Reply to Anonymous Referee

Thanks for the reviewer's helpful comments. We have given our point-to-point response to your comments in the revised manuscript.

In order to carefully address the comments, we made extensive model experiments, including
(1) We have simulated the case during the 2017-2018 winter (January 2018 as a baseline simulation), and also added a sensitivity experiment that air temperature is 2°C higher than that in January 2018.
(2) As required by the reviewer (although this is not the focus of the study), we also studied the impact of a decrease of 2°C over the Tibetan Plateau on the air quality in the Sichuan Basin, via designing a set of experiments that air temperature respectively decreases by 2°C during the 2013-2014 and 2017-2018 winters.
(3) To address the reviewer's comment, we have added two new experiments that air temperature increases by 0.5°C, 1.0°C during the 2013-2014 winter, to give a general evaluation for the contribution of the warming plateau on the air quality in the basin.

The detailed explanation of these new model runs is given in the revised paper and in this response. We believe that these extensive new model runs will significantly enhance the quality of the paper.

General comments:

Thanks to the authors for their efforts on this manuscript. The results sound reasonable. The increment of 2C degree have resulted in a weaker winter Tibetan Plateau Monsoon, which may induce decreased high-pressure system at the surface over the TP and decreased air flows from the TP to the Sichuan Basin. The decreased air flows, therefore, was the dominant reason for the improvement of air quality in the Sichuan Basin. However, I will not recommend publication for this manuscript at current condition.

Major comments：

Comment 1. I wonder whether the simulations are greatly dependent on simulation background. The authors compared the baseline simulation and sensitivity simulations during DJF from 2013-2014. How about the similar simulations during winter in other years? I suggested that the authors may compare a sensitive experiment with baseline experiment by using initial and boundary data in winter from 2017-2018. In these experiments, a decrease of

2C degree can be set in the sensitivity experiment. If the simulations could provide a worse air quality in the Sichuan Basin, that will be fine.

Response: Your comment is right, and the simulation is dependent of the simulation background, but not greatly. We have simulated the case during the 2017-2018 winter (January 2018 as a baseline simulation), and also added a sensitivity experiment that air temperature is 2°C higher than that in January 2018. The results are somewhat different from those in January 2014, but the conclusions are consistent. We added Figures S7-S8, Figure S10, Figure S12 in supplementary materials to make sure of a robust conclusion.

In order to respond to the reviewer' comment about the impact of a decrease of 2°C over the TP on the air quality in the Sichuan Basin during the 2017-2018 winter, we also design a set of experiments that air temperature respectively decreases by 2°C during the 2013-2014 and 2017-2018 winters. However, impacts of a warming TP (air temperature increases by 2°C) and a cooling TP (air temperature decreases by 2°C) on the air quality in the Sichuan Basin are actually two studies, and these two impacts are not necessarily opposite completely. There are too many influence factors relate to air quality, and the air temperature and its influence on other factors are only some of them. In fact, the key factors such as winds, RH and PBLH discussed in our study plays important roles in modulating air quality.

Here we investigate the impact of a warming plateau, and the impact of a cooling plateau is out of the scope in our study. To address the reviewer's comment, results of the impact of a cooling plateau on air quality in the basin are followed (Figures 1-4), but not shown in the revised manuscript.

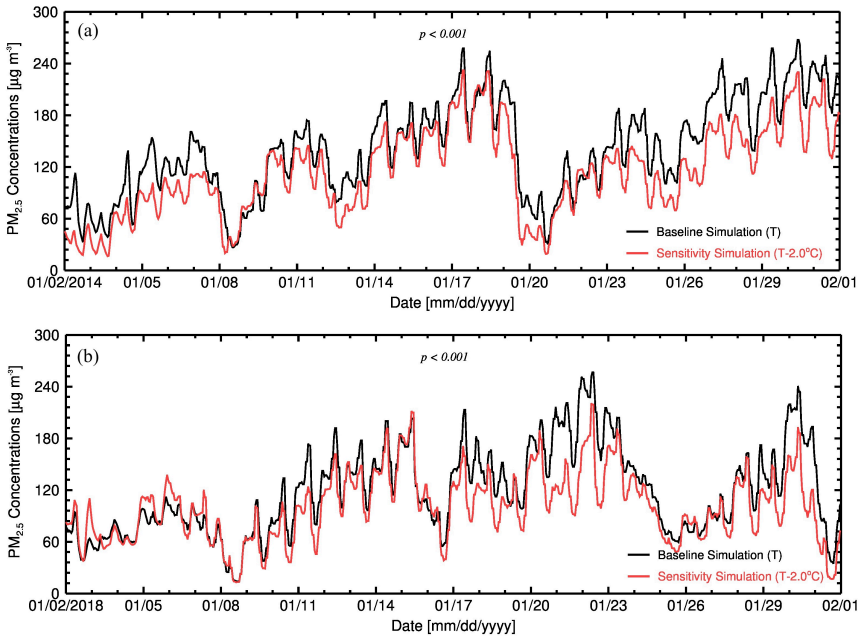

Figure 1 Time series of $PM_{2.5}$ concentration over the basin, the baseline simulation is selected in January

2014 and January 2018, in which the 2°C cooling occur over the plateau relative to the baseline simulation. The differences in $PM_{2.5}$ concentrations between the baseline simulation and sensitivity simulations are significant, exceeding 99.9% confidence level ($p < 0.001$).

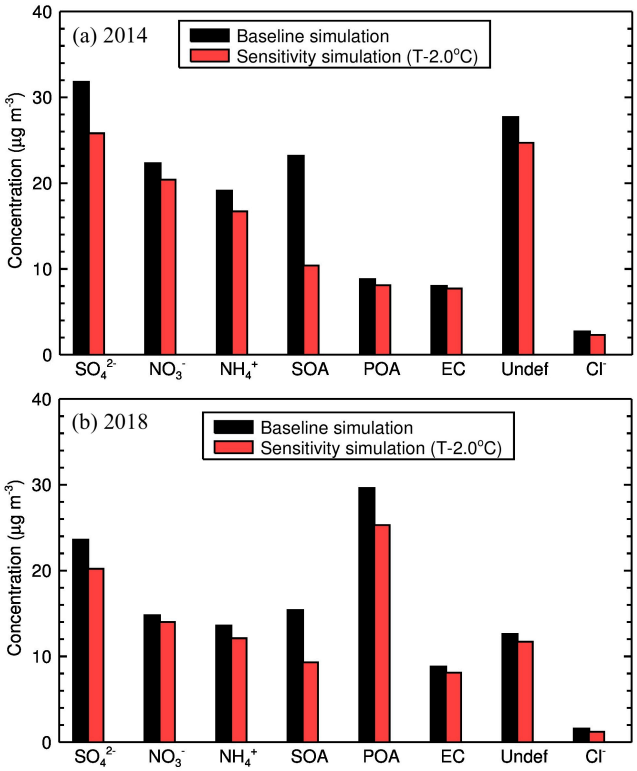

Figure 2 Comparisons of $PM_{2.5}$ chemical composition in the basin with (sensitivity simulation, red bar) and without (the baseline simulation, black bar) the 2.0°C cooling.

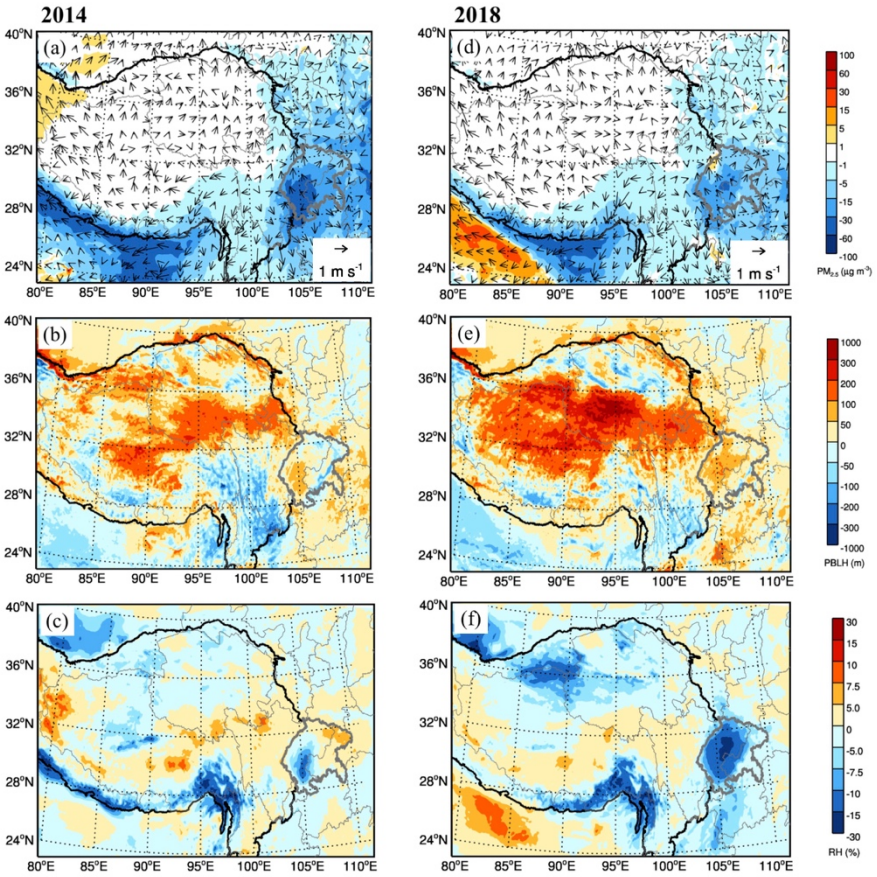

Figure 3 Differences in spatial distributions of surface $PM_{2.5}$ concentration and meteorological parameters (winds, PBLH and RH) between the baseline simulation and sensitivity simulation when the plateau cools by 2.0°C. (a) - (c) for the 2013-2014 winter. (d) - (f) for the 2017-2018 winter.

