from observation and the FULL case, respectively, with the NMB of 16%. In contrast,
430 the NoAFB case failed to capture the decreasing tendency of SWDOWN during haze days,
431 resulting in a larger bias (NMB of 72%) than the FULL case.

432 To examine the model performance for meteorology in the vertical direction, we collected
433 meteorological sounding data at Beijing observatory from the website of University of
434 Wyoming (<http://weather.uwyo.edu/upperair/sounding.html>). Figure S1 and S2 present the
435 average observed and simulated vertical profiles of air temperature, wind speed and relative
436 humidity at 08:00 LST and 20:00 LST during the two haze episodes of 20-26 February and 1-
437 4 March 2014 and the corresponding comparison statistics for these variables in the troposphere
438 and at altitudes below 3 km are listed in Tables S1 and S2. In general, the model is able to
439 generally capture the major features of vertical distribution of key meteorological variables,
440 although the model tends to predict higher relative humidity in the middle-upper troposphere.
441 Such overpredictions are also found for the same region in previous studies, such as WRF-
442 Chem simulation (Gao et al., 2016). The statistics indicate that the model simulated vertical

443 distribution of meteorological variables are within an acceptable accuracy range of current
444 meteorological model predictions.

445

446 3.2 Planetary boundary layer (PBL) height

447 Figure 2b shows the simulated PBL heights at 14:00 LST from the FULL case and NoAFB
448 case during the study period and the observed PBL heights at 14:00 LST determined from air
449 soundings on 18 February (clean), 25 February (severe haze), 4 March (clean) and 11 March
450 (haze), 2014, respectively. There was large variation in PBL height in the afternoon, with higher
451 PBL height in clean days and lower one in haze days, inversely related to the PM_{2.5} level. The
452 FULL case well reproduced the very low PBL height during the most severe haze episode on
453 25 February, with the observed and simulated PBL heights to be 569 m and 587 m, respectively.
454 In clean days, the much higher mixing layer was also well captured, such as, on 4 March, the
455 observed and simulated PBL heights were 2305 m and 2535 m, respectively. It is noteworthy
456 that the simulated PBL heights in the NoAFB case were consistently higher than those in the
457 FULL case, and the PBL height simulation from the FULL case (considering aerosol radiative
458 effects) was apparently in a better agreement with observation than that from the NoAFB case,
459 except for that on 18 February.

460

461 3.3 Mass concentrations of PM_{2.5} and aerosol components

462 Figure 2c shows the hourly PM_{2.5} mass concentrations observed at the IAP site and those
463 from the FULL simulation and NoAFB simulation. The study period was characterized by three
464 haze episodes, which was the episode 1 on 20–26 February, the episode 2 from 1 to 4 March,
465 and the episode 3 from 8 to 11 March. The first episode experienced the most severe pollution
466 with the maximum hourly PM_{2.5} concentration exceeding 480 $\mu\text{g m}^{-3}$ on 25 February. The
467 second and third ones were moderately polluted in terms of magnitude and lasting time. In
468 general, the model reproduced the hourly variation of PM_{2.5} concentrations reasonably well in
469 the FULL case, although the peaks were somewhat underpredicted in some days, which could
470 be partly due to the overprediction of wind speed (Table 1) and potential uncertainties in
471 emission inventories. The low bias in PM_{2.5} concentrations could also contribute to the
472 overprediction of SWDOWN during the first haze episode (20-26 February) discussed in

473 section 3.1. The average PM_{2.5} concentrations during the study period were 142.0 $\mu\text{g m}^{-3}$ and
474 131.4 $\mu\text{g m}^{-3}$ from observation and the FULL simulation, respectively, with R of 0.8 and NMB
475 of -7% (Table 2), which demonstrates a good model performance for PM_{2.5} predictions for the
476 winter haze periods. A remarkable feature shown in Figure 2 is the significant negative
477 correlation between PM_{2.5} concentration and PBL height and SWDOWN.

478 The comparison between the simulated daily mean surface aerosol components (sulfate
479 (SO_4^{2-}), nitrate (NO_3^-), ammonium (NH_4^+), BC and OC) and observations at the IAP site are
480 presented in Figure 3. The daily mean observation in the figure is an average of the half-day
481 samples, while the original half-day samples are used for statistics calculation in Table 2. The
482 model (from the FULL case) generally exhibits a good performance for inorganic aerosol
483 (sulfate, nitrate and ammonium) concentrations in terms of both daily variation and magnitude
484 (Figure 3a - 3c). It is encouraging that the maximum values on 25 February during the first
485 haze episode and the moderate values on 3 March in the second haze episode are well
486 reproduced, although some low biases occurred in the last few days. On average, the model
487 simulations of 20.3 $\mu\text{g m}^{-3}$, 24.3 $\mu\text{g m}^{-3}$ and 13.9 $\mu\text{g m}^{-3}$ are very close to the observations of
488 21.0 $\mu\text{g m}^{-3}$, 26.0 $\mu\text{g m}^{-3}$ and 14.1 $\mu\text{g m}^{-3}$ for sulfate, nitrate and ammonium, respectively, with
489 Rs of 0.92, 0.88 and 0.91 and NMBs of -4%, -6% and -2%, respectively (Table 2). Most of the
490 online coupled models tended to underpredicted sulfate concentration (Gao et al., 2016; Qiu et
491 al., 2017; Gao et al., 2018), which led to an underestimation of aerosol optical depth and
492 radiative effect. The model in this study improves the simulation of inorganic aerosols, mainly
493 through the inclusion of heterogeneous chemical reactions for inorganic aerosols.

494 The model also reproduced the temporal variation and magnitude of BC (Figure 3d) and
495 OC (Figure 3e) concentrations in Beijing reasonably well. However, the model tended to
496 underpredict the peak OC values on 24–25 February and to overpredict BC concentrations from
497 late February to early March. The low bias in OC simulation during the haze episodes could be
498 attributed to the underprediction of SOC (Figure 3f) due to potentially missing chemical
499 pathways. Uncertainties in the emission inventory could also be a reason. Li et al., (2017a)
500 reported the uncertainties in BC and OC emissions for China could be $\pm 200\%$, larger than those
501 of emissions for gases ($< 70\%$) and primary PMs ($\sim 130\%$). The period mean BC concentrations
502 from observation and simulation were 5.2 $\mu\text{g m}^{-3}$ and 6.7 $\mu\text{g m}^{-3}$, respectively, with R of 0.92

503 and NMB of 28% (Table 2). The period mean simulated and observed POC concentrations
504 were $18.4 \mu\text{g m}^{-3}$ and $15.5 \mu\text{g m}^{-3}$, respectively, with R of 0.93, whereas the simulated SOC
505 concentration was $9.9 \mu\text{g m}^{-3}$, lower than observation ($13.6 \mu\text{g m}^{-3}$) by 27%, with a correlation
506 coefficient of 0.56. For OC (sum of POC and SOC), the simulated value ($28.3 \mu\text{g m}^{-3}$) was very
507 close to the observation ($29.1 \mu\text{g m}^{-3}$), with R of 0.88 and NMB of -3%, respectively, which
508 indicated a generally good model performance for the total OC concentration.

509 It is noteworthy that by considering aerosol radiative effects, the model apparently
510 improved simulations for both $\text{PM}_{2.5}$ and its chemical compositions, which is illustrated by
511 comparing model results between the FULL and NoAFB cases (Figure 2c, Figure 3 and Table
512 2). Another important finding is that the duration of haze episode was prolonged by about 2–3
513 hours by the aerosol radiative feedback compared with that without aerosol feedback (Figure
514 2c).

515 To evaluate the overall model performance on $\text{PM}_{2.5}$ and its gas precursors in the BTH
516 region, we also collected observations at 80 surface stations in 13 cities of the BTH from the
517 website of CNEMC (China National Environmental Monitoring Center)
518 (<http://www.cnemc.cn/>) and made a detailed comparison between observations and model
519 simulations for $\text{PM}_{2.5}$, O_3 , NO_2 and SO_2 . The observed and simulated hourly mass
520 concentrations of these species in the typical cities are presented in Figure S3 - S8 and the
521 statistics for each city and for all the cities are presented in Table S3. The overall model ability
522 is generally satisfactory, with Rs of 0.87, 0.81, 0.60 and 0.74, NMBs of -0.4%, -11%, -17% and
523 0.5% for $\text{PM}_{2.5}$, O_3 , SO_2 and NO_2 , respectively, for all the sites in the BTH region.

524

525 3.4 Aerosol optical parameters

526 Figure 4a and 4b show the measured and simulated hourly aerosol extinction coefficient
527 (EXT) and aerosol absorption coefficient (ABS) at an RH of 10% at the IAP site during the
528 study period. It clearly showed that the model was able to well reproduce the magnitudes and
529 temporal variations of EXT and ABS under dry condition in the FULL case, although the model
530 tended to predict higher ABS in some days possibly due to the overprediction of BC
531 concentration. Single scattering albedo (SSA) which is defined as the ratio of scattering
532 coefficient (EXT minus ABS) to extinction coefficient is also given in Figure 4c. The FULL

533 case generally simulated high SSA values during haze episodes, such as 0.92 on 20–26
534 February, 0.85–0.9 from 1 to 4 March and 0.8–0.9 on 8–11 March, suggesting a dominant role
535 of light scattering aerosols in haze days. It is encouraging that the model reproduced SSA
536 during the severe haze episode (on 20–26 February) quite well, with both the simulation and
537 observation being approximately 0.92. However, SSA observation in clean days (such as on 5–
538 7 March) was lower than that in haze days, and the model tended to overpredict SSA in clean
539 days, which could be attributed to uncertainties in measurement. In clean days, both the
540 denominator (EXT) and numerator (EXT minus ABS) were small, a subtle perturbation in EXT
541 and/or ABS can result in a large variation in SSA. A previous observational study in Beijing
542 suggested that SSA observation was more uncertain in clean days than in polluted days because
543 the observed aerosol extinction coefficient was too low in clean days (Jing et al., 2015). On
544 average, the observed EXT, ABS and SSA values were 0.51 km^{-1} , 0.048 km^{-1} and 0.85,
545 respectively, whereas, the corresponding FULL simulations were 0.53 km^{-1} , 0.052 km^{-1} and
546 0.88, with Rs of 0.8, 0.7 and 0.7 and NMBs of 4%, 10% and 5%, respectively (Table 2). The
547 above comparison demonstrates a good ability of the model in estimating aerosol optical
548 properties during the study period, which could be attributed to both the good performance for
549 aerosol compositions and the realistic representation of aerosol properties (aerosol size
550 distribution, mixing state, hygroscopic growth etc.), which is based on real-time measurements
551 in Beijing.

552 Besides EXT and ABS measured under dry condition, measurements of AOD at the four
553 CARSNET sites around Beijing (Nanjiao, Tianjin, Gucheng and Shangdianzi) were also used
554 to evaluate the model ability in simulating aerosol optical parameters in real atmosphere
555 (Figure 5). At the Nanjiao site, which is about 50km southeast of Beijing downtown (Figure
556 5a), AOD measurement was unavailable in most days during the first haze episode (20 to 26
557 February), with only two data (around 4.8) available on 25 February. The simulated daily AOD
558 from the FULL case varied from 3.1 to 4.0 during 24 - 26 February, somewhat lower than the
559 observation. The model tended to simulate lower AOD during the third haze episode (8 to 11
560 March), which can be partly attributed to the predicted lower aerosol concentrations. The
561 measured AODs in Gucheng (southwest to Beijing) and Tianjin were similar in terms of
562 variation and magnitude (Figures 5b and 5c), showing high values during pollution periods

563 with the maximum daily AOD exceeding 4.0 in Gucheng and 3.5 in Tianjin. The FULL case
564 reproduced the AOD variations and magnitudes reasonably well at the two sites although low
565 biases still occurred during 8 to 11 March in Gucheng. For the regional background site
566 Shangdianzi (Figure 5d), the magnitude and variation of AOD were similar to those in Nanjiao,
567 suggesting that the haze episodes were regionally distributed because the temporal variations
568 and magnitudes of AOD were generally consistent at the four sites.

569 Table 3 summaries the performance statistics for daily mean AOD. In general, the model
570 reproduced the temporal variation and magnitude of AOD around Beijing reasonably well with
571 the overall R of 0.81 (0.67–0.90) and NMB of -8.6% (-15.6%–6.2%). The underestimation is
572 mainly contributed by the low biases during the third haze episode (8 to 11 March) when
573 inorganic aerosol concentrations were underestimated (Figure 3a–3c). In addition, the
574 limitation in AOD samples during the severe haze episode in Nanjiao and Shangdianzi could
575 amplify the negative bias. At the Gucheng and Tianjin sites where more samples were available,
576 the mean measured AODs were 1.7 and 1.4, respectively, agreeing well with the simulated
577 values of 1.5 and 1.3 from the FULL case.

