Abstract: In this study, we present results from 12 years of black carbon (BC) measurements at 14 sites around Helsinki metropolitan area (HMA) and at one background site outside the HMA. The main local sources of BC in the HMA are traffic and residential wood combustion in fireplaces and sauna stoves. All the BC measurements were conducted optically and therefore we refer to the measured BC as equivalent BC (eBC). Measurement stations were located in different environments that represented traffic environment, detached housing area, urban background, and regional background. The measurements of eBC were conducted from 2007 through 2018; however, the times and the lengths of the time series varied at each site. The largest annual mean eBC concentrations were measured at the traffic sites (from 0.67 to 2.64 $\mu\text{g m}^{-3}$) and the lowest at the regional background sites (from 0.16 to 0.29 $\mu\text{g m}^{-3}$). The annual mean eBC concentrations at the detached housing and urban background sites varied from 0.64 to 0.80 $\mu\text{g m}^{-3}$ and from 0.42 to 0.68 $\mu\text{g m}^{-3}$, respectively. The clearest seasonal variation was observed at the detached housing sites, where residential wood combustion increased the eBC concentrations during the cold season. Diurnal variation of eBC concentration in different environments depended clearly on the local traffic and residential wood combustion. The dependency was not as clear for the other air pollutants, which were NO_x and mass concentration of particles smaller than 2.5 μm ($\text{PM}_{2.5}$). At four sites, which had at least four-year-long time series available, the eBC concentrations had statistically significant decreasing trends that varied from -10.4 to -5.9 % yr^{-1} . Compared to trends determined at urban and regional background sites, the absolute trends decreased fastest at traffic sites, especially during the morning rush hour. Relative long-term trends of eBC and NO_x were similar, and their concentrations decreased more rapidly than that of $\text{PM}_{2.5}$. The results indicated that especially emissions from traffic have decreased in the HMA during the last decade. This shows that air pollution control, new emission standards and a newer fleet of vehicles had an effect on air quality.

1 Introduction

Air pollution is one of the biggest environmental health risks in the world. Air pollution consists of both gaseous components and particulate matter (PM). Lelieveld et al. (2015) estimated that particles smaller than 2.5 μm in diameter ($\text{PM}_{2.5}$) and ozone (O_3) together caused about 3.3 million premature deaths globally in 2010. Majority of these premature deaths were due to $\text{PM}_{2.5}$ (approximately 1.9 million). More than 65 % of the premature deaths caused by $\text{PM}_{2.5}$ were related to cardiovascular diseases, the second largest cause for the $\text{PM}_{2.5}$ -related premature deaths were lung and respiratory diseases, and a small fraction were due to lung cancer (Lelieveld et al., 2015). The causes for the adverse health effects of PM are the PM induced inflammation and toxic materials, which are transported in the respiratory system by the particles.

WHO reported that PM emitted from combustion sources, especially from traffic, is more harmful for health than PM from other sources (Krzyżanowski et al., 2005). Typical combustion sources, which are also discussed in this study, are traffic and domestic wood burning. Traffic emits a complex mixture of gaseous and fine particulate compounds (Rönkkö and Timonen, 2019). Domestic wood burning also emits fine particles including toxic compounds, such as benzo(*a*)pyrene (Hellén et al., 2017). Black carbon (BC), which is defined as black carbonaceous particulate matter, is a good indicator of pollution from combustion because it is a side product of incomplete combustion. Therefore, it is useful to measure BC alongside with the other air quality parameters since BC concentration can give additional information about the health effects of aerosol particles than just PM, which does not only originate from combustion (Janssen et al., 2011). BC is not just an indicator on bad air quality, but the BC particles themselves also have adverse health effects. BC particles, which are around the size range of ~100 nm, can penetrate deep in the respiratory system and all the way in the alveolar region, from where the particles can be transported in the blood circulation system and further on in the organs.

Due to its black appearance, BC absorbs solar radiation and decreases the albedo of reflecting surfaces (i.e., snow and ice sheets). BC has been estimated to be one of the largest warming agents in the climate change (Stocker et al., 2013). Since BC is emitted in the air as particles, its lifetime in the atmosphere is relatively short (few weeks) compared to greenhouse gases (tens of years). Therefore, in addition to improving air quality, cutting down the BC emissions would have rather fast effects in the radiative forcing slowing down the rate of global warming. In order to reduce BC emissions there has been, for example, a suggestion of implementing a BC footprint similar to the CO_2 footprint (Timonen et al., 2019).

Several recent studies have reported decreasing long-term trends of BC concentration in different types of environments including urban areas (e.g., Sun et al., 2020; Kutzner et al., 2018; Singh et al., 2018; Font and Fuller, 2016). In Finland, the concentration of BC and its trends has been studied especially in background sites (Hienola et al., 2013; Hyvärinen et al., 2011), but not that much in urban areas. The previous studies about BC concentration in the Helsinki metropolitan area (HMA)

are mainly from shorter campaigns (Aurela et al., 2015; Dos Santos-Juusela et al., 2013; Helin et al., 2018; Järvi et al., 2008; Pakkanen et al., 2000; Pirjola et al., 2017).