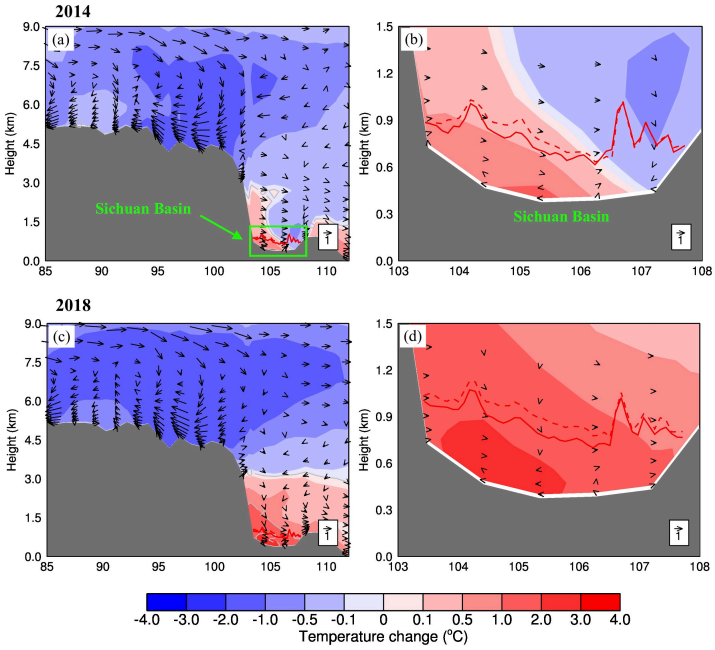

Figure 4 Vertical profiles of changes in temperature (shading and gray contour) and winds (arrows) along 30°N when the plateau cools by 2°C. The gray shaded area presents topography. The green box for the

Sichuan Basin, and the red solid (baseline simulation) and dash (sensitivity simulation) lines for the PBL height. (a) - (b) for the 2013-2014 winter, and (c) - (d) for the 2017-2018 winter.

Figure 1 shows that a cooling plateau also leads to a reduction of $PM_{2.5}$ concentration in the basin, and both the primary and secondary aerosols in $PM_{2.5}$ decrease when the plateau cools by 2°C (Figure 2). Here referring to the impact of a warming plateau, we briefly analyze the reason why $PM_{2.5}$ concentration decreases in the basin (Figures 3-4). In comparison with results from a warming and a cooling plateau, the significant differences are from the pressure change. Definitely, changes in the wind fields induced by the pressure change are opposite over the eastern plateau and the basin under these opposite circumstances (Figure 3a and Figure 3d, Figure 4). Nonetheless, wind changes both have enhanced the transport of pollutants in the Sichuan Basin to the surrounding regions, regardless of whether the plateau is warming or cooling.

The significant impact of the cooling or warming over the Tibetan Plateau on the basin concentrates on the temperature change. We found that a warming plateau is conducive to a cooling basin (Figure 10, Figures S11-12 in our study), vice versa, a cooling plateau is conducive a warming basin (as shown here). We speculate that the change of pressure gradient induced by the temperature change can explain the cause-to-effect relationship, referring to the text in Lines 349-354: "*We speculate that changes in the surface pressure can account for the maximal temperature reduction here. After the warming, surface pressure decreases in the basin (Figure 8, Figure S9b and Figure S9f, Figure S10b), which produces more convergent airflow (as shown in Figure 7, Figure S9a and Figure S9e, Figure S10a). The strengthened convergent airflow induces an intensified ascending motion, conducive to a reduction of temperature in the basin.*"

Changes in the RH and PBLH within the basin due to the temperature change over the plateau are not significant, so differences in the impacts of the changed RH and PBLH in the basin on air quality are not significant. In summary, air quality is all improved when the plateau is warming or cooling, this is mainly because that changes in winds are conducive to pollutants' transport. Changes in the RH and PBLH are conducive to $PM_{2.5}$ reduction in the basin.

Comment 2. In the model, the authors set to the 2°C warming at all grids covering the TP in the initial and boundary fields. However, this condition has not been considered for regions surrounding the TP. Have you considered gradual decrease in air temperature from the TP to the surrounding regions of the TP in the model?

Response: Yes, we considered that the temperature change follows the change in the true case, however, it is hardly to achieved it.

First of all, the settings of vertical layers and intervals are different between the model and reanalysis data, and we cannot accurately match them consistent with the true vertical profile of air temperature change. Secondly, we aim to calculate the impact of a warming plateau on air quality in the basin, so the warming in the surrounding regions of the plateau is not allowed to be considered. If we also consider the warming in these regions, we cannot separate the impact of the plateau and surrounding regions. Most importantly, the warming in surrounding regions is not significant (Figure 3 in the revised version), so the temperature from the plateau to the basin is not gradually decreased.

Thus, we select an average temperature change over the plateau as a sensitivity experiment to explain a warming plateau on the air quality in the basin.

Comment 3. Would you like to give general evaluation for the contribution of the warming of the TP on the air quality in the Sichuan Basin? For instance, when the air temperature increases by 0.5 degree or 1 degree, I wonder whether the air quality in the Sichuan Basin will be improved.

Response: We have added three new experiments that air temperature increases by 0.5°C, 1.0°C during the 2013-2014 winter, and air temperature increases by 2.0°C during the 2017-2018 winter over the plateau. Results show that air quality in the basin is also improved, consistent with the conclusion summarized in the original text. We added the results in Figs 5-6, Figures S6-S12 in Supplementary materials in the revised version.

The re-written text is also added in the revised manuscript:

Key points, Lines 21-25: *A warming plateau leads to an enhanced easterly wind, an increased PBLH and a decreased RH in the Sichuan Basin.*

The 2 ° C warming significantly reduces $PM_{2.5}$ concentration in the basin by 25.1 μg m^{-3}, of which secondary aerosol is 19.7 μg m^{-3}.

Abstract, Lines 34-39: *Here we use the WRF-CHEM model to lay emphasis on the impact of the 2 ° C warming on air quality in the basin. The model results show that the 2 ° C warming causes an enhanced easterly wind, an increase in the Planetary Boundary Layer height (PBLH) and a decrease in the relative humidity (RH) in the basin. Enhanced easterly wind increases $PM_{2.5}$ transport from the basin to the plateau. The elevated PBLH strengthens vertical diffusion*

of $PM_{2.5}$, while the decreased RH significantly reduces secondary aerosol formation.

Introduction, *Lines 90-103: In Section 4, we design three sets of numerical simulations to calculate the impact of climate change on air quality. One group includes two baseline simulations in two periods (January 2014 and January 2018), which are constrained by observed surface meteorological parameters and pollutant concentrations. The second group includes three sensitivity simulations during the 2013-2014 winter, which uses the same emission inventory and meteorological fields as the baseline simulation except for the changed air temperature. We also set the third sensitivity simulation, in which the plateau is also warming, but on the basis of the period for the 2017-2018 winter.*

Data and Methods, Lines 166-185: *According to the meteorological records at weather stations, surface air temperature risen by an average of 2°C from 2013 to 2017 over the plateau (Table S1). ERA-interim reanalysis data also show that the troposphere (600hPa - 250hPa) over the plateau is warming during the 2013-2017 period, and the temperature increment shows a parabolic pattern with the altitude, by an average increase of ~2°C (Figure S1).Thus, we design several sensitivity simulations, with an average temperature increase in the troposphere over the plateau, to assess impacts of a warming plateau on air quality in the basin. To eliminate the influence of simulation background, we conduct two baseline simulations for the 2013-2014 winter (January 2014) and the 2017-2018 winter (January 2018) as the control groups. The other two sets focus on sensitivity simulations that reflect an observational increase in air temperature over the plateau. At the year of 2014, the sensitivity simulation uses the same emission inventory and meteorological conditions as the baseline simulation except that the temperature in the troposphere over the plateau respectively increases by 0.5°C, 1.0°C and 2.0°C. The third group is a sensitivity simulation with an increase of 2.0°C on the basis of air temperature in January 2018. In the domain, we set to the warming at all grids covering the plateau (the region surrounded by the dark line in Figure 1b) in the initial and boundary fields. In order to ensure a persistent influence of the warming, we drive the initial field with a 0.5°C, 1.0°C , and 2°C increment every day in January 2014, and a 2°C increment every day in January 2018. Then, by comparing the difference between the sensitivity simulations and the baseline simulation, we determine the impact of the warming over the plateau on air quality in the basin.*

Results and Discussion, Lines 257-267: *To examine impacts of a warming plateau on $PM_{2.5}$ concentration in winter in the basin, we set three levels of temperature increase of 0.5°C, 1.0°C and 2.0°C over the plateau. Time series of $PM_{2.5}$ concentrations in these simulations (with and without the warming over the plateau) are respectively calculated. The results show that $PM_{2.5}$ concentration in the basin is significantly reduced (Figure 5). In comparison with three levels*

of temperature increase, the maximal reduction occurs in the case of 2°C warming, with an average of 25.1 μg m^{-3} ($p < 0.001$). Under the circumstance of the 2°C warming, the maximal hourly reduction reaches to 84.6 μg m^{-3} (Figure S6a) and the maximal percentage reduction is about 64.4% (Figure S6b). We also calculate the changes in $PM_{2.5}$ concentration and its percentage under the influence of the 2°C warming on the basis of January 2018 (Figure S7), of which the result is consistent with Figure S6, though there must inevitably be some differences in the magnitude.