578 In summary, the above comparisons demonstrate that RIEMS-Chem was capable in
579 reproducing the spatial distribution and temporal variation of meteorological variables (air
580 temperature, wind speed, surface shortwave radiation, PBL height etc.), concentrations of total
581 PM_{2.5} mass and its chemical compositions and aerosol optical properties during the winter haze
582 periods around Beijing. It is also noteworthy that the inclusion of aerosol radiative effects
583 apparently improved the overall model performance for both meteorological variables and
584 aerosol physical and chemical properties, highlighting the necessity to develop online coupled
585 chemistry-meteorology model for both air quality and climate research. The good agreement
586 above increases confidence in the reliability of the following model results on aerosol radiative
587 effects and feedback.

588

589 **4 Aerosol radiative effects and feedbacks**

590 4.1 Distributions of meteorological variables and near surface PM_{2.5} concentration

591 The period-mean distributions of near-surface wind speed (WS10), temperature (T2),

592 relative humidity (RH2), PBL height and PM_{2.5} concentration are shown in Figures 6a to 6e.
593 During the study period, westerly winds dominated the northwestern parts of the BTH region
594 while southeasterly prevailed over the southeastern parts, as a result, the near-surface wind
595 speeds were fairly weak over the convergence zone from southern Hebei province to Beijing
596 (Figure 6c). Such wind pattern indicated that pollutants from southern parts of the domain (such
597 as Shandong and Henan provinces) can be transported northward to Beijing, Tianjin and Hebei,
598 and air pollutants over the weak-wind regions were easily accumulated to high level. Near-
599 surface temperature showed an apparent south-to-north gradient, with surface air temperature
600 in a range of 4 °C to 6 °C over the southern BTH region, -2 °C to 2 °C in the vicinity of Beijing
601 and parts of central Hebei, and lower than -2 °C in northern parts of the domain (Figure 6a).
602 Relative humidity was higher (~65% to 75%) over northern areas and lower (~55% to 65%)
603 over southern areas (Figure 6b). PBL height also exhibited an apparent gradient in spatial
604 distribution (Figure 6d), ranging from 800-1000 m in northern Hebei and Inner Mongolia to
605 about 600-700 m in southern Beijing, Tianjin and southern Hebei. A belt of high PM_{2.5}
606 concentration spread from southwest to northeast (Figure 6e), with the maximum value up to
607 150 µg m⁻³ in the vicinity of Shijiazhuang and Beijing and Tianjin. The regions with high PM_{2.5}
608 concentrations generally corresponded well to the weak-wind areas shown in Figure 6c.

609 Averaged over the BTH region and the entire study period, the simulated T2, WS10, RH2,
610 PBL height and PM_{2.5} concentration from the FULL case were 0.61 °C, 1.2 m s⁻¹, 67.0%, 698.4
611 m and 90.0 µg m⁻³, respectively. According to the “Technical Regulation on Ambient Air
612 Quality Index” prescribed by Chinese Ministry of Environmental Protection in 2012, a
613 pollution event occurs when 24-hr mean PM_{2.5} concentration ≥ 75 µg m⁻³. Totally, there were
614 11 days with domain and daily average PM_{2.5} concentration exceeding 75 µg m⁻³ in the BTH
615 region, with the maximum exceeding 136 µg m⁻³, indicating the severity of air pollution during
616 the study period.

617

618 4.2 Distributions of AOD, SSA and aerosol radiative effects

619 Figure 6f shows that high AODs mainly distributed from northern Beijing to southwestern
620 Hebei, southern Shanxi and northern Henan provinces, with the maximum up to 1.1. As AOD
621 was determined by vertical profiles of aerosol compositions and RH, the spatial distribution of

622 AOD was somewhat different from that of PM_{2.5} concentration. During the study period, the
623 regional mean AOD in the BTH region was 0.78 (Table 4), about twice the long-term observed
624 value of about 0.4 in February and March in the same region (Song et al., 2018).

625 The simulated SSAs were above 0.88 in the BTH region (Figure 6g), with relatively lower
626 values (0.88 - 0.9) in the areas of high PM_{2.5} concentration and higher ones (0.92 - 0.98) in the
627 relatively clean areas. On average, the simulated SSA in the BTH was 0.91 (Table 4), within
628 the range of 0.87 to 0.95 measured in the same region in January 2013 (Che et al., 2014) but
629 slightly lower than the model simulated annual mean of 0.95 over eastern China (Zhuang et al.,
630 2013).

631 All-sky aerosol radiative effects at the surface (ARE_{surf}), at the top of atmosphere (ARE_{TOA})
632 and in the atmosphere (ARE_{atm}) under all-sky condition are presented in Figures 6h to 6j.
633 During the study period, aerosols induced a negative ARE both at the surface and TOA and a
634 positive ARE in the atmosphere over the BTH. The distribution of ARE resembles that of AOD,
635 generally showing stronger effects over southwestern Hebei, Shanxi and northern Henan
636 provinces where high AOD occurred. Moderate AREs appeared over Beijing, Tianjin and
637 central Hebei, while relatively weak AREs appeared over the northern domain. The domain
638 average AREs in the BTH region during the period were estimated to be -37 W m⁻², 19 W m⁻²
639 and -18 W m⁻² at the surface, in the atmosphere and at the TOA, respectively (Table 4). The
640 indirect radiative effect was also estimated to be about -2 W m⁻² at the surface and the TOA on
641 average, much smaller than the direct radiative effect; therefore, the total aerosol radiative
642 feedback is predominated by direct radiative effect during the study period.

643 The domain average all-sky AREs during the first haze episode (20-26 February) were -57
644 W m⁻², 25 W m⁻² and -32 W m⁻² at the surface, in the atmosphere and at the TOA, respectively,
645 and the values were further enhanced to -123 W m⁻², 53 W m⁻² and -70 W m⁻² in terms of
646 daytime mean. The maximum AREs at the surface and at TOA reached -384 W m⁻² and -231
647 W m⁻², respectively, at 13:00 LST on 23 February in the vicinity of Shijiazhuang.

648 In Beijing, the estimated mean AREs were -70 W m⁻², 32 W m⁻² and -38 W m⁻² at the
649 surface, in the atmosphere and at the TOA, respectively, during the first haze episode, whereas
650 the maximum ARE at the surface reached -304 W m⁻² at 13:00 LST on 22 February, which was
651 associated with the high PM_{2.5} concentration (453 μg m⁻³) at that time.

652 Based on in-situ surface measurements, Che et al. (2014) estimated that during haze
653 periods in January 2013, the mean daytime AREs at Nanjiao and Xianghe were approximately
654 -42 W m^{-2} and -50 W m^{-2} at TOA, and -120 W m^{-2} at the surface at both sites. In this study, the
655 daytime AREs averaged over the severe haze period (20–26 February) at TOA were estimated
656 to be -77 W m^{-2} and -74 W m^{-2} at Nanjiao and Xianghe, while the corresponding AREs at the
657 surface were -146 W m^{-2} and -140 W m^{-2} , respectively. Che et al. (2014) also reported the
658 maximum daily mean surface ARE of -220 W m^{-2} at Nanjiao during a severe haze episode in
659 January 2013, in this study, the corresponding ARE was estimated to be approximately -200 W
660 m^{-2} at the same site during the severe haze episode in February 2014. Therefore, the magnitudes
661 of AREs during haze episodes simulated from this study agreed favorably with the above
662 observational based estimations around Beijing, despite the different time period.

663

664 4.3 The feedback effects on meteorological variables and aerosols

665 Figure 7a–7e shows the mean differences in T2, RH2, wind speed, PBL height and near
666 surface $\text{PM}_{2.5}$ concentration induced by the radiative feedback due to all aerosols (FULL minus
667 NoAFB) in the domain during the study period.

668 The aerosol radiative effects led to a reduction in surface shortwave radiation and thus
669 surface air temperature in the entire domain. The magnitude of T2 variation decreased from
670 south to north of the BTH, with $-1.6 \text{ }^\circ\text{C}$ to $-2 \text{ }^\circ\text{C}$ in southern Hebei and $-1.2 \text{ }^\circ\text{C}$ to $-1.8 \text{ }^\circ\text{C}$ in
671 southern Beijing, respectively. Correspondingly, RH2 increased by 10%-16% in the above
672 regions. The changes in wind speed showed a patchy pattern, with decreases by $\sim 0.1 \text{ m s}^{-1}$ in
673 southern Hebei, increases by $\sim 0.2 \text{ m s}^{-1}$ in central Hebei, and decreases in most parts of Beijing.
674 Wind vector shows an anomalous northerly wind of $\sim 0.5 \text{ m s}^{-1}$ in the BTH region. Due to the
675 reduction in surface shortwave radiation, PBL height decreased over the entire region, with the
676 maximums up to 240 m in southern Hebei and northern Tianjin. The changes in PBL height
677 varied from -210 m in southern Beijing to -90m in northern Beijing. $\text{PM}_{2.5}$ concentrations were
678 consistently enhanced over the entire region, with the maximum increase up to $33 \text{ } \mu\text{g m}^{-3}$ in
679 southern Hebei and portions of Beijing and Tianjin. In most of the BTH region, the percentage
680 increase of $\text{PM}_{2.5}$ exceeded 25%, with the maximum increase exceeding 33% in the vicinity of
681 Shijiazhuang. It is of interest that the regions with the maximum increase of $\text{PM}_{2.5}$ generally

682 corresponded to those with the maximum decrease in PBL height. The presence of aerosols
683 reduced solar radiation reaching the ground surface, resulting in decreases in surface air
684 temperature and PBL height and an increase in relative humidity, all of which favored
685 accumulation and formation of aerosols due to weakened vertical mixing and enhanced
686 secondary aerosol formation.

687 The aerosol feedback during the first haze episode was further explored due to the much
688 higher PM_{2.5} level than the period average. Figure 7f–7j show the mean changes in
689 meteorological variables and PM_{2.5} concentrations during the first haze episode (20–26
690 February). In general, the changes induced by aerosol feedback were larger during the severe
691 haze episode than those over the entire study period. T₂ decreased by 1.8 °C to 2.7 °C along
692 with an increase up to 20% in RH in southern Hebei and southern parts of Beijing and Tianjin.
693 Different from the entire period average, wind speed decreased consistently in the BTH, with
694 a maximum decrease of 1 m s⁻¹. PBL height decreased by ~300 m in southern Hebei,
695 corresponding to the areas with large air temperature decrease. This resulted in a consistent
696 increase in PM_{2.5} concentrations in the study domain, with the maximum increases exceeding
697 50% around Shijiazhuang and approximately 40% in Beijing and Tianjin, apparently higher
698 than the entire period averages. If for daytime mean, the percentage changes of PM_{2.5} in the
699 above areas increased to 70% and 60%, respectively (figure not shown). It is striking that the
700 simulated maximum increase in hourly PM_{2.5} concentration can be up to 372 µg/m³ (186%) in
701 the vicinity of Shijiazhuang at about 10:00 LST on 24 February during the first haze episode,
702 which demonstrates the substantial impact of the radiative feedback on PM_{2.5} concentration
703 and haze formation.

704 It is worthwhile to further explore the effect of aerosol feedback during haze evolution.
705 We divided haze episode into three stages, the growth stage is defined as the time period of
706 PM_{2.5} increase from clean condition to heavy pollution level, the persistence stage means the
707 duration period of haze and the dissipation stage means the period with a sharp decrease in
708 PM_{2.5} concentration usually along with a cold front passage. During the first heavy haze
709 episode (20–26 February) in Beijing, aerosol radiative feedback caused the increases in PM_{2.5}
710 concentration of 55 µg m⁻³, 84 µg m⁻³ and 40 µg m⁻³, with the fractional changes of 31%, 41%
711 and 67%, respectively, during the growth, persistence and dissipation stages. The larger

712 fractional change of $PM_{2.5}$ in the dissipation stage is due to the relatively large feedback-
713 induced increase and the lowest $PM_{2.5}$ concentration in the NoAFB case in this stage. During
714 the second haze episode (1–4 March), the increases in $PM_{2.5}$ concentration due to aerosol
715 feedback were $25 \mu\text{g m}^{-3}$, $45 \mu\text{g m}^{-3}$ and $24 \mu\text{g m}^{-3}$, with the fractional changes of 21%, 35%
716 and 34%, respectively, which are lower than the feedback effect during the first haze episode.
717 So, in terms of magnitude, the largest feedback effect on $PM_{2.5}$ occurred in the persistence stage,
718 followed by that in the growth stage, although the fractional change of $PM_{2.5}$ was larger in the
719 dissipation stage.