65

The objective of this study is to investigate the spatio-temporal variability of BC in different types of environments in the HMA. Our objective is also to clarify how the proximity of combustion sources, which in HMA are mainly traffic and residential wood combustion (Helin et al., 2018; Savolahti et al., 2016), affected the BC concentrations. In this study, we utilize BC data measured at various different locations in the HMA and at one site outside the HMA. The measurements were conducted during 2007–2018. To study how the variability of BC differed from the variability of the monitored and regulated air quality parameters, we also included parallel measurements of PM_{2.5} and NO_x in this study.

70

2 Measurements and methods

2.1 The field sites

The HMA consists of four different cities (Helsinki, Espoo, Vantaa, and Kauniainen) and it is the most densely populated area in Finland. In 2020, the total population in the HMA was about 1.4 million. Helsinki is the capital of Finland and it is located in the southern coast of the country (60°10'N, 24°56'E). The HMA locates on the seaside of the Gulf of Finland and therefore the climate in the area is a transition zone between oceanic and continental climate and typically defined as humid continental climate. On average, the coldest month during the measurement period (2009–2018) was February (-5 °C) and the warmest month was July (19 °C). The mean wind speed over the whole measurement period was about 4 m s⁻¹. For more detailed information about the meteorological parameters, see Fig. S1.

80

The measurements of BC concentration were conducted at 15 sites. We classified the stations into four categories: traffic environment (TR), detached housing area (DH), urban background (UB), and regional background (RB). The locations of the measurement sites are presented in Fig. 1; the exact coordinates and aerial photos of the stations are provided in Sect. S2. Fourteen of the measurements sites were located in the HMA and one of the RB sites was located circa 200 km north of the HMA in Hyytiälä. At some of the stations, the measurements have been repeated or conducted on a long-term basis and at some of the stations, the measurements lasted only for one year. The measurement periods for each site are shown in Table 1.

85

Six traffic stations, TR1 – TR6, located close to a busy street or road (Sect. S2.1). At these sites, traffic was the dominating source of pollution. Detailed information, such as traffic counts (TC), fraction of heavy-duty (HD; i.e., trucks and buses), and the distance of the station to the closest traffic lines are presented in Table 2.

90

Detached housing stations, DH1 – DH5, located in residential areas that consisted of separate one-family houses, small streets, and some forests and parks (Sect. S2.2). The traffic rates at these areas were low; for example, the traffic rates on the streets

95 next to DH1 and DH5 were about 2 600 vehicles per day, which was way less than at the TR sites (Table 2). According to a survey study, up to 90 % of the one-family households burned wood to warm up houses and/or saunas, but less than 2 % of the households used wood combustion as the main heating source (HSY, 2016, in Finnish only; Hellén et al., 2017).

100 Background sites were categorized as urban and regional background sites. Urban background stations, UB1 and UB2, located close to the central area but not in vicinity of busy roads (Sect. S2.3). UB2 is also known as SMEAR III (Station for Measuring Ecosystem-Atmosphere Relations; Järvi et al., 2009). Regional background stations, RB1 and RB2, located in rural areas, about 20 and 200 km away from Helsinki, respectively (Sect. S2.3). RB sites represented the concentration levels outside the urban area without local pollution sources. RB2 is also part of the SMEAR network, better known as SMEAR II (Hari and Kulmala, 2005).

105

2.2 Measurements of equivalent black carbon

The Helsinki Region Environmental Services Authority (HSY), which is the authority monitoring the air quality in the HMA, arranged the measurements at 13 of the sites. Institute for atmospheric and Earth system research (INAR) arranged the measurements at the RB2, and the Finnish Meteorological Institute (FMI) together with INAR conducted the measurements at the UB2.

110

All the BC measurements were conducted optically, meaning that the BC concentration was derived from the light absorption of the particles and hence we refer to the measured BC as equivalent black carbon (eBC; Petzold et al., 2013). At 11 of the stations, the measurements of eBC were conducted by using only a Multi-angle absorption photometer (MAAP; Thermo Fisher Scientific, model 5012), and at three of the stations (DH4, DH5, and RB2) all or at least part of the measurements were conducted by using an Aethalometer (Magee Scientific, models AE31 and AE33). The instruments used at different sites are listed in Table S1.