Lines 275-289: *To better understand the impact of a warming plateau on $PM_{2.5}$ concentration, we also calculate changes in $PM_{2.5}$ chemical composition in the basin. Both primary and secondary aerosols in $PM_{2.5}$ decreases more significantly with an increase in temperature increment (Figure 6), except for the nitrate due to its competition for ammonia with sulfate (Feng et al., 2018). As a result, the more sulfate is reduced under the case of the 2°C warming, the less nitrate is reduced. As shown in Figure 6, the warmer the plateau is, the more $PM_{2.5}$ concentration and its chemical composition in the basin decrease, suggesting that a warming plateau has increasing implications for air quality in the basin. Here we show that the maximal impact of the plateau under the case of the 2°C warming, in which secondary aerosol reduces by 19.7 μg m^{-3}, accounting for 78.5% of the total reduction, greatly larger than the reduction of primary aerosol. For example, the largest reduction is SOA, reducing from 23.2 μg m^{-3} in the base case to 10.8 μg m^{-3} in the 2°C warming case. The second reduction is sulfate (from 31.8 μg m^{-3} to 28.6 μg m^{-3}). The next are nitrate and ammonium (22.3 μg m^{-3} and 19.1 μg m^{-3} in the base case, and 20.2 μg m^{-3} and 17.5 μg m^{-3} in the 2°C warming case). Significance testing of the difference in every chemical composition between the baseline simulation and the 2°C warming case is also given in Table S2.*

Lines 292-295: *Thus, we emphasize the impact of the 2°C warming over the plateau on $PM_{2.5}$ concentration in the basin in our study. Meanwhile, we analyze the case for the 2017-2018 winter, in which a similar change in $PM_{2.5}$ chemical composition is obtained when the plateau becomes 2°C warmer (Figure S8).*

Lines 302 -307: *Enhanced easterly winds and weakened westerly winds are both in favor of the east-to-west transport of pollutants from the basin to the plateau. We also show changes in $PM_{2.5}$ concentration and winds under the cases of 0.5°C and 1.0°C warming in January 2014, consistent with the result of the 2°C warming, except that the reduction of $PM_{2.5}$ concentration and the change in wind speed are fewer (Figure S9a and Figure S9e). The case in January 2018 (Figure S10a) is also similar to the result of the 2°C warming.*

Lines 332-335: *Our results suggest that the warming plateau plays different roles in the PBL development over the plateau and the basin. Due to the warming, the PBLH decreases in most*

areas of the plateau, but it increases over the basin (Figure 9, Figure S9c and Figure S9g, Figure S10c). The maximal rise occurs under the case of the 2°C warming, by 50 - 200 m over the basin (Figure 9 and Figure S10c).

Lines 337-352: *Thus, we explore the underlying cause that leads to the difference in the PBLH in the domain. The PBLH is strongly related to the changes in vertical temperature and wind, Figure 10 and Figures S11-12 display vertical profiles of changes in temperature and winds in the plateau and the basin. Results show that the warming causes a maximal warm layer around 1 km above the ground of the plateau. Noticeably, the warm layer acts as a dome covering 4.5 km above the Sichuan Basin (Figure 10a, Figure S11a and Figure S11c, Figure S12a). Xu et al. (2017) also finds out a significant warm plume extending from the plateau to the downstream Sichuan Basin and Yangtze River Delta by use of NCEP/NCAR reanalysis data. We suggest that this is probably due to a sharp topography decrease (from ~ 5 km in the plateau to < 1 km in the basin) which leads to a warm plume via subsidence. In the basin, there is a decrease in the temperature from the lower troposphere to ~ 4 km, with a maximal temperature reduction (0.5 - 2°C) located at 1.5 km to 3 km above the ground (Figure 10a, Figure S11a and Figure S11c, Figure S12a). We speculate that changes in the surface pressure can account for the maximal temperature reduction here. After the warming, surface pressure decreases in the basin (Figure 8, Figure S9b and Figure S9f, Figure S10b), which produces more convergent airflow (as shown in Figure 7, Figure S9a and Figure S9e, Figure S10a).*

Lines 375-380: *We examine the influence of in the RH change induced by a warming plateau on $PM_{2.5}$ concentration in the basin. Results show that there is remarkable change in RH in the basin due to the warming of the plateau (Figure 11, Figure S9d and Figure S9h, Figure S10d). In the baseline simulation, the RH varies in the range of 40% - 80% over the basin (Figure 11a). However, the RH varies from 50% to 70% in the 2 °C warming simulation (Figure 11b), suggesting that the basin becomes drier when the plateau is warmer.*

Conclusions, Lines 407-411: *The most significant impact of the plateau on $PM_{2.5}$ concentration in the basin occurs under the case of the 2°C warming. Through an enhanced horizontal transport, a reduced RH and an increased PBLH, the warming plateau significantly reduces $PM_{2.5}$ concentration in the basin. A larger pressure gradient from the basin to the plateau is favorable for an east-to-west transport for pollutants within the basin.*

Lines 421-422. *On average, $PM_{2.5}$ concentration reduces by 25.1 μg m^{-3} on the basis of the 2013-2014 winter, of which the primary and secondary aerosols decrease by 5.4 μg m^{-3} and 19.7 μg m^{-3}, respectively.*

The Warming Tibetan Plateau improves winter air quality in the Sichuan Basin, China

Abstract

Impacts of global climate change on the occurrence and development of air pollution have attracted more attentions. This study investigates impacts of the warming Tibetan Plateau on air quality in the Sichuan Basin. Meteorological observations and ERA-interim reanalysis data reveal that the plateau has been rapidly warming during the last 40 years (1979-2017), particularly in winter when the warming rate is approximately twice as much as the annual warming rate. Since 2013, the winter temperature over the plateau has even risen by 2 ° C. Here we use the WRF-CHEM model to lay emphasis on the impact of the 2 ° C warming on air quality in the basin. The model results show that the 2 ° C warming causes an enhanced easterly wind, an increase in the Planetary Boundary Layer height (PBLH) and a decrease in the relative humidity (RH) in the basin. Enhanced easterly wind increases $PM_{2.5}$ transport from the basin to the plateau. The elevated PBLH strengthens vertical diffusion of $PM_{2.5}$, while the decreased RH significantly reduces secondary aerosol formation. Overall, $PM_{2.5}$ concentration is reduced by 17.5% (~25.1 μg m^{-3}), of which the reduction in primary and secondary aerosols is 5.4 μg m^{-3} and 19.7 μg m^{-3}, respectively. These results reveal that the recent warming plateau has improved air quality in the basin, to some certain extent, mitigating the air pollution therein. Nevertheless, climate system is particularly complicated, and more studies are needed to demonstrate the impact of climate change on air quality in the downstream regions as the plateau is likely to continue warming.

Keywords: climate change, air quality, Tibetan Plateau, WRF-CHEM model

1 Introduction

The Tibetan Plateau is known as the third pole because of its high altitude and large area. It is also regarded as an important response region to the Northern Hemisphere, and even global climate due to its sensitivity to climate change. Previous studies on the Tibetan Plateau show that the region was experiencing warming in the second half of the 20th century, especially in the winter months (Kuang and Jiao, 2016; Liu and Chen, 2000; Rangwala et al., 2009). The warming plateau not only plays a significant role in driving the weather and climate change, as well as the ecological system, but also has an important impact on air quality in the downstream regions. Xu et al. (2016) suggest that the thermal anomaly over the Tibetan Plateau obviously increases haze frequency and surface aerosol concentration in central-eastern China.

However, the impacts of climate change on air quality in China are still unclear. Some researches hold the opinion that climate change induced by greenhouse gas emission increases severe haze occurrence and intensity in winter at Beijing, and its impact will continue in the future (Cai et al., 2017; Zou et al., 2017). Similarly, Xu et al. (2017) suggest that climate warming anomaly in the lower and middle troposphere over the continent around the Yangtze River Delta leads to more haze days in winter during recent decades. On the contrary, another opinion suggests that climate change in the past two decades is favorable for air pollution dispersion in northern China via enhancing mid-latitude cold surges in winter (Zhao et al., 2018). If cold surge is strong enough, pollutants would be transported to the downstream regions, causing a better air quality in the upstream region but a worse one in the downstream region. Thus, there may be regional differences in the impact of climate change on air quality.

Previous studies on air pollution in China are concentrated in the developed regions,

such as the North China Plain, the Yangtze River Delta and the Pearl River Delta. Few studies have paid attention to the Sichuan Basin, although the region is undergoing severe air pollution, and mean $PM_{2.5}$ concentration is more than 110 μg m^{-3} in winter (Qiao et al., 2019; Tao et al., 2017; Wang et al., 2018; Yang et al., 2011). Thus, it is necessary to explore the underlying causes that leads to air pollution in the Sichuan Basin.

The Sichuan Basin locates in the downstream region of the Tibetan Plateau, and its weather conditions are obviously affected by the plateau (Duan et al., 2012; Hua, 2017; Zhao et al., 2019). For instance, the foggy weather, southwest vortex and low-level shear line over the basin are closely associated with the plateau (Zhu et al., 2000). These changes in weather conditions induced by the plateau undoubtedly affect the development and dispersion of air pollution in the basin, because the huge terrain can trigger a thermodynamic forcing, which is of great importance for weather conditions in the surrounding regions (Bei et al., 2016; 2017; Zhao et al., 2015).