720 Table 5 summarized the average feedback-induced changes in meteorological variables
721 and $PM_{2.5}$ concentrations over the BTH region during the entire and the first haze periods.
722 During the study period, due to the radiative feedback by all aerosols (FULL minus NoAFB),
723 surface air temperature and wind speed decreased by $1.4 \text{ }^\circ\text{C}$ and 0.04 m s^{-1} , respectively, with
724 RH increased by 8.7% in the BTH. PBL height was reduced by 160 m (or a percentage change
725 of -18.6%) on average, along with a reduction of $3.3 \text{ m}^2 \text{ s}^{-1}$ (-27.0%) in vertical diffusivity
726 coefficient (K_z), resulting in an increase of $PM_{2.5}$ level by $20.0 \mu\text{g m}^{-3}$ (28.6%). It is noticed
727 that the above changes were strengthened during the severe haze episode on 20–26 February,
728 with the 7-day average decreases in T2, WS10, PBL height and K_z being up to $-1.8 \text{ }^\circ\text{C}$, -0.5 m
729 s^{-1} , -183.6 m (-31.0%) and $3.9 \text{ m}^2 \text{ s}^{-1}$ (-48.8%), respectively, and the $PM_{2.5}$ concentration
730 increased by $45.1 \mu\text{g m}^{-3}$ with a percentage increase of 38.7%. Because aerosols affect solar
731 radiation in daytime, in term of daytime mean, the 7-day mean changes in T2, WS10 and PBL
732 height were estimated to be $-2.5 \text{ }^\circ\text{C}$, -0.6 m s^{-1} and -307.3 m (-37.6%), respectively, leading to
733 an increase of $49.3 \mu\text{g m}^{-3}$ (48.5%) in $PM_{2.5}$ concentration.

734 The impact of aerosol radiative feedback in Beijing (Table 6) was stronger than the
735 regional mean. During the first haze episode, the 7-day average changes in T2, WS10, RH2,
736 PBL and $PM_{2.5}$ were estimated to be $-2.1 \text{ }^\circ\text{C}$, -0.6 m s^{-1} , 17.0%, -195.6 m (-35.9%) and $68.0 \mu\text{g}$
737 m^{-3} (39.1%), respectively, and the daytime mean change in $PM_{2.5}$ concentration increased to
738 $83.2 \mu\text{g m}^{-3}$ (60%), respectively.

739 Table 7 presents the average changes in major aerosol components (BC, sulfate and nitrate)
740 in $PM_{2.5}$ induced by the feedback effect. Over the BTH region, the feedback caused the average
741 increases in sulfate and nitrate by $5.0 \mu\text{g m}^{-3}$ (46.4%) and $6.8 \mu\text{g m}^{-3}$ (37.3%), respectively, for

742 the entire period, and by up to $12.6 \mu\text{g m}^{-3}$ (66.9%) and $14.6 \mu\text{g m}^{-3}$ (40.9%), for the first haze
743 episode. The feedback-induced increases in BC was $0.9 \mu\text{g m}^{-3}$ (25.1%) and $1.9 \mu\text{g m}^{-3}$ (32.9%),
744 respectively, for the entire period and the first haze episode. It was noticed that the feedback-
745 induced changes in sulfate and nitrate concentrations were larger than that in BC concentration.
746 This was because that the concentrations of secondary aerosols were increased not only by
747 weakened vertical diffusivity but also by enhanced chemical reactions due to the radiative
748 feedback, which will be discussed in detail in section 5.2.

749 The above analysis demonstrates a significant impact of aerosol feedback on $\text{PM}_{2.5}$
750 concentration during winter haze episodes in the BTH region. Previous modeling studies
751 reported different degrees of aerosol radiative feedback in east China. Gao et al. (2015)
752 simulated an increase of near surface $\text{PM}_{2.5}$ concentrations to be 10-50 $\mu\text{g m}^{-3}$ or 5-25% in the
753 BTH during a severe haze episode on 10-15 January 2013 by using WRF-Chem. For the similar
754 time period and region, Wang et al. (2014a) reported an increase in $\text{PM}_{2.5}$ concentrations by
755 15-50 $\mu\text{g m}^{-3}$ or 10-30% by using a regional coupled model NAQPMS. Wu et al. (2019) used
756 WRF-Chem to investigate a haze episode from 5 December 2015 to 4 January 2016 in the
757 North China Plain and found that the aerosol radiative effects can enhance near-surface $\text{PM}_{2.5}$
758 concentration by $10.2 \mu\text{g m}^{-3}$ (7.8%) on average.

759 The results from this study demonstrate a stronger aerosol-radiation feedback than
760 previous modeling studies, with an average increase in $\text{PM}_{2.5}$ concentration by up to $45.1 \mu\text{g m}^{-3}$
761 m^{-3} (38.7%) during a severe haze episode and further to $49.3 \mu\text{g m}^{-3}$ (48.5%) for daytime mean
762 over the BTH region. This study also highlights that the aerosol feedback effect can result in
763 an increase of hourly $\text{PM}_{2.5}$ concentrations by up to $372 \mu\text{g m}^{-3}$ (186%) in the vicinity of
764 Shijiazhuang during the severe haze episode. The stronger feedback effect in this study than
765 previous model simulations is mainly due the predicted higher concentration of aerosol
766 components (especially inorganic aerosols) and aerosol optical properties, which are also in a
767 better agreement with observations. It is noticed that a recent study (Zhong et al., 2018a)
768 reported that the aerosol feedback effect contributed over 70% to $\text{PM}_{2.5}$ increase during the
769 cumulative explosive stage of haze event in winter Beijing based on integrated analysis of
770 observations from 2013 to 2016, which suggested a dominant role of the feedback effect in
771 haze formation.

772

773 **5 Process analysis of haze evolution and aerosol radiative feedback**

774 The process analysis (PA) method calculates the Integrated Process Rates (IPRs) and is
775 applied to quantify the individual contributions of different physical and chemical processes to
776 variations of PM_{2.5} and its chemical components. These processes include emission, horizontal
777 and vertical advections (HADV and VADV), horizontal and vertical diffusions (HDIF and
778 VDIF), dry deposition (DDEP), cloud (CLD, including aqueous chemistry and wet scavenging),
779 gas chemistry (GAS), thermodynamic chemistry (Thermo) and heterogeneous chemistry
780 (HET). The focus of this study is Beijing, so the model grid cell near the surface having Beijing
781 is selected for analysis.

782

783 5.1 The mechanism of haze evolution related to various processes

784 5.1.1 Haze evolution during 20–26 February

785 There was a severe haze event lasting for about 7 days, with the maximum hourly PM_{2.5}
786 up to 482 $\mu\text{g m}^{-3}$ on 26 February. This haze was initially formed on 20 February, with the
787 observed surface PM_{2.5} concentration less than 50 $\mu\text{g m}^{-3}$ on 19 February, rapidly increased to
788 343 $\mu\text{g m}^{-3}$ on 20 February, and reached 482 $\mu\text{g m}^{-3}$, followed by rapid haze dissipation on 26
789 February due to the arrival of a cold front.

790 PA was used to provide insights into the evolution mechanism of the haze episode, which
791 was divided into the clean, growth, persistence and dissipation stages in this study. Figure 8
792 shows the average process budgets for changes in PM_{2.5} (which is the sum of sulfate, nitrate,
793 ammonium, BC, OC, SOC and primary PM_{2.5}) and its major components in Beijing during the
794 four stages of the first haze period (Figure 8) from the FULL simulation. Figure 8a shows the
795 hourly IPRs of PM_{2.5} by physical and chemical processes. The emission of primary aerosols
796 was the largest contributor to the PM_{2.5} mass with a constant IPR of 29.8 $\mu\text{g m}^{-3} \text{ h}^{-1}$ (not shown
797 in Figure 8a for clarity) due to the use of a monthly based emission inventory. Chemical
798 processes (GAS, Thermo and HET) also contributed largely to PM_{2.5}, with generally larger
799 contributions in the growth and persistence stages. Thermodynamic equilibrium processes and
800 gas chemistry accounted for over 2/3 of the chemical contributions, with the former process

801 mainly accounting for the formation of nitrate and ammonium and the latter one for sulfate
802 formation. The contribution from heterogeneous reactions was generally small, but when
803 conditions were favorable (such as high RH and high aerosol concentration providing sufficient
804 reaction surfaces), its contribution would also be significant, such as on the morning of 22
805 February, at nighttime from 23 to 24 February, and on the mornings of 25 and 26 February.
806 Vertical diffusion and dry deposition consistently removed $PM_{2.5}$ from the atmosphere. In
807 general, the larger IPRs from both VDIF and DDEP during the clean and dissipation stages
808 resulted in lower $PM_{2.5}$ concentrations, whereas the lower IPRs from VDIF and DDEP in the
809 growth stage favored aerosol accumulation. In the persistence stage, the IPRs of VDIF and
810 DDEP were generally small. It should be noted that on every midday, when PBL was fully
811 developed, the vertical diffusion reached the daily maximum, producing distinctly large
812 negative IPRs of VDIF. Advections (HADV and VADV) and horizontal diffusion either
813 contributed to the accumulation or loss of $PM_{2.5}$. During this severe haze episode, horizontal
814 diffusion served as a sink of $PM_{2.5}$, producing a negative IPR of HDIF through the event.
815 Horizontal advection served as a sink of $PM_{2.5}$ in most of the time, leading to a negative IPR
816 of HADV, however, when the removal of $PM_{2.5}$ by vertical diffusion was strong at the midday,
817 aerosols were advected to Beijing from surrounding areas due to mass balance, resulting in a
818 positive IPR of HADV. The positive IPR of VADV during the growth and persistence stages of
819 this event indicated that the downward transport of aerosols from upper levels also contributed
820 to the $PM_{2.5}$ increase, such as on the mornings of 22 and 25 February. In general, the IPRs
821 (represented the net effect of all processes, denoted by the red line in Figure 8a) exhibited small
822 positive values from evening to next morning on every day, indicating a gradually increasing
823 $PM_{2.5}$ concentration, whereas on every midday, relatively large negative IPRs occurred,
824 indicating an apparent decrease in $PM_{2.5}$ concentration at that time. It should be mentioned that
825 even in the persistence stage, the diurnal variation of $PM_{2.5}$ occurred although the change rates
826 were generally weaker than those in the growth and dissipation stages.

827 Figure 8b to 8f show the mean IPRs for $PM_{2.5}$ and its major chemical components as well
828 as the key meteorological variables averaged over each stage to help interpret the formation
829 and evolution mechanism of this severe haze episode.

830 In the clean stage, emission and chemistry were the two major processes for $PM_{2.5}$

831 production (Figure 8b). Emission contributed predominately to PM_{2.5} production (IPRs of 29.8
832 $\mu\text{g m}^{-3} \text{ h}^{-1}$), whereas the contributions of gas ($9.2 \mu\text{g m}^{-3} \text{ h}^{-1}$) and thermodynamic chemistry
833 ($7.3 \mu\text{g m}^{-3} \text{ h}^{-1}$) were comparable. The most influential process for PM_{2.5} removal was vertical
834 diffusion, with the IPRs of $-30.3 \mu\text{g m}^{-3} \text{ h}^{-1}$, comparable to that of emission. Dry deposition was
835 the second most important process for PM_{2.5} loss ($-12.2 \mu\text{g m}^{-3} \text{ h}^{-1}$), followed by horizontal
836 diffusion. Advection had a negligible effect on PM_{2.5} in this stage. In the growth stage, it is
837 noteworthy that the contributions from vertical diffusion (VDIF) and dry deposition (DDEP)
838 to PM_{2.5} removal decreased markedly from $-30.3 \mu\text{g m}^{-3} \text{ h}^{-1}$ and $-12.2 \mu\text{g m}^{-3} \text{ h}^{-1}$ in the clean
839 stage to $-21.6 \mu\text{g m}^{-3} \text{ h}^{-1}$ and $-9.2 \mu\text{g m}^{-3} \text{ h}^{-1}$, respectively (Figure 8b), mainly due to the decrease
840 in wind speed and the increase in stability indicated by the reduced vertical diffusivity
841 coefficient K_z (Figure 8f), leading to increases in concentrations of all species. It is impressive
842 that the contributions from chemical processes (GAS+Thermo+HET) increased apparently
843 compared with those in the clean stage, with the IPRs from gas, thermodynamic and
844 heterogeneous chemistry increase to $12.1 \mu\text{g m}^{-3} \text{ h}^{-1}$, $16.0 \mu\text{g m}^{-3} \text{ h}^{-1}$ and $5.4 \mu\text{g m}^{-3} \text{ h}^{-1}$,
845 respectively. The increase in the contribution from heterogeneous chemistry was mainly
846 attributed to the increase in relative humidity and aerosol surfaces, upon which heterogeneous
847 reactions took place. It is noticed that the contribution of thermodynamic chemistry increased
848 with increasing relative humidity as well along with haze formation (Figure 8f). The increase
849 in the contribution of thermodynamic chemistry was remarkable (with IPR from 7.3 to $16 \mu\text{g}$
850 $\text{m}^{-3} \text{ h}^{-1}$), because gas precursors of aerosols increased due to weakened vertical diffusivity and
851 higher relative humidity during haze period favored condensation from gas to aerosol phase. It
852 is of interest that vertical advection also contributed to PM_{2.5} production (IPR of $5.4 \mu\text{g m}^{-3} \text{ h}^{-1}$)
853 in this stage, which indicated a potential downward import of PM_{2.5} from upper layer. It is
854 also noticed that horizontal advection contributed to PM_{2.5} loss ($-12.8 \mu\text{g m}^{-3} \text{ h}^{-1}$). This is
855 because the strong gradient between the increased PM_{2.5} level in Beijing caused by weakened
856 vertical diffusivity and the relatively lower PM_{2.5} level in the surrounding areas, which led to
857 an outflow of PM_{2.5}. In the growth stage, the net variation rate (IPR) of PM_{2.5} concentration
858 was $14.1 \mu\text{g m}^{-3} \text{ h}^{-1}$, in which emissions, chemical processes (GAS+Therm+HET) and physical
859 processes (HADV+VADV+HDIF+VDIF+DDEP) contributed $29.8 \mu\text{g m}^{-3} \text{ h}^{-1}$, $33.5 \mu\text{g m}^{-3} \text{ h}^{-1}$
860 and $-49.2 \mu\text{g m}^{-3} \text{ h}^{-1}$, respectively. In the persistence stage, chemical production rate of PM_{2.5}