115

At all of the stations, the head of the sampling line was located 4 m above the ground. The concentration of eBC was measured for particles smaller than 1 μm (PM_{1}). However, at DH1 the eBC concentration was measured for $\text{PM}_{2.5}$ for first half of the year, but since most of the eBC mass concentration falls in the PM_{1} (Vallius et al., 2000), the cut-off size should not have caused big difference in the results. Sample air was dried with an external dryer or by warming up the sample to 40 °C at most of the stations, but at TR1, UB2, DH5 and DH4 (only the first half of year) the sample air was not dried. Even if there was no drier, the sample air warmed up to the room temperature, which decreased the RH, when the outdoor temperature was lower than the indoor temperature (i.e., the sample air was dried passively during the cold period, however, in summer, when the temperature difference was smaller, the RH did not necessarily decrease).

125

130 The MAAP determines the absorption coefficient of aerosol particles by collecting the particles on a filter medium and by measuring the intensity of light penetrating the filter and the intensity of light that is scattered from the filter in two different angles (Petzold and Schönlinner, 2004). The absorption coefficient is determined from these measurements by using a radiative transfer scheme. The eBC concentration is obtained from the absorption coefficient by using a mass absorption cross-section (MAC) value of $6.60 \text{ m}^2 \text{ g}^{-1}$ (Petzold and Schönlinner, 2004). The MAAP operates only at one wavelength, which is 637 nm.

135 The Aethalometer measures the eBC concentration at seven wavelengths (370, 470, 520, 590, 660, 880, and 950 nm). Here we chose to use the 880 nm channel, since it is the recommended and most commonly used wavelength to report the eBC measured by an Aethalometer. Similarly to MAAP, the Aethalometer collects the sample aerosol particles on the filter material, but unlike the MAAP, the Aethalometer only measures the attenuation of light through the filter. Therefore, the Aethalometer is prone to error caused by the increasing filter loading. In the newer model, AE33, this is automatically taken into account in real time as the instrument applies the so-called “dual-spot correction” to the data (Drinovec et al., 2015). For AE33, the recommended MAC value of $7.77 \text{ m}^2 \text{ g}^{-1}$ at 880 nm was used in this study (Drinovec et al., 2015). For the older model, AE31, a correction algorithm needs to be applied by the user (e.g., Collaud Coen et al., 2010). AE31 determines the BC concentration from the so-called attenuation coefficient and it uses mass attenuation cross-section value of $16.62 \text{ m}^2 \text{ g}^{-1}$ at 880 nm.

145 At DH4, model AE33 Aethalometer was used for the first half of the measurement period (1 January 2017 – 5 May 2017) and at DH5, the whole data set was measured with an AE33. At these two stations, HSY corrected the eBC concentration by multiplying the concentration by 0.75, according to a comparison with MAAP. At RB2, an older model AE31 was used. The AE31 was first corrected for the filter loading error by using the correction algorithm suggested by Virkkula et al. (2007). After the filter loading correction, a comparison with MAAP showed that the AE31 data had to be multiplied by 1.08 to acquire similar concentrations (Sect. S3).

150 **2.3 Measurements of NO_x and PM_{2.5}**

NO₂ and the mass of particles smaller than 2.5 μm (PM_{2.5}) are regulated pollutants based on the Air Quality Directive (2008/50/EC) and therefore they are always measured at the air quality stations. In this study, we used NO_x (NO + NO₂) data instead of the regulated NO₂, since NO_x describes better the primary traffic emissions. Even though there was much more NO_x and PM_{2.5} data available compared to eBC data, we used only NO_x and PM_{2.5} data that was measured parallel to eBC in order to make the comparison and trend analysis systematic.

160 The PM_{2.5} concentration was measured with various different instruments, which are listed for each station in Table S1. The instruments were based on four different methods: 1) attenuation of β-radiation (Thermo model FH 62 I-R); 2) tapered element oscillating microbalance (TEOM; Thermo different models); 3) optical detection (Grimm 180); and 4) collecting the particles in a cascade impactor and manually weighting the collected particles. The instruments, which use the methods 1 – 3, measure

the concentration continuously. At RB2, where the PM_{2.5} concentration was measured by collecting the particles in a cascade impactor and weighting the collected particles about three times a week so the time interval of these measurements varied from two to three days. To compare the PM_{2.5} measurements to BC concentration at RB2, the PM_{2.5} concentration was interpolated to match the timestamps of the eBC measurements.

165

NO_x mass concentration [NO_x] was derived from the measurements of NO and NO₂ so that

$$[\text{NO}_x] = 1.533 \cdot [\text{NO}] + [\text{NO}_2]. \quad (1)$$

The mass concentration of NO and NO₂ were measured by instruments, which are based on the chemiluminescence method.

The instruments used at each station are listed in Table S1.