This study therefore focuses on how climate change on the Tibetan Plateau affects air quality in the Sichuan Basin in recent years. Section 3 analyzes the temperature change on the plateau in the past four decades, and especially emphasizes the change in recent five years. In Section 4, we design three sets of numerical simulations to calculate the impact of temperature change on air quality. One group includes two baseline simulations in two periods (January 2014 and January 2018), which are constrained by observed surface meteorological parameters and pollutant concentrations. The second group includes three sensitivity simulations during the 2013-2014 winter, which uses the same emission inventory and meteorological fields as the baseline simulation in January 2014 except for a changed air temperature. We also set the third sensitivity simulation, in which the plateau is also warming, but on the basis of the period for the 2017-2018 winter. We compare the difference in $PM_{2.5}$ concentrations in these cases,

and also calculate differences in meteorological parameters that include winds (wind speed and direction), air temperature, and relative humidity (RH), as well as the Planetary Boundary Layer height (PBLH). Based on the differences in $PM_{2.5}$ concentration and meteorological parameters above, we finally explain the cause-to-effect relationship between a warming plateau and changes in the winds, PBLH and RH in the Sichuan Basin. Moreover, we calculate the effect of the relationship on air quality in the basin.

2 Data and Methods

2.1 Observations

To ensure a robust result, we use two datasets of surface air temperature in this study. One is the European Center for Medium-Range Weather Forecasts (ECMWF) ERA-Interim monthly mean reanalysis data (1979-2018), obtained from the website of http://apps.ecmwf.int/datasets/, with the finest horizontal resolution of 0.125°×0.125°. The other is hourly and monthly mean weather-station observations from the National Oceanic and Atmospheric Administration (NOAA), available from http://gis.ncdc.noaa.gov/map/viewer/#app=clim&cfg=cdo&theme=hourly&layers=1&node=gis.

Figure 1 shows the distribution of weather stations over the Tibetan Plateau, and these weather stations widely cover the entire plateau. Trends of annual mean and winter surface air temperature over the plateau are analyzed, and the winter is averaged over 3-month periods (December-January-February). Additionally, we use ambient air quality data to validate the model performance. Since 2013, the data are released by Ministry of Environmental Protection, China at http://www.aqistudy.cn/, including hourly $PM_{2.5}$, CO, and O_3 mass concentrations. The monitoring stations for air quality

are also shown in Figure 1.

2.2 Model configuration and experiments

A state-of-the-art regional dynamical and chemical model (WRF-CHEM model) is used in the study. The simulation domain covers the Tibetan Plateau and the Sichuan Basin (Figure 1). The Tibetan Plateau covers about 2.5 million km^2, with the averaged elevation of 4500 m, and the Sichuan Basin covers about 0.16 million km^2, with the elevation in the center of the basin less than 1000 m (250 - 700 m). The model is set by a horizontal grid resolution of 9 km (451 × 221 grids), with 35 vertical sigma levels. The model description in detail is seen by Grell et al. (2005). The evaluation of the model performance has been conducted by many previous studies (Li et al., 2011a; Tie et al., 2009; 2007). In this study, we use the Goddard longwave and shortwave radiation parameterization (Dudhia, 1989), the WSM 6-class graupel microphysics scheme (Hong and Lim, 2006), the Mellor-Yamada-Janji (MYJ) planetary boundary layer scheme (Janjić, 2002), the unified Noah land-surface model (Chen and Dudhia, 2001) and Monin-Obukhov surface layer scheme (Janjić, 2002). For chemical schemes, we use a new flexible gas-phase chemical module and the Community Multiscale Air Quality (CMAQ, version 4.6) aerosol module developed by the US EPA (Binkowski, 2003). Gas-phase atmospheric reactions of volatile organic compounds (VOCs) and nitrogen oxide (NOx) use the SAPRC-99 (Statewide Air Pollution Research Center, version 1999) chemical mechanism. Inorganic aerosols use the ISORROPIA version 1.7, referring to Li et al. (2011a) and Feng et al. (2016). A SO_2 heterogeneous reaction mechanism on aerosol surfaces involving aerosol water is added (Li et al., 2017a), and NO_2 heterogeneous reaction to produce HONO is also considered (Li et al., 2010). The secondary organic aerosol (SOA) calculation uses a non-traditional volatility basis-set approach by Li et al. (2011b). The photolysis rates are calculated by a fast Tropospheric Ultraviolet and Visible (FTUV) radiation transfer model, in which the impacts of

aerosols and clouds on the photochemistry processes are considered (Li et al., 2011a; Tie et al., 2003; 2005). The wet deposition is calculated by the method used in CMAQ and the dry deposition follows Wesely (1989).

We use the MIX anthropogenic emission inventory for the year of 2010, and it is available at Multi-resolution Emission Inventory for China (http://www.meicmodel.org/dataset-mix.html), consisting of industrial, power, transportation, and agricultural as well as residential sources (Li et al., 2017b; Zhang et al., 2009). The emission inventory is constructed by a 'bottom-up' approach based on national and provincial activity data and emission factors. To improve the emission inventory accuracy, we use a 'top-down' method here to constrain the emission inventory. We compare the simulated value with the measured value time and again until the simulations are close to the measurements. The biogenic emissions are online calculated by the Model of Emissions of Gases and Aerosol from Nature (MEGAN) (Guenther et al., 2006). Initial and boundary meteorological fields in the model are driven by 6-hour 1° × 1° NCEP (National Centers for Environmental Prediction) reanalysis data. Chemical lateral conditions are provided by a global chemistry transport model – MOZART (Model for OZone And Related chemical Tracer, version 4), with a 6-h output (Emmons et al., 2010; Tie et al., 2005). The spin-up time of the WRF-CHEM model is 1 day.

According to the meteorological records at weather stations, surface air temperature risen by an average of 2°C from 2013 to 2017 over the plateau (Table S1). ERA-interim reanalysis data also show that the troposphere (600hPa - 250hPa) over the plateau is warming during the 2013-2017 period, and the temperature increment shows a parabolic pattern with the altitude, by an average increase of ~2°C (Figure S1).Thus, we design several sensitivity simulations, with an average temperature increase in the troposphere over the plateau, to assess impacts of a warming plateau on air quality in

the basin. To eliminate the influence of simulation background, we conduct two baseline simulations for the 2013-2014 winter (January 2014) and the 2017-2018 winter (January 2018) as the control groups. The other two sets focus on sensitivity simulations that reflect an observational increase in air temperature over the plateau. At the year of 2014, the sensitivity simulation uses the same emission inventory and meteorological conditions as the baseline simulation except that the temperature in the troposphere over the plateau respectively increases by 0.5°C, 1.0°C and 2.0°C. The third group is a sensitivity simulation with an increase of 2.0°C on the basis of air temperature in January 2018. In the domain, we set to the warming at all grids covering the plateau (the region surrounded by the dark line in Figure 1b) in the initial and boundary fields. In order to ensure a persistent influence of the warming, we drive the initial field with a 0.5°C, 1.0°C , and 2°C increment every day in January 2014, and a 2°C increment every day in January 2018. Then, by comparing the difference between the sensitivity simulations and the baseline simulation, we determine the impact of the warming over the plateau on air quality in the basin.

3 The warming Tibetan Plateau in the last four decades

Figure 2 shows the variability and linear trend of surface air temperature at 10 weather stations over the Tibetan Plateau in winter during the last four decades (1979 - 2017). The winter mean temperature recorded from all the weather stations exhibits an obvious annual fluctuation and the linear regression shows a significant rising trend. Clearly, the plateau is continuously undergoing a warming phase, albeit with regional differences in the warming magnitude. The warming rates in different regions vary in the range of 0.5 - 1.0°C decade^{-1}. Compared with the warming rate of annual mean temperature (Figure S2), the warming rate in winter is approximately twice as much, suggesting that the warming in winter is more significant.

Using the ERA-interim reanalysis data, Figure 3 shows the temperature change during the same period (1979 - 2017). The result is consistent with weather records, showing that air temperature is significantly rising in most parts of the plateau. The maximal warming rate is around 0.6 - 0.8°C decade^{-1}, appeared in the central and southern plateau. The warming in the rest areas is slighter, with a rate of 0.3 - 0.6 °C decade^{-1}. Particularly, the averaged warming rate in the vast central plateau reaches about 1.0°C yr^{-1} in recent five years (Figure S3), greater than the warming rate during the entire 40 years (Figure 3). Both the observation records and reanalysis data evidently show that the plateau has been warming in the last four decades, and also the warming trend for recent years is more significant.

From the above temperature change analysis, we notice that there is obviously a positive temperature anomaly between 2013 and 2017 winters, implying for an accelerating warming over the plateau. The observational temperature in winter increases by about 2°C between 2013 and 2017. Therefore, we assess the impact of a warming plateau on air quality in the Sichuan Basin.

4 Results and Discussion

4.1 Model validation

To systemically evaluate the model performance on simulation O_3, CO and $PM_{2.5}$ mass concentrations, three statistical indices are used. They are the mean bias (MB), root mean square error (RMSE), and index of agreement (IOA). The calculation formulas are given in Text S1. The IOAs of air temperature and RH are 0.85 and 0.79, respectively (Figure S4a and Figure S4b), suggesting that the model well captures the diurnal cycle of temperature and the variability of RH. However, the calculated wind speed is overestimated, especially in the region between the Tibetan Plateau and the

Sichuan Basin. This is because there is a dramatic elevation drop in the region, which makes it difficult for the model to replicate the observed wind speed and direction.

Figure 4 shows comparisons of hourly O_3, CO and $PM_{2.5}$ concentrations between the model simulations and measurements. The result shows that the simulated CO mean level is close to the measurement, with a MB of 0.11 mg m^{-3}, indicating that the model reasonably reproduces the meteorological fields and long-range transport. Because the chemical lifetime of CO is relatively long (~months), the variability of CO is dominantly determined by the meteorological fields and atmospheric transport process. For the simulation of O_3, in addition to the effects of meteorological fields and atmospheric transport process, its variability is strongly controlled by the photochemical process. The model result shows that the simulated diurnal cycle of O_3 is reasonably agreed with the measurement, with an IOA of 0.79. There is only a small bias between the simulated and measured O_3 mean concentration. The simulated O_3 concentration is 1.7 μg m^{-3} higher than the measurement, suggesting that both the photochemistry and long-range transport well capture the O_3 variability in the region. Finally, the IOA between the simulated and measured $PM_{2.5}$ concentrations is 0.80, indicating that the aerosol module in the model generally captures the measured $PM_{2.5}$ variation.