861 changed slightly, and the production and loss rates of $PM_{2.5}$ were similar, leading to an
862 approximately zero IPR in this stage (Figure 8b). In the dissipation stage, the contribution of
863 vertical diffusion and dry deposition to $PM_{2.5}$ loss increased largely, while the total chemical
864 production rate decreased, which resulted in a net IPR of $-34.8 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating a
865 substantial decrease in $PM_{2.5}$ concentration (Figure 8b). It was also noticed that HADV
866 contributed to $PM_{2.5}$ production in this stage, which was due to mass import to Beijing from
867 upwind areas by northwesterlies.

868 It should be mentioned that the contribution of emission was unchanged because the
869 monthly based emission inventory from MEIC was used, and the contribution of cloud process
870 was generally negligible throughout the period because there was little cloud and precipitation
871 during the study period.

872 We further use PA to interpret evolution processes of primary (BC) and secondary (sulfate
873 and nitrate) aerosols.

874 Black carbon is considered to be inert and chemical inactive, so it is governed solely by
875 physical processes. In the clean stage, BC production was contributed solely by emission (5.7
876 $\mu\text{g m}^{-3} \text{h}^{-1}$), whereas vertical diffusion and dry deposition contributed equally to BC loss (-2.7
877 $\mu\text{g m}^{-3} \text{h}^{-1}$), and other processes were negligible (Figure 8c). In the growth stage, the
878 contribution of vertical diffusion and dry deposition to BC loss decreased to $-2.0 \mu\text{g m}^{-3} \text{h}^{-1}$ and
879 $-1.7 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively, and the net rate of change was $0.7 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating a rapid
880 increase of BC concentration in this stage (Figure 8c). In the persistence stage, the loss rate by
881 vertical diffusivity and dry deposition further increased mainly due to the increased BC
882 concentration (Figure 8c). It is noticed that horizontal advection somewhat contributed to the
883 loss of BC ($-0.7 \mu\text{g m}^{-3} \text{h}^{-1}$), which indicated an increasing outflow of BC to surrounding areas.
884 The IPR was near zero, indicating a balance of production and loss rate in this stage. In the
885 dissipation stage, BC loss via vertical diffusion and dry deposition processes increased largely,
886 mainly due to increasing wind speed and vertical diffusivity, and the net IPR became $-1.6 \mu\text{g}$
887 $\text{m}^{-3} \text{h}^{-1}$. This absolute value was larger than that in the growth stage ($0.7 \mu\text{g m}^{-3} \text{h}^{-1}$), which
888 indicated a faster decrease in BC concentration than the BC increase in the growth stage (Figure
889 8c).

890 As for secondary aerosols, like sulfate, contribution from direct emission was near zero.

891 In the clean stage, gas chemistry ($5.9 \mu\text{g m}^{-3} \text{h}^{-1}$) was the predominant process for sulfate
892 production, and vertical diffusion contributed most to the loss ($-5.2 \mu\text{g m}^{-3} \text{h}^{-1}$) (Figure 8d). In
893 the growth stage, contribution from vertical diffusion was reduced to $-3.9 \mu\text{g m}^{-3} \text{h}^{-1}$ mainly
894 due to the decreased vertical diffusivity (Figure 8f), whereas positive contribution from gas
895 chemistry increased to $6.6 \mu\text{g m}^{-3} \text{h}^{-1}$, which was resulted from competitive processes. For
896 sulfate formation from gas chemistry ($\text{SO}_2 + \text{OH} \rightarrow \text{H}_2\text{SO}_4$, followed by nucleation or
897 condensation into particulate phase), the oxidation of SO_2 to sulfate was weakened because of
898 decreasing OH radical due to increasing aerosol attenuation of solar radiation, however, SO_2
899 increased due to weakened vertical diffusivity, leading to a slight net increase of sulfate
900 concentration compared with the clean stage. It is noteworthy that the sulfate production rate
901 from heterogeneous reactions increased to $2.7 \mu\text{g m}^{-3} \text{h}^{-1}$, mainly due to the increases in SO_2 ,
902 aerosol surfaces and RH (as well as aerosol water content). All the processes led to a net sulfate
903 production rate of $2.7 \mu\text{g m}^{-3} \text{h}^{-1}$, in which chemistry played a predominant role (IPR of $9.3 \mu\text{g}$
904 $\text{m}^{-3} \text{h}^{-1}$). In the persistence stage, the contribution of gas and heterogeneous processes further
905 increased to $7.4 \mu\text{g m}^{-3} \text{h}^{-1}$ and $4.3 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating an increasing sulfate production
906 through chemical processes (Figure 8d). It is interesting to note that vertical diffusion
907 contributed more to sulfate loss than in the growth stage, which was mainly due to the higher
908 sulfate level than in the growth stage while vertical diffusivity coefficients were almost the
909 same. The net IPR in this stage was just $0.2 \mu\text{g m}^{-3} \text{h}^{-1}$, which indicated an approximate balance
910 of production and loss. In the dissipation stage, increasing vertical diffusivity was the dominant
911 process for sulfate loss, and chemical contribution decreased. It is noticed a positive
912 contribution to sulfate from horizontal advection (IPR of $4.3 \mu\text{g m}^{-3} \text{h}^{-1}$), which was due to an
913 import of sulfate from upwind areas of Beijing by northwesterly winds, like those for $\text{PM}_{2.5}$
914 and BC.

915 For nitrate, in the clean stage, thermodynamic process ($4.5 \mu\text{g m}^{-3} \text{h}^{-1}$) was the largest
916 contributor to nitrate production (Figure 8e). During the growth stage, the contribution of
917 thermodynamic processes ($10.2 \mu\text{g m}^{-3} \text{h}^{-1}$) increased by over a factor of two and was larger
918 than the contribution from heterogeneous process (Figure 8e). The substantial increase in the
919 contribution of thermodynamic processes to nitrate production was due to the combined effects
920 of the increased level of nitrate precursors (HNO_3 and NH_3) resulting from weakened

921 diffusivity and the increased RH along with the decreased air temperature, which were
922 favorable for gas to aerosol conversion. The contribution of heterogeneous reactions increased
923 as well due to the increased aerosol surface and relative humidity. The net rate of nitrate change
924 in this stage was $5.3 \mu\text{g m}^{-3} \text{ h}^{-1}$. In the persistence stage, the contribution from heterogeneous
925 reactions changed slightly while the contribution from thermodynamic process somewhat
926 reduced (Figure 8e). This is because more NH_3 was consumed to neutralize the increased
927 sulfate, leaving less NH_3 to react with HNO_3 , and thus producing fewer nitrate. The near zero
928 net IPR of nitrate in this stage also indicated a balance of production and loss. In the dissipating
929 stage, the contribution of chemical processes was almost the same as that in the clean stage,
930 while physical processes dominated the loss and the net IPR of nitrate (Figure 8e).

931

932 5.1.2 Haze evolution during 1–4 March

933 We also investigate another haze period of 1–4 March using PA (Figure 9). The hourly
934 IPRs by different processes are shown in Figure 9a. An apparent difference between this
935 episode and the first one was the positive IPRs of HADV during this episode, especially in the
936 growth stage from 21:00 (LST) on 1 March to 9:00 (LST) on 2 March, which indicated that
937 horizontal transport contributed to the haze formation. Another difference is that the chemical
938 processes, especially heterogeneous reactions contributed less to the $\text{PM}_{2.5}$ mass during the
939 persistence stage, such as from 10:00 (LST) on 2 March to 3:00 (LST) on 4 March, which will
940 be discussed below.

941 The IPRs for $\text{PM}_{2.5}$ and its components and meteorological variables averaged over each
942 stage during this episode are calculated and presented in Figure 9b to 9f. For BC (Figure 9c),
943 the most evident difference from the first haze episode occurred in the growth stage, in which
944 horizontal advection contributed $1.5 \mu\text{g m}^{-3} \text{ h}^{-1}$ to BC production, which was comparable in
945 magnitude to the negative contributions from vertical diffusion and dry deposition ($-1.3 \mu\text{g m}^{-3} \text{ h}^{-1}$),
946 suggesting the import of BC into Beijing from surrounding areas. The wind direction in
947 the south of Beijing at this stage was southerly and wind speed was about $2\text{--}3 \text{ m s}^{-1}$, so the
948 transport of pollutants from southern Hebei apparently contributed to the increase of BC level
949 in Beijing. Differently, during the first haze event on 20–26 February, wind direction was
950 easterly, bringing less polluted air mass from the Bohai Sea and northern Tianjin, so horizontal

951 advection contributed less to BC in Beijing. This transport feature was also reflected in the
952 change rates of sulfate (Figure 9d), nitrate (Figure 9e) and PM_{2.5} (Figure 9b) concentrations.
953 An observational study for the same haze period in Beijing (Ma et al., 2017) also suggested the
954 important role of regional transport from the south of Beijing in haze formation.

955 For sulfate (Figure 9d), although chemical processes still contributed most to sulfate
956 production in the growth stage ($6.0 \mu\text{g m}^{-3} \text{h}^{-1}$), it is noticed that gas chemistry ($5.9 \mu\text{g m}^{-3} \text{h}^{-1}$)
957 accounted for most of the sulfate production, whereas contribution from heterogeneous
958 reactions was smaller than that in the first haze episode mainly due to lower relative humidity.
959 In the growth stage, the net IPR was $1.9 \mu\text{g m}^{-3} \text{h}^{-1}$, 30% smaller than that for the first haze,
960 indicating a weaker secondary aerosol formation during this haze episode. In the persistence
961 stage, sulfate production from gas phase oxidation was almost balanced by the loss from dry
962 deposition and vertical diffusion, resulting in a net IRP of $-0.1 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating a small
963 variation of sulfate concentration during this stage on average.

964 For nitrate, in the growth stage, it is of interest to note that heterogeneous reactions (5.5
965 $\mu\text{g m}^{-3} \text{h}^{-1}$) dominated over thermodynamic processes ($2.7 \mu\text{g m}^{-3} \text{h}^{-1}$) in nitrate formation,
966 which could be due to the low RH in this stage. Fountoukis and Nenes (2007) indicated that
967 nitrate aerosol is hardly formed in the ISORROPIA II model when RH is below 40%. The
968 average RH is about 37% during this haze episode, resulting in more nitrate formed by
969 heterogeneous reactions. The net IPR in the growth stage was $3.7 \mu\text{g m}^{-3} \text{h}^{-1}$, approximately
970 30% smaller than that in the first haze episode. In the persistence stage when relative humidity
971 increased to 51%, nitrate formation via thermodynamic processes became important, and due
972 to competition, nitrate formation from heterogeneous reactions was reduced.