170 **2.4 Meteorological measurements**

The meteorological station measuring wind direction (WD), wind speed (WS), temperature (T), pressure (p), relative humidity (RH), and precipitation, was located in a rooftop (78 m a.s.l) close to central Helsinki (Fig. 1). In this study, we used the measurements of meteorological parameters conducted at the rooftop station to represent the meteorological conditions of all the stations located in the HMA. We also included data of the mixing height (MH) for southern Finland. The MH was calculated

175 by MPP-FMI, a meteorological pre-processing model developed by the FMI (Karppinen et al., 2000).

2.5 Data processing

The data quality were assured by the data producer and invalid data were omitted from further analysis. The concentrations were converted to ambient outdoor temperature and to normal atmospheric pressure (1013.25 hPa). In this study, we used one-hour averages for all the variables (only exception is the PM_{2.5} data at RB2). The hourly mean values were calculated if the

180 hour had at least 75 % of valid data. The hour of day always refers to the local time (note that winter and summer times are used in Finland) and the time stamp of the measurements are reported in the middle of the averaging period.

2.5.1 Trend analysis

We used seasonal Mann-Kendall test and Sen's slope estimator (Gilbert, 1987) in determining the statistical significances and the slopes of the long-term trends. Mann-Kendall test and Sen's slope estimator are non-parametric statistical methods, which

185 allow missing data points. The method determines the trends for each season (here we used months) separately and tests if the trends for different seasons are homogeneous. We used monthly median values in the trend analysis and we required at least 14 days of valid data for each month, otherwise the month was not taken into account in the trend analysis. Similar analysis has been used in various trend studies (e.g., Collaud Coen et al., 2007; Collaud Coen et al., 2013; Li et al., 2014; Zhao et al., 2017).

190 3 Results and discussion

3.1 Spatial variation

The statistics of eBC, PM_{2.5}, and NO_x concentrations from each site are presented in Fig. 2. The figure includes all the data and the statistics were determined by using the 1 h mean values. Figure 2 shows that the arithmetic mean values differed from the median values, which means that the data of the air pollutants was not normally distributed at any station and that the data
195 was skewed to the right (i.e., small concentrations occurred more often and therefore the median values were smaller than the means).

As expected, the highest mean eBC concentrations were observed at the TR sites, where the mean eBC concentration varied from 0.77 to 2.08 $\mu\text{g m}^{-3}$ (at TR6 and TR3, respectively). At the DH sites, the mean eBC concentration varied from 0.64 to
200 0.80 $\mu\text{g m}^{-3}$, which were rather similar mean values as observed at the TR1, TR5, and TR6 (0.84, 0.83, and 0.77 $\mu\text{g m}^{-3}$, respectively). At the UB sites, the mean eBC concentrations were around 0.52 $\mu\text{g m}^{-3}$, which was clearly lower than at the TR and DH sites. The lowest mean eBC concentrations, which were 0.28 $\mu\text{g m}^{-3}$, were observed at the RB sites that had no local BC sources in vicinity.

205 Previous studies have shown that in addition to the traffic count, the BC concentration near traffic lines depends on various factors: the distance to the traffic lines (Enroth et al., 2016; Massoli et al., 2012; Zhu et al., 2002); the speed limit (Lefebvre et al., 2011); and the fraction of heavy-duty vehicles (Clougherty et al., 2013; Weichenthal et al., 2014). The surrounding buildings, vegetation and the wind conditions affect the dilution and therefore the BC concentrations as well (Abhijith et al., 2017; Brantley et al., 2014; Pirjola et al., 2012). Also, close by intersections may affect the BC concentrations if they induce
210 traffic build-ups; BC emissions from vehicles that accelerate are higher than the emissions from a steadily moving vehicle (Imhof et al., 2005).

The abovementioned factors are probably the reason for the relatively big differences between the different TR stations and explain, for example, why the eBC concentration at TR3 was notably higher than at the other TR sites. TR3 was located in a
215 street canyon right next to a very busy traffic line. According to Table 2, the traffic count on the closest street next to TR3 was around 44 400 vehicles per weekday and the fraction of heavy-duty vehicles was 14 %. The traffic count and fraction of heavy-duty vehicles was higher than for example on the street next to TR1 or at the street next to TR2. The area around TR3 consisted also of a few busy intersections and the location in a street canyon probably increased the eBC concentrations even further.

220 The effects of total traffic count and traffic count of heavy-duty vehicles (HD) on the eBC concentration were studied in more detail in the supplementary material (Fig. S9), where the annual mean eBC concentrations were compared against the estimated weekday traffic counts of all vehicles and of HD vehicles in the nearest street or road. The annual means of eBC concentration

correlated better with the number of HD vehicles passing the station ($R = 0.82$) than with the total traffic count ($R = 0.71$). In general, the number of HD vehicles passing the TR1, TR5, and TR6 per day was low compared to TR2, TR3, and TR4, and this was also seen in the mean concentration of eBC, which was the highest for the TR2 – TR4. This result was expected, since the BC emissions from HD vehicles are higher compared to light-duty vehicles (Imhof et al., 2005).