However, there are some noticeable discrepancies between the simulations and the measurements. For instance, the simulated magnitude of $PM_{2.5}$ concentration is larger than the measurement, and its mean level is underestimated by 13.1 μg m^{-3}, less than 10% of the measurement (~153.5 μg m^{-3}). These discrepancies are likely due to the biases in the uncertainties in emission inventory and small-scale dynamical fields. During the period of Jan 17th to Jan 20th, the observed wind speed concentrates in the range of 1 - 2 m s^{-1}, with an average of 1.3 m s^{-1}, while the simulated wind speed is obviously higher, with an average of 2.0 m s^{-1} (Figure S4c). The observed prevailing

wind is northerly wind while the simulated prevails easterly wind (Figure S4d). Figure S5a shows that $PM_{2.5}$ concentration is lower in the north to the Sichuan Basin while higher to in the east to the basin. Therefore, the overestimated $PM_{2.5}$ concentration is mainly caused by the departure of winds, which results in a false transport from the east to the basin. This is also shown by the overestimation of CO concentration because the observed northerly wind is not well simulated due to the complicated topography.

4.2 Change in winter $PM_{2.5}$ concentration over the basin

To examine impacts of a warming plateau on $PM_{2.5}$ concentration in winter in the basin, we set three levels of temperature increase of 0.5°C, 1.0°C and 2.0°C over the plateau. Time series of $PM_{2.5}$ concentrations in these simulations (with and without the warming over the plateau) are respectively calculated. The results show that $PM_{2.5}$ concentration in the basin is significantly reduced (Figure 5). In comparison with three levels of temperature increase, the maximal reduction occurs in the case of 2°C warming, with an average of 25.1 μg m^{-3} ($p < 0.001$). Under the circumstance of the 2°C warming, the maximal hourly reduction reaches to 84.6 μg m^{-3} (Figure S6a) and the maximal percentage reduction is about 64.4% (Figure S6b). We also calculate the changes in $PM_{2.5}$ concentration and its percentage under the influence of the 2°C warming on the basis of January 2018 (Figure S7), of which the result is consistent with Figure S6, though there must inevitably be some differences in the magnitude. Interestingly, the maximal reduction always occurs while $PM_{2.5}$ concentration reaches a peak value, which suggests that the impact of the warming plateau is extremely significant during the period of high $PM_{2.5}$ concentration. This result is similar to previous studies which also point out that extreme weather plays important roles in affecting air quality (De Sario et al., 2013; Hong et al., 2019; Tsangari et al., 2016; Zhang et al., 2016). That is to say, the impact of the warming plateau on air quality is apt to be amplified in extremely high $PM_{2.5}$ concentrations.

To better understand the impact of a warming plateau on $PM_{2.5}$ concentration, we also calculate changes in $PM_{2.5}$ chemical composition in the basin. Both primary and secondary aerosols in $PM_{2.5}$ decreases more significantly with an increase in temperature increment (Figure 6), except for the nitrate due to its competition for ammonia with sulfate (Feng et al., 2018). As a result, the more sulfate is reduced under the case of the 2°C warming, the less nitrate is reduced. As shown in Figure 6, the warmer the plateau is, the more $PM_{2.5}$ concentration and its chemical composition in the basin decrease, suggesting that a warming plateau has increasing implications for air quality in the basin. Here we show that the maximal impact of the plateau under the case of the 2°C warming, in which secondary aerosol reduces by 19.7 μg m^{-3}, accounting for 78.5% of the total reduction, greatly larger than the reduction of primary aerosol. For example, the largest reduction is SOA, reducing from 23.2 μg m^{-3} in the base case to 10.8 μg m^{-3} in the 2°C warming case. The second reduction is sulfate (from 31.8 μg m^{-3} to 28.6 μg m^{-3}). The next are nitrate and ammonium (22.3 μg m^{-3} and 19.1 μg m^{-3} in the base case, and 20.2 μg m^{-3} and 17.5 μg m^{-3} in the 2°C warming case). Significance testing of the difference in every chemical composition between the baseline simulation and the 2°C warming case is also given in Table S2. The *p*-values of most chemical composition in $PM_{2.5}$ are far less than 0.001 except that the *p*-value of EC is 0.0011 (Table S2), implying for an extremely significant reduction of every chemical composition in $PM_{2.5}$ within the basin when the plateau warms by 2°C. Thus, we emphasize the impact of the 2°C warming over the plateau on $PM_{2.5}$ concentration in the basin in our study. Meanwhile, we analyze the case for the 2017-2018 winter, in which a similar change in $PM_{2.5}$ chemical composition is obtained when the plateau becomes 2°C warmer (Figure S8).

There are also significant changes in the spatial distribution of $PM_{2.5}$ concentration. Figure 7 shows the spatial distribution of changes in surface $PM_{2.5}$ concentration and

winds after 2°C warming over the plateau. Apparently, there is a larger decrease in $PM_{2.5}$ concentration in the whole basin, and the maximal reduction is more than 30 μg m^{-3}. By contrast, $PM_{2.5}$ concentration increases by 5 - 15 μg m^{-3} at the eastern edge of the plateau. Wind patterns show that easterly winds over the basin enhance while westerly wind over the plateau weaken (Figure S5 and Figure 7). Enhanced easterly winds and weakened westerly winds are both in favor of the east-to-west transport of pollutants from the basin to the plateau. We also show changes in $PM_{2.5}$ concentration and winds under the cases of 0.5°C and 1.0°C warming in January 2014, consistent with the result of the 2°C warming, except that the reduction of $PM_{2.5}$ concentration and the change in wind speed are fewer (Figure S9a and Figure S9e). The case in January 2018 (Figure S10a) is also similar to the result of the 2°C warming.

We further compare the difference in the surface pressure between the baseline and sensitivity simulations, and find out that surface pressure over the plateau and the basin all decreases when the plateau warms (Figure 8a and 8b). Over the plateau, the pressure drop has a decrease characteristic from west to east (Figure 8c, Figure S9b and Figure S9f, Figure S10b), which results in a decreased pressure gradient and a weakened westerly wind. While in the basin, the pressure drop is less than the plateau. This leads to an increased pressure gradient from the basin to the plateau, inducing an intensified easterly wind. The enhanced easterly wind causes an increased transport of $PM_{2.5}$ from the basin to the plateau. On the other hand, the weakened westerly wind and the enhanced easterly wind are convergent at the border between the plateau and the basin (Figure 7, Figure S9a and Figure S9e, Figure S10a), jointly leading to an increase in $PM_{2.5}$ concentration at the eastern edge of the plateau. Additionally, northerly winds over the basin slightly enhance, conducive to diluting the air and reducing $PM_{2.5}$ concentration. Both easterly winds transport and northerly winds dilution are favorable for a reduction of $PM_{2.5}$ concentration in the basin. In addition to the wind effect, there are also other important factors to produce the $PM_{2.5}$ reduction in the basin, such as the

PBLH and RH, which will be analyzed as follows.

4.3 Impact of PBLH on $PM_{2.5}$ concentration

Previous studies show that the PBL development plays an important role in diffusing pollutants (Miao et al., 2017; Su et al., 2018; Tie et al., 2015). Here we calculate the change in the PBLH due to the 2°C warming over the plateau, and then analyze the effect of the change in PBLH on $PM_{2.5}$ concentration in the basin.

Our results suggest that the warming plateau plays different roles in the PBL development over the plateau and the basin. Due to the warming, the PBLH decreases in most areas of the plateau, but it increases over the basin (Figure 9, Figure S9c and Figure S9g, Figure S10c). The maximal rise occurs under the case of the 2°C warming, by 50 - 200 m over the basin (Figure 9 and Figure S10c). As known, a shallow PBL constrains $PM_{2.5}$ near the surface via suppressing vertical dispersion (Fan et al., 2011; Iversen, 1984). Conversely, a deep PBL is favorable for $PM_{2.5}$ diffusion. Thus, we explore the underlying cause that leads to the difference in the PBLH in the domain. The PBLH is strongly related to the changes in vertical temperature and wind, Figure 10 and Figures S11-12 display vertical profiles of changes in temperature and winds in the plateau and the basin. Results show that the warming causes a maximal warm layer around 1 km above the ground of the plateau. Noticeably, the warm layer acts as a dome covering 4.5 km above the Sichuan Basin (Figure 10a, Figure S11a and Figure S11c, Figure S12a). Xu et al. (2017) also finds out a significant warm plume extending from the plateau to the downstream Sichuan Basin and Yangtze River Delta by use of NCEP/NCAR reanalysis data. We suggest that this is probably due to a sharp topography decrease (from ~ 5 km in the plateau to < 1 km in the basin) which leads to a warm plume via subsidence. In the basin, there is a decrease in the temperature from the lower troposphere to ~ 4 km, with a maximal temperature reduction (0.5 - 2°C)

located at 1.5 km to 3 km above the ground (Figure 10a, Figure S11a and Figure S11c, Figure S12a). We speculate that changes in the surface pressure can account for the maximal temperature reduction here. After the warming, surface pressure decreases in the basin (Figure 8, Figure S9b and Figure S9f, Figure S10b), which produces more convergent airflow (as shown in Figure 7, Figure S9a and Figure S9e, Figure S10a). The strengthened convergent airflow induces an intensified ascending motion, conducive to a reduction of temperature in the basin. As a result, the zone where the maximal temperature drop appears, overlaps with the zone with the maximal ascending motion. Furthermore, the intensified updraft increases the vertical temperature gradient and the instability in the lower troposphere of the basin, thereby causing a higher PBLH than that in the non-warming case (Figure 10b, Figure S11b and Figure S11d, Figure S12b). On the contrary, the change in vertical temperature profile leads to a decreased vertical temperature gradient and increased thermal stability in the lower troposphere of the plateau, in which the PBLH decreases.