973 For PM_{2.5} (Figure 9b), in the growth stage, the IPR of PM_{2.5} concentration was $13.0 \mu\text{g m}^{-3}$
974 h^{-1} , in which emission, chemical processes (GAS+Therm+HET) and physical processes
975 (HADV+VADV+HDIF+VDIF+DDEP) contributed $29.8 \mu\text{g m}^{-3} \text{h}^{-1}$, $23.9 \mu\text{g m}^{-3} \text{h}^{-1}$ and -40.7
976 $\mu\text{g m}^{-3} \text{h}^{-1}$, respectively. It is noteworthy that horizontal advection process (HADV) contributed
977 $22.4 \mu\text{g m}^{-3} \text{h}^{-1}$ to PM_{2.5} production in this episode, which was comparable to the total chemical
978 production of $23.9 \mu\text{g m}^{-3} \text{h}^{-1}$. This reveals the comparable contributions to PM_{2.5} in Beijing
979 from local sources and regional transport during this haze episode. In the persistence stage,
980 because of the change in wind direction and lower wind speed, the regional transport of PM_{2.5}

981 became weak. The IPRs were $-4.0 \mu\text{g m}^{-3} \text{h}^{-1}$ for HADV and $1.2 \mu\text{g m}^{-3} \text{h}^{-1}$ for VADV,
982 respectively, which were obviously smaller than those in the first haze episode. In the
983 dissipation stage, physical processes except HADV all contributed to the loss of $\text{PM}_{2.5}$.
984 Compared with the first haze episode, the negative IPR of VADV decreased mainly due to the
985 larger wind speeds in this episode, as more $\text{PM}_{2.5}$ was removed by VADV, the remaining $\text{PM}_{2.5}$
986 loss by vertical diffusion decreased, consequently a weakened VDIF. The positive IPR of
987 HADV increased as well due to larger wind speed than that in the first episode in this stage.

988 The above process analyses reveal that for the first haze episode (20–26 February) in
989 Beijing, local emissions and chemical processes were the main contributors to the formation
990 and persistence of the haze event. However, for the second haze (1–4 March), regional transport
991 or horizontal advection played a more important role in haze formation, with a similar
992 magnitude to local emissions and chemical productions in the growth stage. In all, for both
993 episodes, local emission, chemical reaction and horizontal advection were major processes
994 contributing to $\text{PM}_{2.5}$ increase, whereas vertical processes (diffusion, dry deposition and
995 advection) were major processes for $\text{PM}_{2.5}$ removal. As the pollution level increased, the
996 contribution of secondary aerosols through chemical formation to $\text{PM}_{2.5}$ increased apparently
997 in Beijing.

998

999 5.2 Contributions of physical and chemical processes to the aerosol feedback

1000 5.2.1 The first haze episode (20–26 February)

1001 Figure 10 shows the contributions of each process to the feedback-induced difference in
1002 the change rates of $\text{PM}_{2.5}$ and its major components (ΔIPR) during the first haze episode (20–
1003 26 February), which were derived from the difference between cases with and without aerosol
1004 radiative effects (FULL minus NoAFB).

1005 The definition of the four stages during haze evolution is the same as that in section 5.1.1.
1006 For BC (Figure 10b) in the clean stage, the aerosol feedback caused a decrease in vertical
1007 diffusion and advection (Figure 10e), leading to an increase in BC concentration with the ΔIPR
1008 of $0.40 \mu\text{g m}^{-3} \text{h}^{-1}$ from VDIF+VADV, concurrently, the feedback caused an increased loss of
1009 BC through horizontal diffusion (HDIF) and advection (HADV) and dry deposition (DDEP)
1010 due to the increased BC concentration, with the ΔIPR of $-0.39 \mu\text{g m}^{-3} \text{h}^{-1}$ from

1011 HADV+HDIF+DDEP (Figure 10b). The net ΔIPR was near zero, which indicated a negligible
1012 feedback effect during the clean stage. In the growth stage, the feedback caused a pronounced
1013 decrease in vertical diffusivity, advection, as well as dry deposition velocity, leading to apparent
1014 increases in BC level, with the contributions to $\Delta IPRs$ from VDIF, VADV, and DDEP being
1015 $0.50 \mu\text{g m}^{-3} \text{h}^{-1}$, $0.50 \mu\text{g m}^{-3} \text{h}^{-1}$ and $0.20 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively (Figure 10b). The increase in
1016 BC concentration consequently led to an increase in outflow via HADV and HDIF, with the
1017 $\Delta IPRs$ of $-0.63 \mu\text{g m}^{-3} \text{h}^{-1}$ and $-0.12 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively, which tended to reduce BC
1018 concentration. The total effect by summing the processes exhibited a net positive ΔIPR of 0.44
1019 $\mu\text{g m}^{-3} \text{h}^{-1}$, which indicated an apparent increase in BC concentration due to the feedback. In
1020 the persistence stage, the sign of ΔIPR for each process was the same as that in the growth
1021 stage, and the ΔIPR by vertical processes ($0.84 \mu\text{g m}^{-3} \text{h}^{-1}$ from VADV+VDIF+DDEP) was
1022 generally balanced by that of horizontal processes ($-0.80 \mu\text{g m}^{-3} \text{h}^{-1}$ from HADV+HDIF) and
1023 led to a net ΔIPR of $0.04 \mu\text{g m}^{-3} \text{h}^{-1}$ (Figure 10b), which indicated the difference in the BC
1024 change rate between the FULL and NoAFB cases was small in this stage. In the dissipating
1025 stage, the $\Delta IPRs$ were negative for all the processes except for HADV. This was because of the
1026 higher BC levels due to the feedback, which caused more BC to be removed than without
1027 feedback, although the vertical diffusion coefficient was smaller due to the feedback. The
1028 positive ΔIPR from HADV suggested the enhanced BC import into Beijing from upwind
1029 regions due to the feedback. The sum of these processes produced a net ΔIPR of $-1.20 \mu\text{g m}^{-3}$
1030 h^{-1} , which indicated a larger decreasing rate of BC concentration (from haze to clean level) due
1031 to aerosol feedback in this stage.

1032 For sulfate (Figure 10c), in the clean stage, the feedback-induced changes were as small
1033 as those for BC. In the growth stage, besides the positive $\Delta IPRs$ by VDIF, VADV and DDEP
1034 as those for BC, the most impressive feature was the larger contributions from GAS and HET,
1035 with the $\Delta IPRs$ being $0.29 \mu\text{g m}^{-3} \text{h}^{-1}$ and $1.73 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively, much larger than those
1036 ($0.11 \mu\text{g m}^{-3} \text{h}^{-1}$ and $0.23 \mu\text{g m}^{-3} \text{h}^{-1}$) in the clean stage because of the increased gas precursors,
1037 aerosol surfaces and RH due to the feedback effect, which enhanced chemical formation
1038 (Figure 10c, 10e). The sum of the $\Delta IPRs$ by all the processes was $1.92 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating
1039 an apparent increase in sulfate concentration due to the feedback effect. In the persistence stage,
1040 the $\Delta IPRs$ by GAS and HET increased. However, the ΔIPR of VDIF became negative, which

1041 could be explained by the increased sulfate concentration due to aerosol feedback caused more
1042 sulfate to be removed through vertical diffusion, leading to a negative Δ IPR of VDIF, although
1043 the vertical diffusion coefficient was reduced by the feedback. In the dissipation stage, the
1044 Δ IPR by HET decreased because the feedback-induced differences in the concentrations of
1045 precursors and aerosols became smaller. The large negative Δ IPR by VDIF indicated a larger
1046 decreasing rate in sulfate concentration from the persistence to clean stages due to the feedback.

1047 For nitrate (Figure 10d), the feedback-induced IPR changes in the clean stage were similar
1048 to those for sulfate. In the growth stage, remarkable increases in nitrate formation from Thermo
1049 and HET processes occurred, with the Δ IPRs of $3.30 \mu\text{g m}^{-3} \text{h}^{-1}$ and $0.50 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively
1050 (Figure 10d). The increased gas precursors and RH due to the aerosol feedback reinforced
1051 chemical formation processes. In this stage, the overall Δ IPR was $3.90 \mu\text{g m}^{-3} \text{h}^{-1}$, suggesting
1052 a faster increasing rate in nitrate concentration in consideration of aerosol feedback. In the
1053 persistence stage, the Δ IPR by Thermo was smaller than that in the growth stage (Figure 10d).
1054 This could be explained that the apparent increase in sulfate concentration via HET and GAS
1055 due to the feedback (Figure 10c) in this stage consumed more ammonia, which inhibited the
1056 formation of nitrate ammonium via thermodynamic processes. The net Δ IPR by all the
1057 processes in this stage was near zero, which indicated that the radiative feedback exerted little
1058 effect on the change rate of nitrate concentration during this stage. In the dissipation stage, the
1059 attenuation of solar radiation by aerosols was weakened because of the decrease in aerosol
1060 concentration, meanwhile, the concentrations of gas precursors (NO_x) were elevated due to the
1061 feedback, the combined effect resulted in an increase of photochemical production of HNO_3 ;
1062 in addition, RH was increased due to the feedback as well, as a result, nitrate formation via
1063 thermodynamic process was enhanced, leading to a positive Δ IPR of $3.73 \mu\text{g m}^{-3} \text{h}^{-1}$ by Thermo
1064 in this stage.

1065 For $\text{PM}_{2.5}$, the net Δ IPR due to aerosol feedback in the clean stage was $0.30 \mu\text{g m}^{-3} \text{h}^{-1}$, in
1066 which $1.22 \mu\text{g m}^{-3} \text{h}^{-1}$ was from chemical processes (GAS+Thermo+HET) and $-0.90 \mu\text{g m}^{-3} \text{h}^{-1}$
1067 from physical processes (HADV+VADV+HDIF+VDIF+DDEP) (Figure 10a). In the growth
1068 stage, the net Δ IPR was $9.50 \mu\text{g m}^{-3} \text{h}^{-1}$, which meant in every hour, approximate $9.50 \mu\text{g m}^{-3}$
1069 of $\text{PM}_{2.5}$ mass was elevated in Beijing due to the feedback effect. The above feedback-induced
1070 difference in the change rate of $\text{PM}_{2.5}$ (Δ IPR) resulted from a combined effect from chemical

1071 processes ($7.27 \mu\text{g m}^{-3} \text{h}^{-1}$) and physical processes ($2.23 \mu\text{g m}^{-3} \text{h}^{-1}$), which suggested that
1072 chemical processes contributed more to the $\text{PM}_{2.5}$ increase than physical processes. However,
1073 it was noted that the increased contribution from chemical processes was related to increasing
1074 gas precursors, which was partly associated with physical processes. It was noteworthy that the
1075 positive ΔIPR s were contributed by both chemical processes (GAS, Thermo and HET) and
1076 vertical movements (VADV, VDIF and DDEP) (Figure 10a). The sum of positive ΔIPR s was
1077 $22.88 \mu\text{g m}^{-3} \text{h}^{-1}$, in which $7.27 \mu\text{g m}^{-3} \text{h}^{-1}$ was from chemical processes and $15.61 \mu\text{g m}^{-3} \text{h}^{-1}$
1078 from vertical movements. This suggested a larger feedback-induced $\text{PM}_{2.5}$ increase through
1079 vertical movements than via chemical processes. However, the outflow (HADV+HDIF) of
1080 $\text{PM}_{2.5}$ was also enhanced due to the increased $\text{PM}_{2.5}$ level by aerosol feedback, producing a
1081 negative ΔIPR ($-13.38 \mu\text{g m}^{-3} \text{h}^{-1}$), and partly offsetting the positive ΔIPR ($15.61 \mu\text{g m}^{-3} \text{h}^{-1}$)
1082 by vertical movements, resulting in a net ΔIPR of $2.23 \mu\text{g m}^{-3} \text{h}^{-1}$ from all the physical processes.
1083 In the persistence stage, the sign of ΔIPR s by different processes generally resembled those in
1084 the growth stage except that of VDIF whose ΔIPR was negative, which indicated more removal
1085 though VDIF mainly due to the increased secondary aerosol concentrations by aerosol
1086 feedback. The net ΔIPR by all the processes was $0.40 \mu\text{g m}^{-3} \text{h}^{-1}$ in this stage, indicating a small
1087 influence of aerosol feedback on the change rate of $\text{PM}_{2.5}$ concentration. In the dissipating stage
1088 (Figure 10a), the large negative ΔIPR from VDIF indicated more $\text{PM}_{2.5}$ mass was removed via
1089 vertical diffusion while considering aerosol feedback, although the feedback induced a smaller
1090 vertical diffusivity coefficient. The net ΔIPR of $-24.60 \mu\text{g m}^{-3} \text{h}^{-1}$ indicated a larger decreasing
1091 rate of $\text{PM}_{2.5}$ concentration in the FULL case than in the NoAFB case.