The distance from the stations to the edge of nearest street varied, which has an effect on the measured eBC concentration (Massoli et al., 2012; Zhu et al., 2002). A study by Enroth et al. (2016) estimated that eBC concentration decreased by 50 % at 33 m distance from the road. TR2 and TR3, where we observed rather high concentrations, were located right next to the street (in a 0.5 m distance), whereas the other stations had a longer distance to the nearest street (3 – 20 m). Previous studies have also shown that tall trees in street canyons may deteriorate the air quality by preventing dispersion (Abhijith et al., 2017) and this may also have affected the higher measured concentrations at TR2 and TR3. In Mäkelänkatu street, which is next to TR2, there are two lines of trees framing the tram lines in middle the street (Fig. S3b) and in Mannerheimintie street, which is next to TR3, there are trees planted between the traffic lines and pavements (Fig. S3c).

Compared to the HMA, higher concentrations of eBC have been reported at other urban areas in Europe. For example, Sun et al. (2019) reported median values of 2.0, 0.9, and 0.4 $\mu\text{g m}^{-3}$ at several German TR, UB and RB sites, respectively, measured during 2009–2018. Singh et al. (2018) reported on average eBC concentrations of 1.83 and 1.34 $\mu\text{g m}^{-3}$ measured at several urban center and UB sites in the United Kingdom during 2009–2011. Krecl et al. (2017) observed mean eBC concentration of 2.1 $\mu\text{g m}^{-3}$ at a street canyon site in Stockholm during weekdays in spring 2013. Becerril-Valle et al. (2017) reported mean eBC values of 3.7 $\mu\text{g m}^{-3}$ at a TR site and 2.33 $\mu\text{g m}^{-3}$ at an UB site measured in Madrid in 2015. The BC concentrations reported by other studies at different environments are higher than the eBC concentrations measured at corresponding environments in the HMA. Already the concentrations at the RB sites are lower than those measured at other European sites. Generally, the air quality in the HMA and in southern Finland was good. Finland is isolated from the more populated continental Europe by the Baltic sea and therefore long-range pollution from the more polluted continental area affects southern Finland less. Due to its coastal location, the HMA affected by the sea breeze and is therefore well diluted. Compared to other European metropolitan areas, the HMA is small and the area is not as densely populated as many other European capital areas.

In addition to eBC, we also studied the variations of $\text{PM}_{2.5}$ and NO_x , presented in Figs. 2b and 2c, respectively. The spatial variation of NO_x was partly similar to that of eBC; the highest concentrations were measured at the TR sites and the lowest at the RB sites. At the TR sites, the mean concentrations varied between from 44 to 147 $\mu\text{g m}^{-3}$ (at TR5 and TR3, respectively) and the variation between the stations was rather similar to the variation of eBC. Like BC, NO_x is highly dependent on the traffic related parameters such as the traffic count, the fraction of heavy traffic, the speed limit etc., which explain the similar variation observed. For the RB sites, however, the mean NO_x (2 $\mu\text{g m}^{-3}$) was relatively low compared to eBC at RB sites. Another difference to eBC was that, the NO_x concentration at the DH sites was relatively lower, which was expected, since

the NO_x emissions from residential wood combustion are low. The correlation between eBC and NO_x concentrations at each station are presented in Fig. S8a. As the likeness in the spatial variability already suggested, the eBC and NO_x had rather similar sources and therefore they were expected to correlate. The correlation coefficient (R) between these variables was the highest at the TR stations ($0.80 \leq R \leq 0.90$) and lower at the DH stations ($0.63 \leq R \leq 0.73$). At the background sites, the correlation coefficient varied more ($0.55 \leq R \leq 0.83$).

For $\text{PM}_{2.5}$, there were not as clear patterns between different station categories as there were for eBC and NO_x . At the TR sites, the mean $\text{PM}_{2.5}$ concentration varied from 5.6 to 11.3 μgm^{-3} (at TR6 and TR3, respectively) and at the DH sites, the variation was rather similar: from 5.6 to 11.3 μgm^{-3} (at DH4 and DH2, respectively). The mean concentration of $\text{PM}_{2.5}$ at the background sites was not as clearly lower as it was for eBC and NO_x . These results show that $\text{PM}_{2.5}$ did not depend on local primary pollution sources as much as eBC or NO_x did. $\text{PM}_{2.5}$ includes all different kind of aerosol particles, especially secondary aerosol, which may be anthropogenic or biogenic in origin. In this size range, non-anthropogenic particles (e.g., secondary particles of biogenic origin; Dal Maso et al., 2005) are also contributing. The differences in the sources of eBC and $\text{PM}_{2.5}$ concentrations were also seen in the correlation between these two variables; the R between these two variables at different stations were notably lower ($0.36 \leq R \leq 0.67$) than the R between eBC and NO_x concentrations (Fig. S7b).