On the other hand, the convergent airflows by a weakened westerly wind over the plateau and a strengthened easterly wind in the basin triggers an ascending motion on the east side of the plateau (Figure 10a, Figure S11a and Figure S11c, Figure S12a), which is also beneficial to the development of the PBLH in the basin. Consequently, the elevated PBL facilitates vertical diffusion, leading to a reduction in $PM_{2.5}$ concentration over the basin.

4.4 Effect of RH on $PM_{2.5}$ concentration

In addition to the PBLH, ambient RH is a key factor for secondary aerosol formation (Tie et al., 2017; Wang et al., 2016). Previous studies indicate that aerosol hygroscopic growth cannot occurs until the humidity exceeds 50% (Liu et al., 2008). When the humidity is greater than 60%, hygroscopic growth factor of urban aerosol increases significantly with humidity (Liu et al., 2008).

We examine the influence of in the RH change induced by a warming plateau on $PM_{2.5}$ concentration in the basin. Results show that there is remarkable change in RH in the basin due to the warming of the plateau (Figure 11, Figure S9d and Figure S9h, Figure S10d). In the baseline simulation, the RH varies in the range of 40% - 80% over the basin (Figure 11a). However, the RH varies from 50% to 70% in the 2 °C warming simulation (Figure 11b), suggesting that the basin becomes drier when the plateau is warmer.

The RH comparison between these numerical simulations reveals that the warming causes a decrease in the RH within the basin (Figure 11c, Figure S9d and Figure S9h, Figure S10d). These changes in RH have critical effects on the secondary aerosol formation. As explained by Tie et al. (2017), the reduction of RH (especially during the stage of RH from 80% to 70%) causes a significant decrease of hygroscopic growth on the aerosol surface, resulting in less water surface for producing secondary aerosol, such as sulfate and nitrate. As a result, $PM_{2.5}$ concentration decreases in the basin. There are also some fingerprints of the RH's effect on $PM_{2.5}$ concentration. Firstly, the spatial distributions of RH reduction and $PM_{2.5}$ concentration reduction have similar patterns (Figure 11c and Figure 7, Figure S9a and Figure S9d, Figure S9e and Figure S9h, Figure S10a and Figure S10d), and the region with more humidity decrease overlaps the region with more $PM_{2.5}$ decreases. Secondly, as shown in Figure 6, the changes in $PM_{2.5}$ compositions indicate that the reduced $PM_{2.5}$ concentration is mainly caused by the decrease in secondary aerosol concentration. Therefore, the RH change also plays an important role for $PM_{2.5}$ concentration in the basin.

5 Conclusions

ERA-interim reanalysis data and observation records at 10 weather stations show that

the Tibetan Plateau is significantly warming during the past four decades (1979-2017), particularly in winter. The temperature increase rate is 0.5°C decade^{-1} to 1.0°C decade^{-1} in winter, approximately twice as much as the increase rate of annual mean temperature. In recent 5 years (2013-2017), the central plateau is significantly warming with an increase rate of 1.0°C yr^{-1}, encompassing the warming rate during the entire 40 years. Rapid warming has caused the winter temperature to increase by an average of 2°C over the entire plateau from 2013 to 2017.

The WRF-Chem model is used to assess the impact of a warming plateau on air quality over the downstream Sichuan Basin. The most significant impact of the plateau on $PM_{2.5}$ concentration in the basin occurs under the case of the 2°C warming. Through an enhanced horizontal transport, a reduced RH and an increased PBLH, the warming plateau significantly reduces $PM_{2.5}$ concentration in the basin. A larger pressure gradient from the basin to the plateau is favorable for an east-to-west transport for pollutants within the basin. A lower ambient RH decreases aerosol hygroscopic growth, which weakens secondary aerosol formation and leads to a significant reduction in secondary aerosol concentration. Moreover, the warming induces an increase in vertical temperature gradient over the basin, strengthening turbulence mixing and elevating PBLH. The elevated PBLH is favorable for vertical diffusion that causes a reduction of $PM_{2.5}$ in the basin. Additionally, the uplift effect by an enhanced ascending motion at the eastern edge of the plateau also contributes to $PM_{2.5}$ reduction within the basin.

In summary, the warming over the plateau in recent five years comprehensively induces a rising PBLH and a drying ambient air over the basin, which greatly reduces $PM_{2.5}$ secondary compositions. On average, $PM_{2.5}$ concentration reduces by 25.1 μg m^{-3} on the basis of the 2013-2014 winter, of which the primary and secondary aerosols decrease by 5.4 μg m^{-3} and 19.7 μg m^{-3}, respectively. Since the plateau is likely to continue warming, in-depth understanding to climate change on the Tibetan Plateau is

472 required. Long-term $PM_{2.5}$ monitoring is also needed to validate the impact of the
473 warming plateau on air quality.

Figure captions

Figure 1 (a) Location map of the Tibetan Plateau (the region surrounded by the dark line) and the Sichuan Basin (the region surrounded by the gray line). (b) The model domain and the distribution of weather stations marked in the triangles over the Tibetan Plateau and air quality stations marked in the circles over the Sichuan Basin.

Figure 2 Trends of observational winter (Dec-Jan-Feb) mean temperature anomaly recorded by 10 weather stations over the Tibetan Plateau during the last four decades (1979-2017).

Figure 3 Trends of ERA-interim reanalysis winter mean temperature over the Tibetan Plateau from 1979 to 2017. The dotted regions show statistical significance with 95% confidence level (p-value < 0.05) from the Student's t test.

Figure 4 Comparison between the observed (black dots) and simulated (blue line) hourly O_3 ($\mu g\ m^{-3}$), CO ($mg\ m^{-3}$) and $PM_{2.5}$ mass concentration ($\mu g\ m^{-3}$) over the Sichuan Basin in January 2014.

Figure 5 Time series of $PM_{2.5}$ concentration over the Sichuan Basin, the baseline simulation is selected in January 2014 and the sensitivity simulations in which 0.5°C, 1.0°C, and 2°C warming occur over the Tibetan Plateau relative to the baseline simulation. The differences in $PM_{2.5}$ concentrations between the baseline simulation and sensitivity simulations are significant, exceeding 99.9% confidence level ($p < 0.001$).

Figure 6 Comparisons of $PM_{2.5}$ chemical composition in the Sichuan Basin between the baseline simulation (black) and sensitivity simulations that the plateau warms by 0.5°C (green), 1.0°C (yellow) and 2.0°C (red).

Figure 7 Difference in spatial distributions of surface $PM_{2.5}$ concentration (shading) and winds (arrows) between the sensitivity simulation and baseline simulation. The negative shows $PM_{2.5}$ concentration decreases and the positive shows $PM_{2.5}$ concentration increases when the Tibetan Plateau is 2°C warming.

Figure 8 Comparison of spatial distributions of sea level pressure (SLP) between the (a) baseline simulation and (b) sensitivity simulation over the Tibetan Plateau and Sichuan Basin. (c) Changes in SLPs (sensitivity simulation *minus* baseline simulation) over the plateau and basin while the plateau becomes 2°C warming.

Figure 9 Spatial change in the PBLH induced by 2°C warming over the Tibetan Plateau. The positive shows the PBLH increases while the negative shows the PBLH decreases.

Figure 10 Vertical profiles of changes in temperature (shading and gray contour) and winds (arrows) along 30°N in January 2014. The gray shaded area presents topography. The green box for the Sichuan Basin, and the red solid (baseline simulation) and dash (sensitivity simulation) lines for the PBLH. (a) The Tibetan Plateau and Sichuan Basin, and (b) The Sichuan Basin.

Figure 11 Comparison of spatial distributions of RH between (a) baseline simulation and (b) sensitivity simulation over the Tibetan Plateau and Sichuan Basin. (c) Similar to Figure 9, but for RH spatial changes when the plateau becomes 2°C warming, and the positive shows the RH increases while the negative shows the RH decreases.

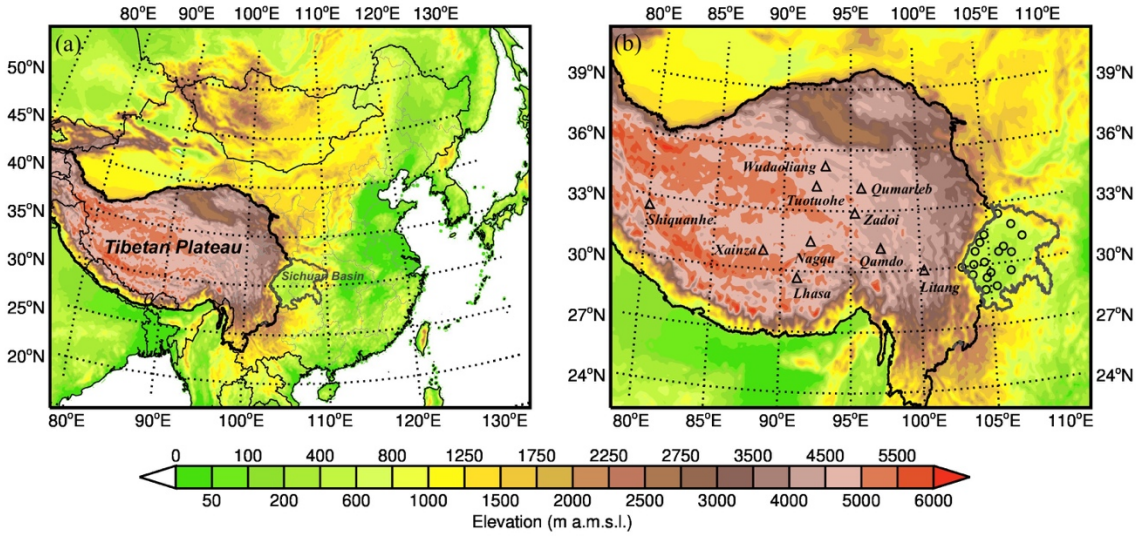

Figure 1 (a) Location map of the Tibetan Plateau (the region surrounded by the dark line) and the Sichuan Basin (the region surrounded by the gray line). (b) The model domain and the distribution of weather stations marked in the triangles over the Tibetan Plateau and air quality stations marked in the circles over the Sichuan Basin.