1092

1093 5.2.2 The second haze episode (1–4 March)

1094 For BC in the second haze episode (1–4 March), the most obvious difference from the first
1095 episode was in the growth stage, in which the ΔIPR by horizontal advection (HADV) was 0.70
1096 $\mu\text{g m}^{-3} \text{h}^{-1}$ (Figure 11b). The radiative feedback led to a weakened vertical diffusivity and a
1097 decreased PBL height (Figure 11e), which favored the accumulation of BC and caused a
1098 positive ΔIPR of $0.40 \mu\text{g m}^{-3} \text{h}^{-1}$ from VDIF. The wind direction in the growth stage was
1099 southerlies as discussed above, bringing aerosols from the south to Beijing. The aerosol
1100 feedback enhanced BC concentration in source regions through reducing vertical diffusivity,

1101 leading to an increased northward flux of BC and a positive Δ IPR from HADV. The higher BC
1102 concentration due to the feedback via HADV and VDIF consequently led to an increase in BC
1103 outflow out of Beijing via vertical advection (VADV) and horizontal diffusion (HDIF), with
1104 the Δ IPRs of $-0.60 \mu\text{g m}^{-3} \text{h}^{-1}$ and $-0.20 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively. In this stage, the net Δ IPR of
1105 BC was $0.20 \mu\text{g m}^{-3} \text{h}^{-1}$, in which $0.50 \mu\text{g m}^{-3} \text{h}^{-1}$ was from horizontal movements
1106 (HADV+HDIF) and $-0.30 \mu\text{g m}^{-3} \text{h}^{-1}$ from vertical movements (VADV+VDIF+DDEP),
1107 indicating that the feedback effect strengthened the contribution of horizontal movements to
1108 surface BC concentration in Beijing. In the persistence stage (Figure 11b), the net Δ IPR was
1109 also near zero ($-0.02 \mu\text{g m}^{-3} \text{h}^{-1}$), indicating that the BC change rate was merely affected by the
1110 feedback in this stage. In the dissipation stage (Figure 11b), the Δ IPRs were negative for all the
1111 processes except for VDIF. This could be attributed to the higher BC levels due to the feedback,
1112 which caused more BC to be removed than without feedback through these processes. The net
1113 Δ IPR was $-0.17 \mu\text{g m}^{-3} \text{h}^{-1}$, the same as that in the growth stage, but with opposite sign.

1114 For sulfate (Figure 11c), in the growth stage, different from the relatively large positive
1115 Δ IPR by chemical processes in the first haze episode, the feedback caused small IPR changes
1116 via chemical production because SO_2 concentration in this episode was lower than that in the
1117 first one and sulfate was mainly formed in upwind regions and transported to Beijing.
1118 Consequently, relatively large sulfate increases through HADV and VDIF in this episode. In
1119 this stage, the feedback caused a slight increase in sulfate concentration by GAS with Δ IPR of
1120 $0.17 \mu\text{g m}^{-3} \text{h}^{-1}$ due to slightly elevated precursors, however, because of the low relative
1121 humidity (mean RH was 38%) and competitive processes, heterogeneous reactions were
1122 depressed. In terms of physical processes, due to the feedback effect, horizontal transport
1123 (HADV) was strengthened (Δ IPR of $1.0 \mu\text{g m}^{-3} \text{h}^{-1}$) due to the increased sulfate concentration
1124 to the south of Beijing, meanwhile, the weakened vertical diffusivity caused an increase in
1125 sulfate concentration by VDIF and DDEP, with the Δ IPRs of $1.0 \mu\text{g m}^{-3} \text{h}^{-1}$ and $0.57 \mu\text{g m}^{-3} \text{h}^{-1}$,
1126 respectively, consequently, the outflow of sulfate out of Beijing was also increased via
1127 vertical advection (VADV) and horizontal diffusion (HDIF). The net Δ IPR in the growth stage
1128 was $0.90 \mu\text{g m}^{-3} \text{h}^{-1}$, indicating an apparent increase in sulfate concentration due to the feedback.
1129 In the persistence stage, the Δ IPRs by GAS and HET changed slightly compared with those in
1130 the growth stage. The negative Δ IPR by VDIF indicated more loss of sulfate by vertical

1131 diffusion while considering aerosol feedback. The net ΔIPR in this stage was $0.02 \mu\text{g m}^{-3} \text{h}^{-1}$,
1132 indicating a negligible feedback effect on sulfate change rate in this stage. In the dissipation
1133 stage, the feedback-induced higher sulfate concentration caused more removal of sulfate via
1134 physical processes except HADV, resulting in a net ΔIPR of $-0.64 \mu\text{g m}^{-3} \text{h}^{-1}$. The positive ΔIPR
1135 from HADV was due to the strengthened import from upwind areas due to the feedback.

1136 For nitrate, in the growth stage, the feedback also induced an increase in nitrate
1137 concentration via horizontal advection like sulfate (Figure 11d). The increases in gas precursors
1138 and aerosol surfaces due to the feedback enhanced nitrate formation, resulting in nitrate
1139 increases via Thermo and HET, with the ΔIPRs of $0.88 \mu\text{g m}^{-3} \text{h}^{-1}$ and $0.46 \mu\text{g m}^{-3} \text{h}^{-1}$,
1140 respectively. To the persistence stage, the chemical production of nitrate increased largely
1141 caused by the feedback, with the ΔIPR of Thermo being $4.30 \mu\text{g m}^{-3} \text{h}^{-1}$. The reason could be
1142 the low RH in the growth stage (38% shown in Figure 9f) left most of nitric acid remained in
1143 gas phase together with the increase in RH due to the feedback (13.2% shown in Figure 11e)
1144 drove its conversion from gas to aerosol phase. Due to the enhanced thermodynamics
1145 production, nitrate formation via heterogeneous reactions was depressed in this stage. The
1146 increased nitrate concentration via Thermo led to larger removal via vertical diffusion, resulting
1147 in a negative ΔIPR of $-4.80 \mu\text{g m}^{-3} \text{h}^{-1}$ by VDIF, and a net ΔIPR of $-0.10 \mu\text{g m}^{-3} \text{h}^{-1}$. In the
1148 dissipation stage, like that in the first haze episode, the reduced aerosol attenuation of solar
1149 radiation and increased RH induced by aerosol feedback led to an increase in nitrate via
1150 thermodynamic process, with the ΔIPR of $1.80 \mu\text{g m}^{-3} \text{h}^{-1}$ by Thermo. Consequently,
1151 heterogeneous reactions were depressed due to competitive processes (ΔIPR of $-0.97 \mu\text{g m}^{-3} \text{h}^{-1}$
1152 by HET). In this stage, because of the higher nitrate concentration, the feedback led to larger
1153 removal by vertical processes (the ΔIPR of VADV+VDIF+DDEP was $-3.23 \mu\text{g m}^{-3} \text{h}^{-1}$), with
1154 a net ΔIPR of $-1.78 \mu\text{g m}^{-3} \text{h}^{-1}$, similar to the ΔIPR in the growth stage but with opposite sign.

1155 For $\text{PM}_{2.5}$ (Figure 11a), the net ΔIPR due to aerosol feedback in the growth stage was 2.40
1156 $\mu\text{g m}^{-3} \text{h}^{-1}$, with $1.40 \mu\text{g m}^{-3} \text{h}^{-1}$ from physical processes (HADV+VADV+HDIF+VDIF+DDEP)
1157 and $1.0 \mu\text{g m}^{-3} \text{h}^{-1}$ from chemical processes (GAS+Thermo+HET), which indicated that the
1158 feedback-induced increase in $\text{PM}_{2.5}$ concentration per hour was produced through larger
1159 contributions from physical processes than chemical processes in this episode. HADV
1160 contributed most to the $\text{PM}_{2.5}$ increase (with ΔIPR of $10.20 \mu\text{g m}^{-3} \text{h}^{-1}$), followed by VDIF

1161 (with ΔIPR of $2.90 \mu\text{g m}^{-3} \text{h}^{-1}$). As mentioned above, the weakened vertical diffusivity caused
1162 by the feedback enhanced aerosol concentrations in the entire BTH region, meanwhile, the
1163 feedback induced a southeast wind anomaly with a slight change in wind speed in the regions
1164 south of Beijing. The combined effect of the elevated aerosol concentrations and southeast
1165 wind anomaly brought more aerosols to Beijing. In the persistence stage, the feedback
1166 increased $\text{PM}_{2.5}$ concentration mainly through chemical processes, with the ΔIPR of $6.05 \mu\text{g}$
1167 $\text{m}^{-3} \text{h}^{-1}$, which was mainly resulted from the enhanced thermodynamic production of
1168 ammonium nitrate, and such increase in aerosol mass due to feedback led to more aerosols to
1169 be diffused than that without feedback, leading to the ΔIPR of $-7.30 \mu\text{g m}^{-3} \text{h}^{-1}$ by VDIF. It is
1170 noticed that the signs of the ΔIPRs by VDIF were opposite between the growth and persistence
1171 stages even though the vertical diffusivities were both decreased. In the growth stage, the $\text{PM}_{2.5}$
1172 concentration was gradually increasing, the effect of the weakened vertical diffusivity was
1173 dominated, resulting in a positive ΔIPR by VDIF which favored further accumulation of
1174 aerosols; in the persistence stage, the aerosol concentration had already been elevated to a high
1175 level, the effect of higher concentration surpassed that of weakened vertical diffusivity due to
1176 the feedback and led to a negative ΔIPR , which meant the feedback caused more loss of $\text{PM}_{2.5}$
1177 via VDIF. In the persistence stage, the net ΔIPR was $0.44 \mu\text{g m}^{-3} \text{h}^{-1}$, in which $-5.6 \mu\text{g m}^{-3} \text{h}^{-1}$
1178 from physical processes and $6.05 \mu\text{g m}^{-3} \text{h}^{-1}$ from chemical processes, which indicated the
1179 feedback-induced overall changes in the change rate of $\text{PM}_{2.5}$ concentration in this stage were
1180 relatively small. In the dissipating stage, the removal of $\text{PM}_{2.5}$ was enhanced by the feedback
1181 through all the processes except HADV mainly due to the increased $\text{PM}_{2.5}$ concentration, the
1182 positive ΔIPR by HADV was caused by the enhanced import from upwind areas due to the
1183 feedback. In this stage, the feedback effect enhanced the removal of $\text{PM}_{2.5}$, which was reflected
1184 by the net negative ΔIPR of $-4.30 \mu\text{g m}^{-3} \text{h}^{-1}$.

1185 The above analyses quantify the key processes contributing to the aerosol radiative
1186 feedback in Beijing during the two haze episodes. In the growth stage of the first haze episode,
1187 the feedback-induced $\text{PM}_{2.5}$ enhancement was attributed to the positive contributions from
1188 chemical processes and vertical movements, but partly offset by the increased outflow of $\text{PM}_{2.5}$
1189 via horizontal advection, resulting in a larger increase in $\text{PM}_{2.5}$ through chemical processes
1190 than that from physical processes. Differently, during the second haze episode, the feedback-

1191 induced $PM_{2.5}$ enhancement in the growth stage was larger by physical processes than that by
1192 chemical processes, and horizontal advection contributed most to the $PM_{2.5}$ enhancement. In
1193 all, the radiative feedback increased the cumulative rate of aerosols in the growth stage via
1194 promoting chemical formations, weakening vertical diffusions and/or enhancing regional
1195 transport by horizontal advection. For both episodes, the radiative feedback exerted small effect
1196 on the change rate of $PM_{2.5}$ concentration during the persistence stage and reinforced the
1197 decreasing rate of $PM_{2.5}$ in the dissipation stage.

1198

1199 **6 Conclusions**

1200 Several severe haze events occurred in the winter of 2014, with the most severe one on
1201 20–26 February. An online-coupled regional atmospheric chemistry/aerosol-climate model
1202 (RIEMS-Chem) was developed and utilized to investigate the mechanisms of haze formation
1203 and aerosol radiative feedback in the Beijing-Tianjin-Hebei (BTH) region. Two numerical
1204 experiments were conducted to explore the aerosol radiative effects (AREs) and feedbacks on
1205 meteorological fields and aerosol distributions. Processes analysis technique was implemented
1206 in RIEMS-Chem to quantify the individual contributions from various physical and chemical
1207 processes to aerosol evolution and radiative feedback. Model performance was
1208 comprehensively evaluated by comparing with a variety of observations for meteorological
1209 variables, surface shortwave radiation, PBL heights, $PM_{2.5}$ and its chemical components, as
1210 well as aerosol optical properties in the BTH region. The comparisons demonstrated that
1211 RIEMS-Chem was able to represent the magnitudes and variations of the above variables
1212 reasonably well, in particular, improving the simulation of inorganic aerosols and AOD, which
1213 was often underpredicted in current on-line coupled models. It is encouraging that by
1214 considering the aerosol radiative effects, the model apparently improved predictions for
1215 meteorological variables, $PM_{2.5}$ and its chemical compositions and aerosol optical properties
1216 in the BTH region, suggesting the importance and necessity for developing chemistry-climate
1217 online coupled models in both air quality and climate research.