The fraction of eBC in the $\text{PM}_{2.5}$ is shown in Fig. 3. eBC was measured mostly in PM_1 , but since most of the BC particles are smaller than 1 μm in diameter, the difference between the cut off diameters should not have a big effect on the results (e.g., Enroth et al., 2016). Higher eBC/ $\text{PM}_{2.5}$ ratio indicated that there was a larger fraction of PM related to combustion sources. The highest median eBC/ $\text{PM}_{2.5}$ ratio were observed at the TR sites where the fraction of eBC varied from 10 to 15 %. The second highest median ratios were observed at the DH sites and at UB1 where the ratios varied from 5 to 9 %. At the RB sites, the median fractions were the smallest: less than 5 %.

The results of the spatial variation showed that eBC concentration and eBC/ $\text{PM}_{2.5}$ ratio depended greatly on the distance to the pollution sources, which were, in this case, traffic and wood combustion. The NO_x was very dependent on the distance to the traffic sources only, since NO_x concentration was not significantly affected by residential wood combustion. Since the $\text{PM}_{2.5}$ has various sources and generally high background levels, it was the least dependent component on the contribution of the local sources.

Figures 2 and 3 included all the data that was collected from 2009 to 2018 and that the sizes of the data sets at each station differed. Therefore, the year-to-year variation caused by the meteorological conditions and changes in the emission rates might have affected the results of spatial variability especially at sites that contained only one year of data (all DH sites and TR4).

290 At DH4, DH5, and RB2, at least part of the measurements were conducted by an Aethalometer. The Aethalometer measured
the eBC at 880 nm, which is a longer wavelength than on what MAAP operated at (637 nm). This could have caused some
difference in the measured eBC concentration in the presence of so-called brown carbon. Brown carbon is organic material,
which absorbs light especially at short wavelengths (Andreae and Gelencsér, 2006). However, since the organic carbon absorbs
light mainly at wavelengths below 600 nm (Kirchstetter et al., 2004) the difference between the MAAP and Aethalometer
295 wavelengths should not cause a notable effect on the observed eBC concentration.

As mentioned in the Sect. 2.2, we applied constant mass absorption cross section (MAC) values to convert the optically
measured absorption data to eBC concentration. However, the MAC may vary depending on the chemical composition, shape
and the mixing state of the PM. The MAC increases for aged BC particles, as the BC particles get coated with a scattering or
slightly absorbing coating, which act as a lens increasing the absorption of the BC core (Lack and Cappa, 2010; Yuan et al.,
300 2020). At TR sites, the freshly emitted BC particles from local traffic probably have no coating on the particles, but at the
remote sites, however, particles are carried over longer distances and the observed BC at these sites is more aged and likely
more coated. Therefore, it is probable that the real MAC at the background sites was higher compared to TR sites. If the
differences in the MAC values were taken into account, it could possibly increase the difference between the traffic and
305 background sites. The source of the BC may also have an effect on the MAC, but for example Yuan et al. (2020) and Zotter et
al. (2017) did not observe notable difference between the MAC for particles originating from traffic or wood combustion. In
addition to spatial variation, the MAC can also vary temporally, which could affect the observed seasonal and diurnal variations
and trends (presented in Sect. 3.2) as well. However, determining the variations of MAC would require extensive long-term
measurements of chemical composition of the BC particles in different environments and therefore further analysis of the
310 effect of MAC is omitted here.

3.2 Temporal variation

3.2.1 Long-term trends

A quick look in Table 1 already showed that the annual eBC mean values had seemingly decreased. To see if the decreasing
eBC trend had a statistical significance, we applied the seasonal Kendal test (see Sect. 2.4.1) to the data sets that were at least
315 four-year-long (TR1, TR2, RB2, and UB1). Even though there was four-years of measurements at the UB2, the station was
omitted from the trend analysis, since the data availability at UB2 in 2016–2017 was not good enough. The seasonal Kendal
test was applied to monthly medians values, which are presented in Fig. 4 for the eBC concentration at TR1, TR2, UB1, and
RB2. We could not apply the trend analysis to any of the DH stations, since none of the DH stations had more than one year
of eBC measurements.

320

A statistically significant (p -value < 0.05) decreasing trend was observed for all of the stations included in the trend analysis (TR1, TR2, UB1, and RB2) as shown in Fig. 4 and in Table 3. The smallest absolute decrease was observed at the background stations UB1 and RB2, where the slopes of the trends were -0.02 and $-0.01 \mu\text{g m}^{-3} \text{yr}^{-1}$, respectively. At TR1 the concentration decreased more rapidly by $-0.04 \mu\text{g m}^{-3} \text{yr}^{-1}$ and at TR2 the decrease was even greater: $-0.09 \mu\text{g m}^{-3} \text{yr}^{-1}$. In addition to the absolute trend, we also determined the relative trends by dividing the absolute slope of the trend by the overall median concentration. At TR1, UB1, and RB2, the relative trends were rather similar: -6.4 , -5.9 , and -7.8% yr^{-1} , respectively. At TR2, the decrease was relatively steeper: -10.4% yr^{-1} .