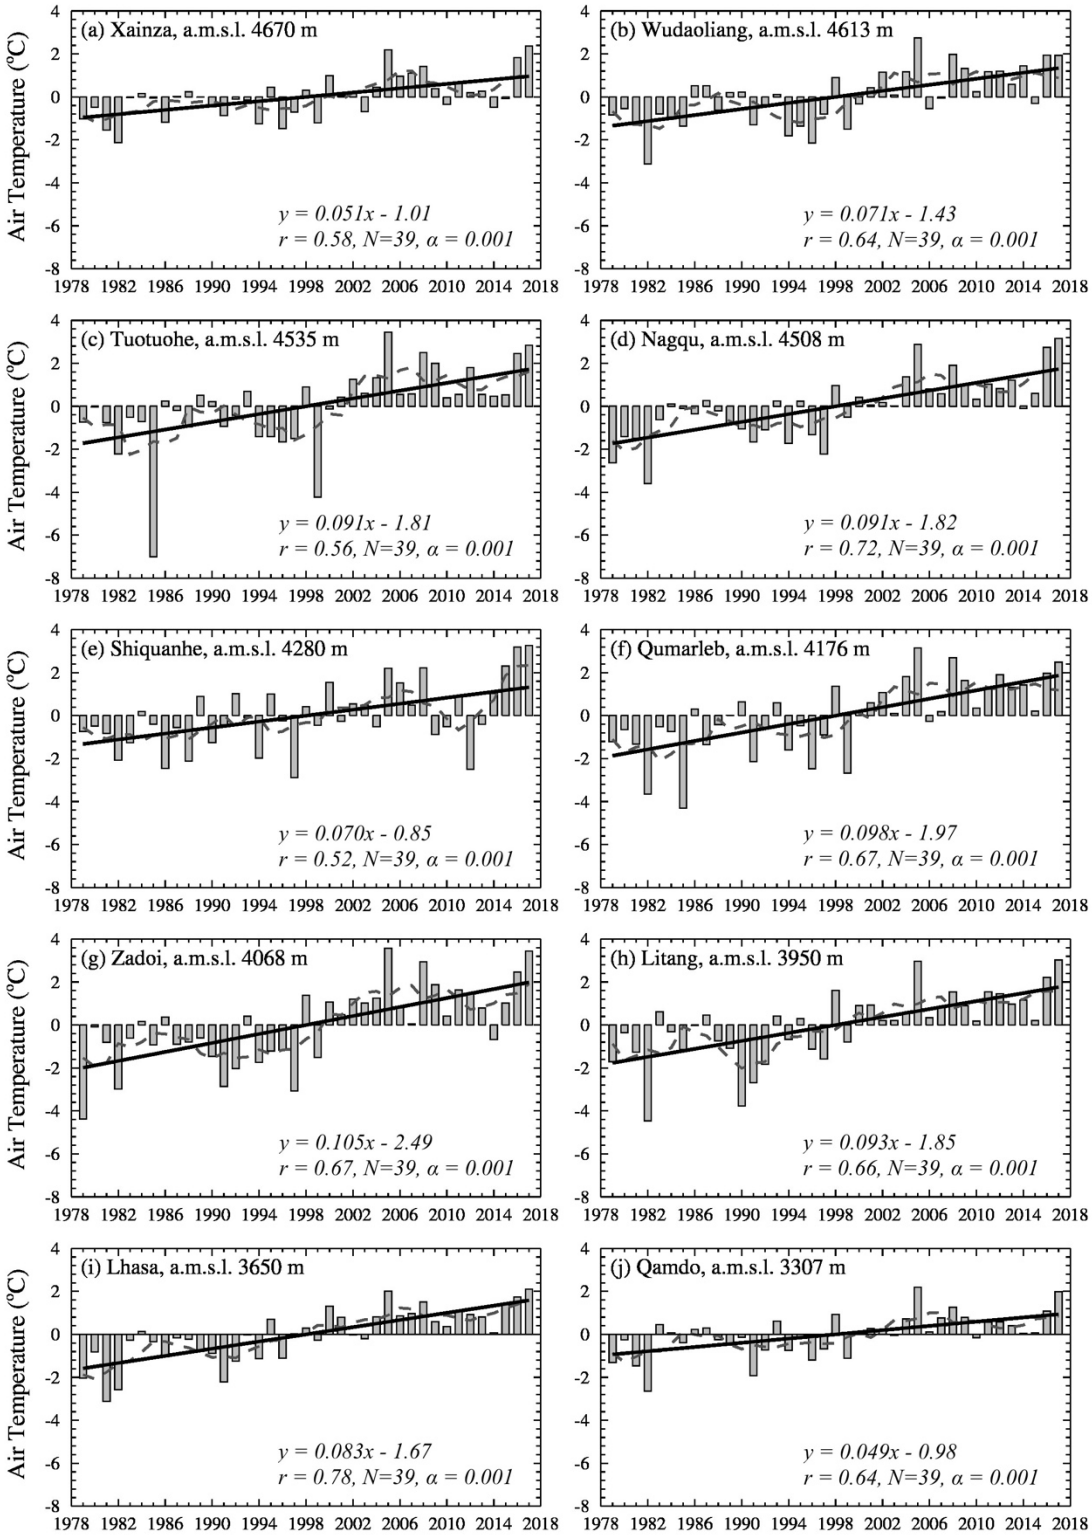

Figure 2 Trends of observational winter (Dec-Jan-Feb) mean temperature anomaly recorded by 10 weather stations over the Tibetan Plateau during the last four decades (1979-2017).

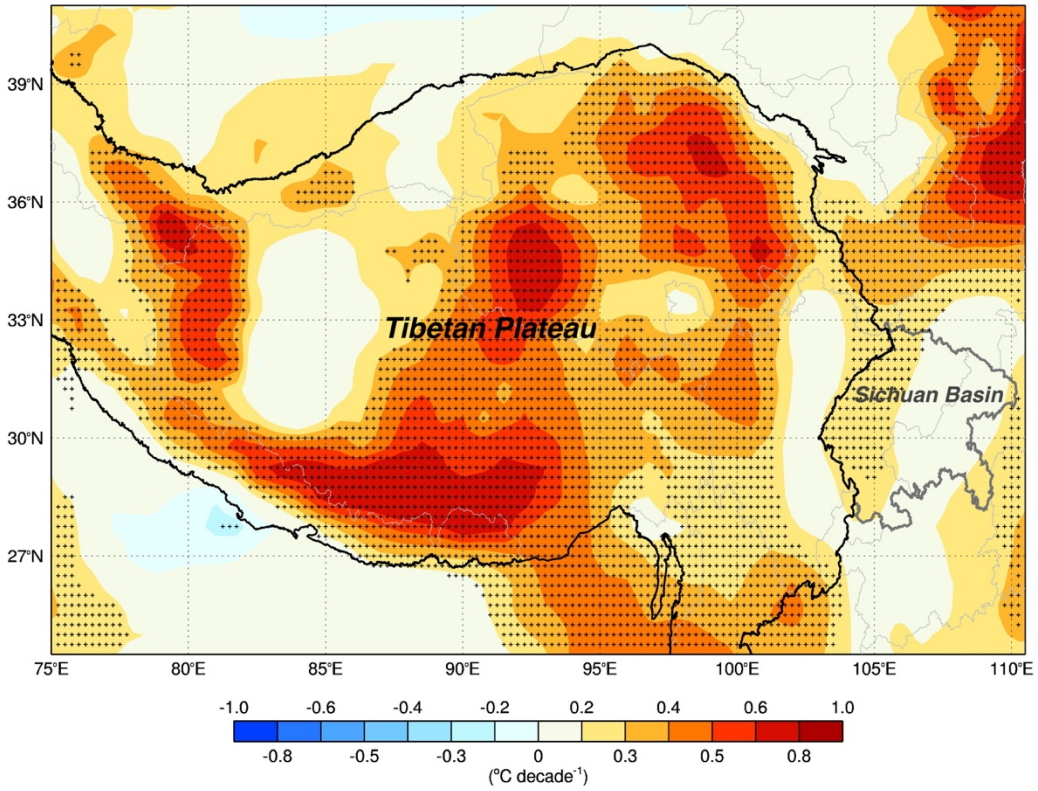

Figure 3 Trends of ERA-interim reanalysis winter mean temperature over the Tibetan Plateau from 1979 to 2017. The dotted regions show statistical significance with 95% confidence level (p-value < 0.05) from the Student's t test.