1218 During the study period, the meteorological conditions were characterized by weak
1219 southerly winds, high RH and low PBL height, which favored aerosol accumulation and haze

1220 formation in the BTH region. The average T2, WS10, RH2, PBL height and PM_{2.5}
1221 concentration from the FULL case were simulated to be 0.6 °C, 1.2 m s⁻¹, 67.0%, 698.4 m and
1222 90.0 µg m⁻³, respectively, over the BTH region during the study period.

1223 The distribution pattern of AOD generally resembled that of PM_{2.5}, with the domain mean
1224 value of 0.78 and the maximum up to 1.1 during the study period. It was noteworthy that the
1225 simulated SSA averaged over the BTH region and the study period was 0.91, which indicated
1226 the dominance of scattering aerosols. The domain and period average AREs at the surface, in
1227 the atmosphere and at the TOA were estimated to be -37 W m⁻², 19 W m⁻² and -18 W m⁻²,
1228 respectively, and they were enhanced to -57 W m⁻², 25 W m⁻² and -32 W m⁻² during the most
1229 severe haze episode (20–26 February). It was striking that the maximum hourly AREs at the
1230 surface and at TOA reached -384 W m⁻² and -231 W m⁻² around noon time in the vicinity of
1231 Shijiazhuang during the first haze episode. The magnitude of the model simulated AREs during
1232 the haze episode in this study agreed favorably with previous observational based estimates.

1233 The aerosol radiative effects generally led to a reduction in surface air temperature in the
1234 entire domain with larger decrease in southern BTH (-1.2 °C to -2 °C), accompanied by an
1235 increase in RH2 (10% to 16%) and a decrease in PBL height (-240 m to -210 m). The changes
1236 in these meteorological variables were strengthened during the severe haze episode. Noticeably,
1237 PM_{2.5} concentrations were consistently increased over the BTH region due to the aerosol
1238 feedback, with the maximum average increase exceeding 33 µg m⁻³ (33%) in southern Hebei
1239 and portions of Beijing and Tianjin during the study period, and the maximum hourly increase
1240 was up to 372 µg m⁻³ (186%) in the vicinity of Shijiazhuang during the severe haze episode. In
1241 terms of domain and period average, the feedback-induced changes were -1.4 °C for T2, -0.04
1242 m s⁻¹ for WS10, 8.7% for RH2, -3.3 m² s⁻¹ for vertical diffusion coefficient, -160.0 m (-19%)
1243 for PBL height and 20.0 µg m⁻³ (29%) for PM_{2.5} concentration. The magnitude of the above
1244 changes were enhanced during the severe haze episode, with the 7-day mean changes in T2,
1245 WS10, RH2, PBL height and PM_{2.5} concentration being -1.8 °C, -0.5 m s⁻¹, 9.8%, -183.6 m (-
1246 31%) and 45.1 µg m⁻³ (39%), respectively, which demonstrated the significant aerosol radiative
1247 feedback on PM_{2.5} accumulation and haze formation. The changes in sulfate and nitrate
1248 concentrations were larger than that in BC concentration because secondary aerosols were
1249 increased not only by weakened vertical diffusivity but also by enhanced chemical reactions

1250 caused by the feedback.

1251 The magnitude of the feedback effect varied remarkably during haze evolution. The
1252 absolute change in $\text{PM}_{2.5}$ concentration caused by the feedback was largest in the persistence
1253 stage, followed by those in the growth stage and in the dissipating stage. In Beijing, the
1254 feedback-induced increases in $\text{PM}_{2.5}$ concentration were $55 \mu\text{g m}^{-3}$, $84 \mu\text{g m}^{-3}$, $40 \mu\text{g m}^{-3}$,
1255 respectively, during the growth, persistence and dissipation stages of the severe haze episode.

1256 PA method was applied to calculate the IPRs for quantifying the individual contributions
1257 from physical and chemical processes to variations of $\text{PM}_{2.5}$ and its chemical components
1258 during haze episodes in Beijing. Two haze episodes were analyzed and compared to elucidate
1259 the mechanism of haze formation and evolution. For the first haze episode, the net IPR for
1260 $\text{PM}_{2.5}$ was $14.1 \mu\text{g m}^{-3} \text{h}^{-1}$ in the growth stage, in which emissions, chemical processes and
1261 physical processes contributed $29.8 \mu\text{g m}^{-3} \text{h}^{-1}$, $33.5 \mu\text{g m}^{-3} \text{h}^{-1}$ and $-49.2 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively,
1262 which indicated a remarkable $\text{PM}_{2.5}$ increase contributed by chemical processes in this stage.
1263 The most influential processes for $\text{PM}_{2.5}$ loss and production were vertical diffusion and
1264 thermodynamic processes, respectively. Compared with the clean stage, the losses by vertical
1265 diffusion and dry deposition reduced largely, and the production by chemical processes
1266 increased, both leading to an evident increase in surface $\text{PM}_{2.5}$ concentrations in the growth
1267 stage. In the persistence stage, the production and loss of $\text{PM}_{2.5}$ were almost equal, resulting in
1268 an approximately zero IPR in this stage. In the dissipation stage, the loss of $\text{PM}_{2.5}$ by vertical
1269 diffusion and dry deposition increased greatly, leading to a net IPR rate of $-34.8 \mu\text{g m}^{-3} \text{h}^{-1}$,
1270 which meant a substantial decrease in $\text{PM}_{2.5}$ concentration.

1271 For the second haze episode, the net IPR for $\text{PM}_{2.5}$ was $13.0 \mu\text{g m}^{-3} \text{h}^{-1}$ in the growth stage,
1272 in which emissions, chemical processes and physical processes contributed $29.8 \mu\text{g m}^{-3} \text{h}^{-1}$,
1273 $23.9 \mu\text{g m}^{-3} \text{h}^{-1}$ and $-40.8 \mu\text{g m}^{-3} \text{h}^{-1}$, respectively. It was noteworthy that the contribution of
1274 horizontal advection to $\text{PM}_{2.5}$ was of a similar magnitude to the contributions from local
1275 emissions and chemical processes, with the mean IPR of $22.4 \mu\text{g m}^{-3} \text{h}^{-1}$, which indicated the
1276 important contribution of regional transport to haze formation in Beijing. Process analysis for
1277 the changes in $\text{PM}_{2.5}$ components during haze evolution was also conducted.

1278 The contribution of each physical and chemical process to the feedback-induced changes
1279 in $\text{PM}_{2.5}$ and its major components were explored and quantified. For the first haze episode,

1280 the fast increase in $PM_{2.5}$ (ΔIPR of $9.5 \mu g m^{-3} h^{-1}$) due to aerosol feedback in the growth stage
1281 was mainly attributed to the changes in vertical movements (VDIF and VADV) and chemical
1282 processes, but the increased outflow via horizontal advection (HADV) partly offset the
1283 increased $PM_{2.5}$ due to vertical movements, which caused a larger contribution to the $PM_{2.5}$
1284 increase from chemical processes (ΔIPR of $7.27 \mu g m^{-3} h^{-1}$) than that from physical processes
1285 (ΔIPR $2.23 \mu g m^{-3} h^{-1}$). However, during the second haze episode, the feedback-induced $PM_{2.5}$
1286 increase (ΔIPR of $2.4 \mu g m^{-3} h^{-1}$) in the growth stage was mainly contributed by physical
1287 processes (ΔIPR of $1.40 \mu g m^{-3} h^{-1}$) rather than that by chemical processes (ΔIPR of $1.0 \mu g m^{-3} h^{-1}$),
1288 and among physical processes, the $PM_{2.5}$ increase was mainly attributed to the increased
1289 horizontal advection (ΔIPR of $10.2 \mu g m^{-3} h^{-1}$). In general, in the growth stage of haze episodes,
1290 the feedback increased the accumulation rate of aerosols mainly through enhancing chemical
1291 formations, weakening vertical diffusions and/or enhancing regional transport by advections.
1292 The feedback-induced changes in the change rate of $PM_{2.5}$ concentration were small during the
1293 persistence stage, and the feedback enhanced the removal rate of $PM_{2.5}$ in the dissipation stage
1294 mainly through increasing vertical diffusion and/or vertical advection.

1295 The results from this study demonstrated a significant impact of aerosol radiative feedback
1296 on meteorology, chemistry, aerosol distribution and evolution during winter haze events in the
1297 BTH region. The mechanism and processes through which the feedback affected haze
1298 formation and evolution were elucidated and quantified. This study is still subject to some
1299 uncertainties: 1.) An internal mixing was assumed for aerosol mixing in this study, but the
1300 mixing state of aerosols is always changing, while this assumption is generally realistic for
1301 haze days, it may overestimate the feedback effect for clean days. 2.) A typical size distribution
1302 measured during haze days was used, whereas the size of aerosol internal mixture could change
1303 to some extent with aging processes. These uncertainties require further development of model
1304 treatment for evolution of aerosol mixing state and size distribution, which is poorly
1305 represented in current online coupled models. 3.) Direct aerosol radiative effect dominated the
1306 feedback effect in this study, so more cases in different regions and seasons; when indirect
1307 effect could be more important are needed to elucidate the complete feedback mechanism at
1308 different spatial and temporal scales. 4.) Finer model grid resolution is expected to be applied
1309 to look into details of the feedback effect at urban scale along with finer emission inventory

1310 (Tao et al., 2020), vertical observations (Wilcox et al., 2016; Wang et al., 2018) and higher
1311 computational efficiency when available in the future. Finally, this study pointed out the
1312 significance and necessity of developing online coupled model for exploring
1313 chemistry/aerosol-weather/climate interactions and for improving meteorological and
1314 chemical predictions in both air quality and climate research in the future.

1661

1662 Figure 1. The model study domain. The shaded areas indicate the Beijing-Tianjin-Hebei (BTH)
1663 region. Markers are observation sites (square: IAP, observations of $PM_{2.5}$, its chemical
1664 components, aerosol extinction coefficient (EXT) and aerosol absorption coefficient (ABS);
1665 circles: observations of meteorological variables; triangles: aerosol optical depth (AOD). The
1666 Xianghe site provides meteorological soundings and hourly surface shortwave radiation
1667 (SWDOWN) measurements; the Tianjin site provides both meteorological variables and AOD).
1668 Hourly O_3 , SO_2 , NO_2 and $PM_{2.5}$ measurements at 13 cities from the CNEMC (China National
1669 Environmental Monitoring Center, <http://www.cnemc.cn/>) are labeled by crosses with numbers
1670 (1-Beijing, 2-Tianjin, 3-Shijiazhuang, 4-Tangshan, 5-Qinhuangdao, 6-Handan, 7-Baoding, 8-
1671 Zhangjiakou, 9-Chengde, 10-Langfang, 11-Cangzhou, 12-Hengshui and 13-Xingtai).