One possible cause for the decreased pollution concentrations could have been the changes in the meteorological parameters that affect the dilution. Teinilä et al. (2019) reported that in HMA the two most important meteorological parameters that affected the PM_{10} concentrations were wind speed (WS) and temperature (T); Järvi et al. (2008) observed that of the meteorological parameters the WS and mixing height (MH) affected the BC concentration the most. The highest concentrations were observed at low WS and MH conditions and when the T was either very high in summer or very low in winter, which indicates stable and stagnant meteorological conditions. Also, a temperature decrease during colder periods could increase the emissions from residential wood combustion. Therefore, in addition to BC, we ran the trend analysis for the time series of WS, T, and MH (time series in Fig. S1). However, we did not observe statistically significant trends for any of these parameters. We also studied the trends for the different seasons separately to see, for example, if the temperatures had increased in the summer months or decreased in winter months, but this analysis did not yield statistically significant trends either. Therefore, it is likely that the decreasing trends of the eBC concentration were not explained by the meteorological factors.

To see how the decrease in eBC concentrations compared to the trends of other air pollutants, we conducted the trend analysis also for the $\text{PM}_{2.5}$ and NO_x data. The resulted trends are also presented in Table 3. The only parameter for which we did not observe a statistically significant decreasing trend was $\text{PM}_{2.5}$ at TR2 (p -value = 0.05). The relative trends varied from station to station, but a common trait was that the concentrations of eBC and NO_x decreased relatively faster than the concentration of $\text{PM}_{2.5}$. The trends of NO_x concentration varied from -19.7% yr^{-1} (TR3) to -4.0% yr^{-1} (RB2) and the trends of $\text{PM}_{2.5}$ concentration varied from -3.9% yr^{-1} (UB1) to -2.7% yr^{-1} (RB2). Since there was a notable decrease in the eBC concentration at TR3 between the years 2010 and 2015 (Table 1), the trend at TR3 was also studied, which is presented in Sect. S5. The analysis showed that the concentrations of eBC, NO_x , and $\text{PM}_{2.5}$ decreased about -12.2 , -8.2 , and -5.6% yr^{-1} , respectively. So also at the TR3, the $\text{PM}_{2.5}$ concentration decreased relatively the slowest.

Compared to $\text{PM}_{2.5}$, the concentrations of eBC and NO_x were more sensitive to the changes in the traffic, since they are more dependent on the local sources than $\text{PM}_{2.5}$ as discussed in the Sect. 3.1. Therefore, the bigger decrease in eBC and NO_x concentrations indicated that especially the emissions from traffic have decreased. Since $\text{PM}_{2.5}$ is not as sensitive to changes in primary traffic related emissions, it explains why the slope of the trend for $\text{PM}_{2.5}$ was relatively smaller than that of eBC

355 and NO_x . In other words, since the pollutant emissions from traffic sources have generally decreased, it clearly affected the trends of eBC and NO_x , which are originating from local traffic sources, but to a lesser extent the trend of $\text{PM}_{2.5}$. Even though the decrease in local traffic emissions was the probable explanation for the decreasing trends especially at the TR and UB sites, changes in the long-range transported pollution likely affected the trends as well. Statistically significant trends were observed also at RB2 indicating that the long-range transported pollution and the emissions in the regional area have also decreased.

360

For eBC and NO_x it is difficult to say which one of the pollutants decreased at faster rate. Their relative decreases were rather similar at TR1 and UB1. At RB2, the decrease in eBC concentration was a more notable if compared to the decrease in NO_x concentration. However, at RB2, there were no local sources so the situation was probably rather complicated and depended on the atmospheric chemistry and aging of the pollutants. At TR2, there was a large difference and NO_x seemed to decrease at double rate compared to eBC, which could be caused, for example, by the fast renewal of the city bus fleet. According to the Helsinki Regional Transport Authority (HSL), in 2015 17 % of the HSL buses were Euro VI or Euro VI energy efficient and in 2018 the fraction had increased to 48 %. A study by Järvinen et al. (2019) showed that moving to Euro VI buses from enhanced environmentally friendly vehicles (EEV) efficiently decreases the NO_x emissions. However, at TR2, the short time series cause uncertainty to the trends and for example, the year-to-year variability caused by the meteorological conditions could cause apparent decrease in pollutant concentrations.