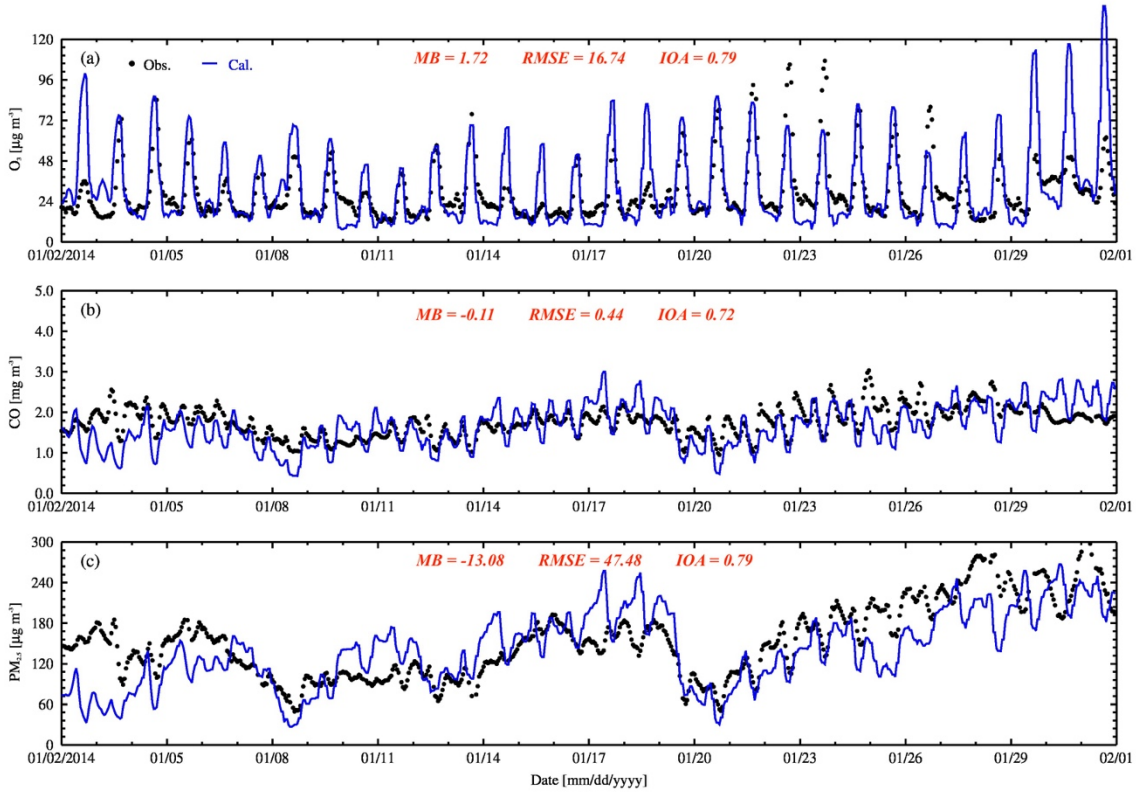

Figure 4 Comparison between the observed (black dots) and simulated (blue line) hourly O_3 (μg m^{-3}), CO (mg m^{-3}) and $PM_{2.5}$ mass concentration (μg m^{-3}) over the Sichuan Basin in January 2014.

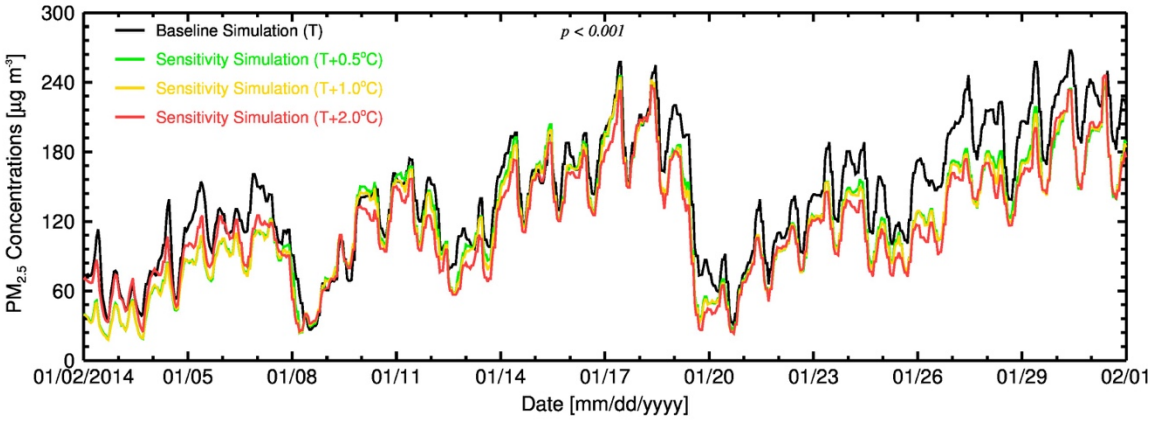

Figure 5 Time series of $PM_{2.5}$ concentration over the Sichuan Basin, the baseline simulation is selected in January 2014 and the sensitivity simulations in which 0.5°C, 1.0°C, and 2°C warming occur over the Tibetan Plateau relative to the baseline simulation. The differences in $PM_{2.5}$ concentrations between the baseline simulation and sensitivity simulations are significant, exceeding 99.9% confidence level ($p < 0.001$).

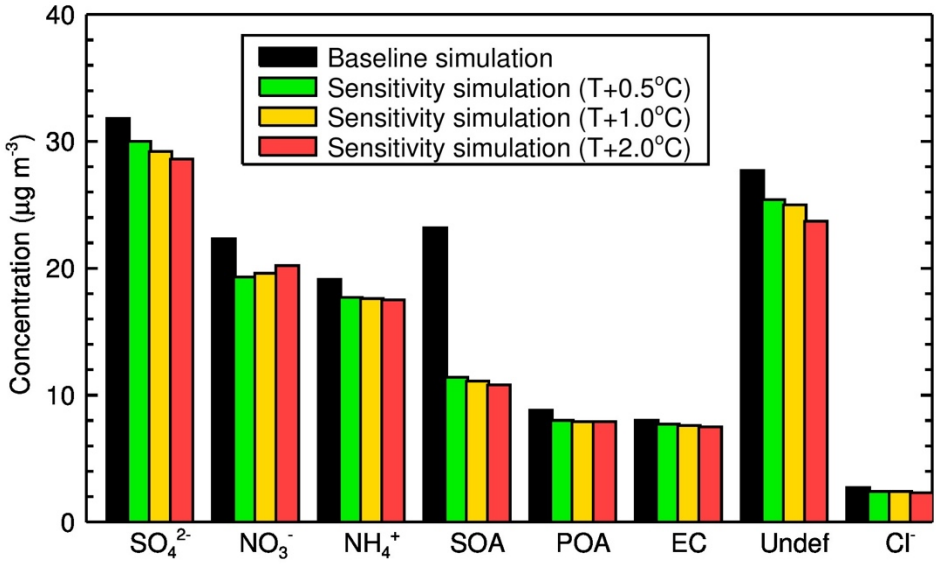

Figure 6 Comparisons of $PM_{2.5}$ chemical composition in the Sichuan Basin between the baseline simulation (black) and sensitivity simulations that the plateau warms by 0.5°C (green), 1.0°C (yellow) and 2.0°C (red).

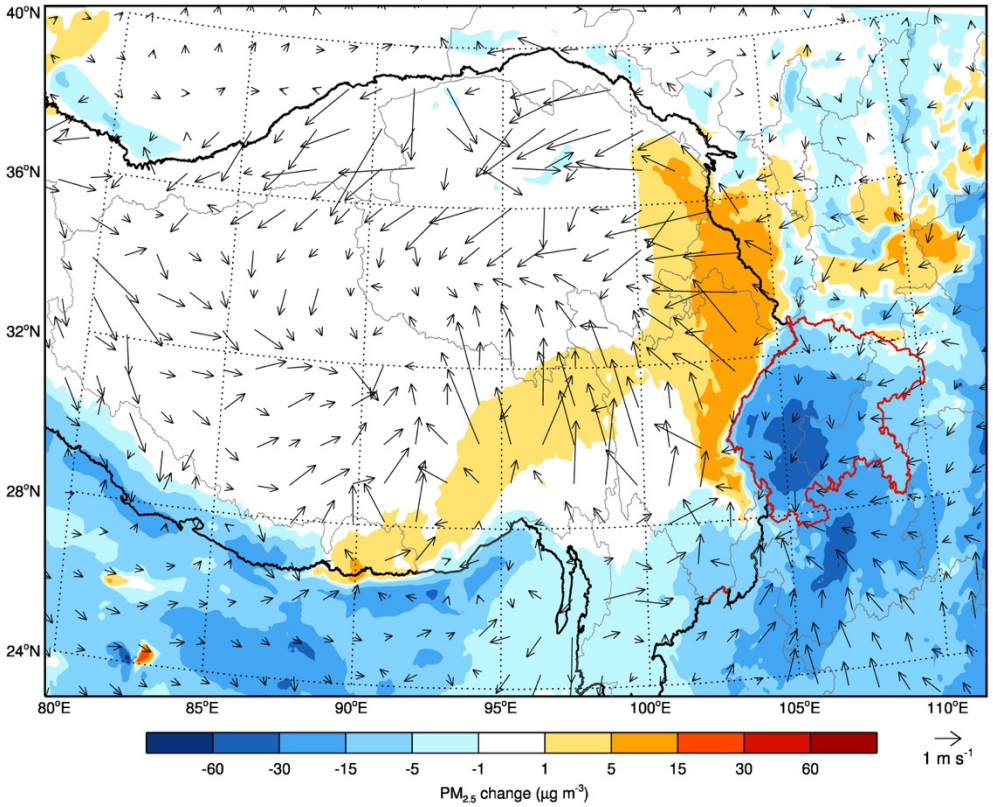

Figure 7 Difference in spatial distributions of surface $PM_{2.5}$ concentration (shading) and winds (arrows) between the sensitivity simulation and baseline simulation. The negative shows $PM_{2.5}$ concentration decreases and the positive shows $PM_{2.5}$ concentration increases when the Tibetan Plateau is 2°C warming.