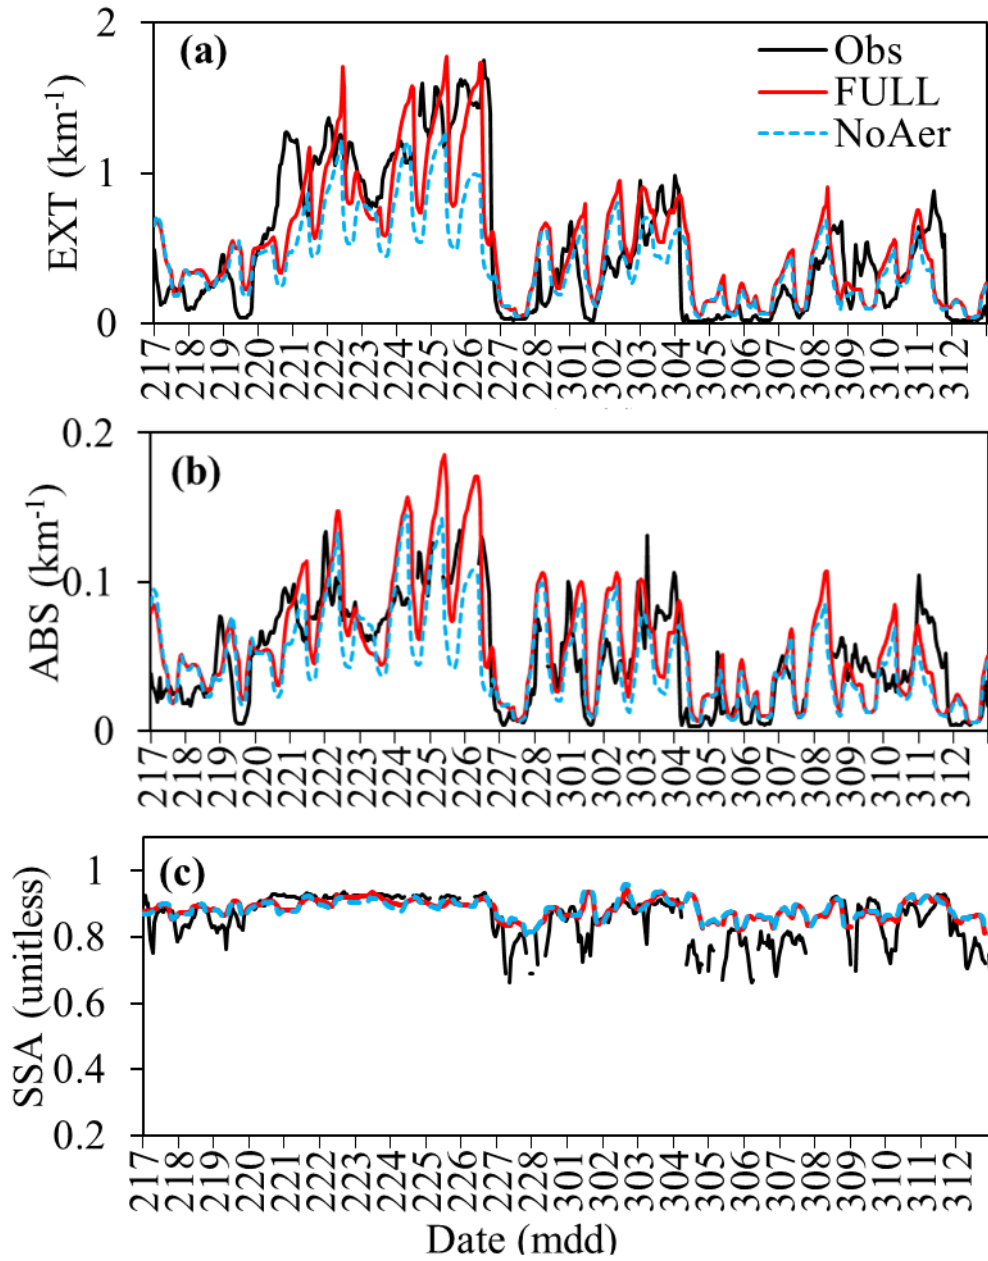

1672

1673 Figure 2. The model simulated and observed (a) hourly SWDOWN at Xianghe, (b) hourly PBL
 1674 height at 14:00 (LST) at Xianghe (note observations are available in the 4 days, numbers are
 1675 observations and corresponding simulations) and (c) hourly $PM_{2.5}$ concentration at IAP in
 1676 Beijing.

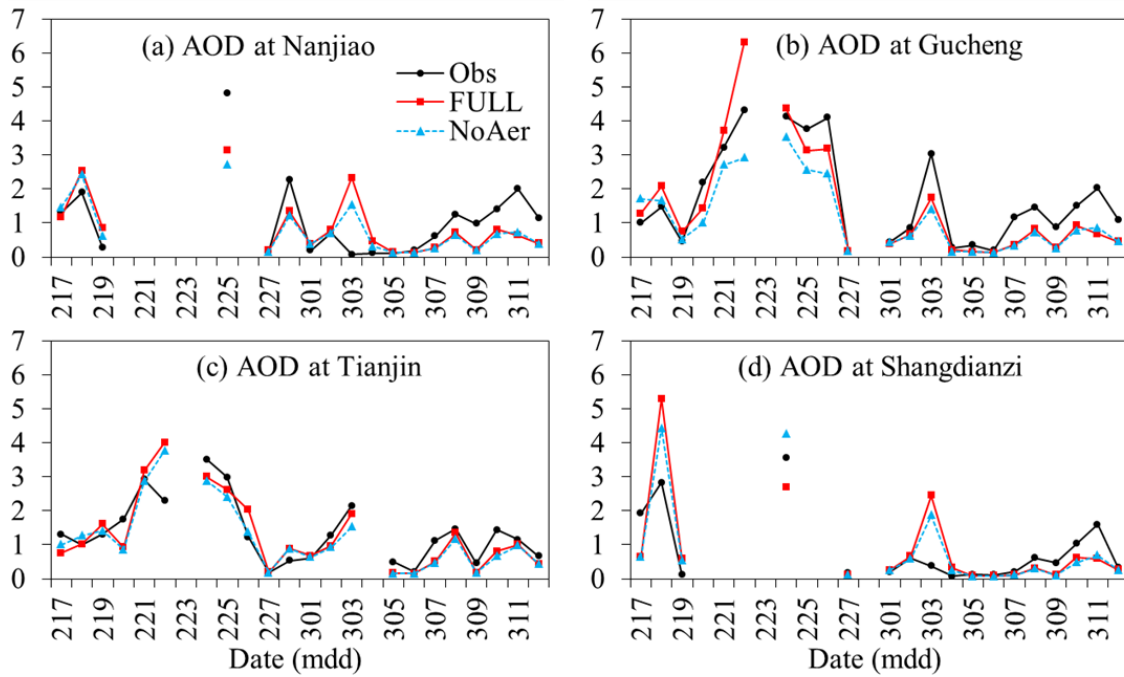

1677

1678 Figure 3. The model simulated and observed daily mean concentrations of aerosol
 1679 compositions in $\text{PM}_{2.5}$ at the IAP site in Beijing.

1680

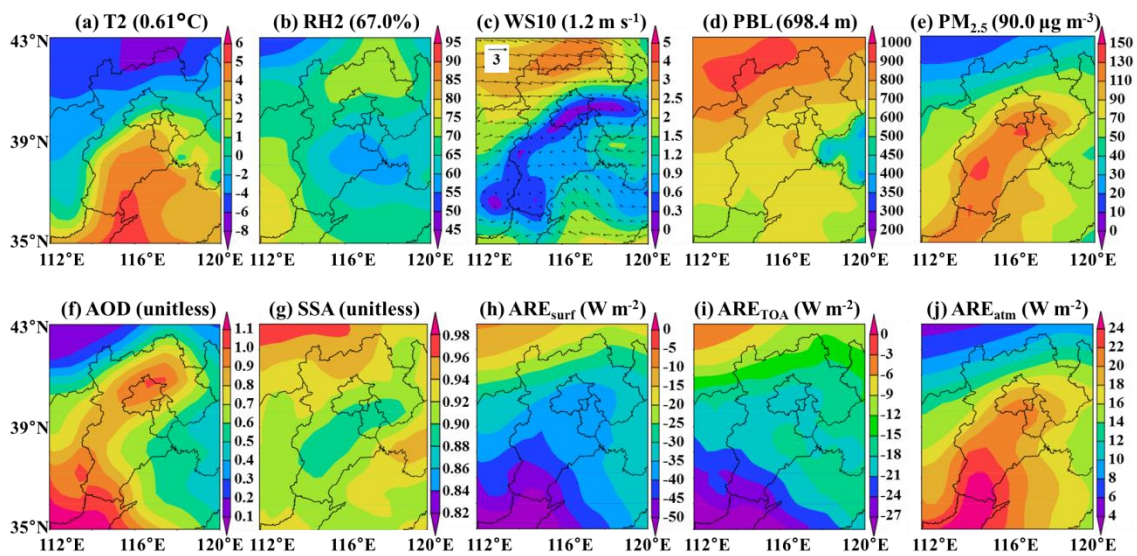

1681 Figure 4. The model simulated and observed hourly (a) aerosol extinction coefficient (EXT),
 1682 (b) absorption coefficient (ABS) and (c) single scattering albedo (SSA) at the IAP site in
 1683 Beijing under dry condition (RH=10%).

1684

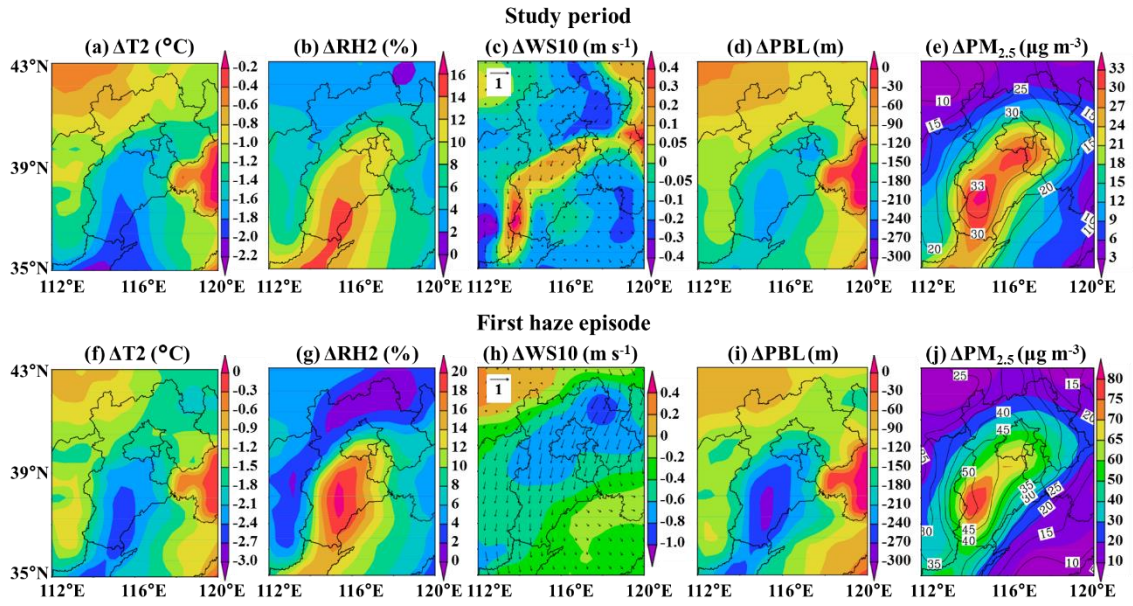

1685 Figure 5. The model simulated and observed daily mean AOD (at 550 nm) at the four sites of
 1686 CARSNET.

1687

1688

1689 Figure 6. The model simulated (a) air temperature (T2), (b) relative humidity (RH2), (c) wind
 1690 speed (WS10), (d) PBL height, (e) PM_{2.5} concentration, (f) AOD, (g) SSA, (h) all-sky ARE at
 1691 the surface, (i) all-sky ARE at the top of atmosphere and (j) all-sky ARE in the atmosphere
 1692 from the FULL case. Numbers in the parentheses are averages over the BTH region during the
 1693 entire study period.

1694

1695 Figure 7. The model simulated feedback-induced changes (FULL minus NoAFB) in (a, f) air
 1696 temperature (T2), (b, g) relative humidity (RH2), (c, h) wind speed (WS10), (d, i) PBL height
 1697 and (e, j) PM_{2.5} concentration averaged over the entire study period (a-e) and over the first haze
 1698 episode (20–26 February) (f-j). Units are given in the parentheses.

Figure 8. The model calculated integrated process rates (IPR) for the first haze episode (20–26 February) in Beijing. (a) hourly IPR, daily PM_{2.5} concentration and the division of the four stages. The nearly constant IPRs of emissions are not shown for clarity. The mean IPRs for (b) PM_{2.5}, (c) BC, (d) sulfate (SO₄²⁻), (e) nitrate (NO₃⁻), and (f) mean meteorological variables in the four stages. Note that zero IPR values are not listed. Units of T2, RH2, WS10, PBL and K_z are °C, %, m s⁻¹, m and m² s⁻¹, respectively.

Figure 9. Same as Figure 8 but for the second haze episode (1–4 March).

Figure 10. The feedback-induced mean changes in IPRs (FULL minus NoAFB) for $PM_{2.5}$ and its chemical components and meteorological variables during the first haze episode (20–26 February) in Beijing. Δ IPRs for $PM_{2.5}$ and its chemical components and Δ meteorological variables are averages over the four stages. Note that zero Δ IPR values (no change) are not shown and the Δ PBL heights are scaled by 0.1. The division of the four stages and units are the same as those in Figure 8.

Figure 11. Same as Figure 10 but for the second haze episode (1–4 March). The division of the four stages are the same as that in Figure 9.

Table 1. Performance statistics for meteorological variables at observation sites in the BTH region. Mean observation (Obs), mean simulation (Sim), correlation coefficient (R) and normalized mean bias (NMB in %) are given. WS10, T2 and RH2 are wind speed at 10 meter, air temperature at 2 meter and relative humidity at 2 meter, respectively. All the sample numbers are 207.