370

The trends at TR1 and UB1 were investigated in more detail, since these stations had the longest time series and they were located closer to local sources in the HMA. To see if the traffic related emissions affected the trends, the trend analysis was conducted separately for each hour so that the monthly median was determined for each hour of the day. Only the data from weekdays was included in the analysis. This trend analysis revealed that there were clear decreases in the eBC and NO_x concentrations around the morning rush hour as shown in Figs. 5a and 5c. The trend of the eBC concentration had a distinctive diurnal cycle in general so that the decrease was more prominent during morning and day and actually there was no statistically significant trend during night time (22 p.m. – 3 a.m.). Similar diurnal pattern was observed for the $\text{PM}_{2.5}$ as well, however, the pattern was not as well defined as for the eBC. At TR1, the $\text{PM}_{2.5}$ data between 8 – 9 a.m. and 9 – 10 p.m. were not included in the trend analysis due to technical issues caused by a disturbance of the air conditioning. In principle, the diurnal trends indicated that the primary emissions from traffic have decreased most prominently, i.e., changes in traffic regulations and technological advancements have decreased especially the eBC and NO_x emissions.

380

According to the report about traffic in Helsinki, the traffic volume in Helsinki increased a bit, by 0.4 % yr^{-1} during the period 2006–2016 (Helsinki, 2017; in Finnish only). However, in general, the number of vehicles entering and exiting the city center (represented by TR1) decreased by 1.5 % yr^{-1} and the number of vehicles entering and exiting the central urban area (represented by TR2, TR3, and UB1) decreased by 0.8 % yr^{-1} during the same period, which obviously decreases the emissions from traffic. The decreases in traffic rates were especially observed in the North-West part of the central urban area (e.g., Fig.

385

S10c), which probably affected the trends observed at TR3. However, at Mäkelänkatu, which is the main street next to TR2
390 where decreasing trends were also observed, there was no clear decrease in the traffic rate (Fig. S10f).

Since the traffic rates did not decrease at all of the stations, it can be concluded that the decreasing trends were due to the
renewal of vehicle and bus fleet as well as cleaner renewable fuels, which have been shown to decrease both BC and NO_x
emissions (Järvinen et al., 2019; Pirjola et al., 2019; Timonen et al., 2017). The exhaust particle number of diesel and gasoline
395 vehicles have been regulated efficiently in order to reduce the traffic emissions. The regulations have enforced the use of diesel
particulate filters (DPFs) in new diesel passenger cars and heavy-duty diesel vehicles, reducing their BC and PM emissions
even more than 90 % up to 99 % if compared to the diesel vehicles without DPF (Bergmann et al., 2009; Preble et al., 2015).
Also, the increased use of biofuels and gas as vehicle fuels, increased share of electric vehicles, and improvements of fuel
economy in internal combustion engines affected the observed trends. E.g., the increase of fuel injection pressure in diesel
400 combustion can improve the fuel economy of engines and simultaneously decrease the BC emissions of engines (Lähde et al.,
2011).

Decreases in the eBC concentration (or absorption coefficient) have also been observed in the Finnish arctic (Dutkiewicz et
al., 2014; Lihavainen et al., 2015). In general declining trends in atmospheric aerosol particle number concentration and
405 particulate material has been observed in various different types of environments in Europe (Asmi et al., 2013). Similar results
for the trend of eBC concentration have been reported at several cities and countries in Europe. In Stockholm, Sweden, Krecl
et al. (2017), reported about 60 % reduction in eBC concentration in a busy street canyon between the years 2006 and 2013
(i.e., -7.5 % yr⁻¹). Singh et al. (2018) observed a statistically significant decreasing trend in eBC concentration at five
measurements stations, which operated during 2009–2016 and were located in different types of environments in the United
410 Kingdom. The trends varied from -0.09 µg m⁻³ yr⁻¹ (-4.7 % yr⁻¹) at an UB site to -0.80 µg m⁻³ yr⁻¹ (-8.0 % yr⁻¹) at a TR station.
A trend study based only in London reported on average -0.59 µg m⁻³ yr⁻¹ (-11 % yr⁻¹) decrease in eBC concentration at three
TR sites for the period 2010–2014 (Font and Fuller, 2016). Kutzner et al. (2018) observed statistically significant decreasing
BC (both eBC and elemental carbon) trends for the period of 2005–2014 at several sites in Germany. The trends at TR sites
varied from -0.31 to -0.15 µg m⁻³ yr⁻¹ and the trends at UB sites varied from -0.03 to -0.02 µg m⁻³ yr⁻¹. Also, a more recent
415 study by Sun et al. (2020) reported decreasing relative trends of eBC in Germany for the period of 2009–2018: from -0.19 to
-0.08 µg m⁻³ yr⁻¹ (-11.3 to -5.0 % yr⁻¹), from -0.08 to -0.03 µg m⁻³ yr⁻¹ (-8.1 to -2.3 % yr⁻¹), and from -0.03 to 0.00 µg m⁻³ yr⁻¹
(-7.8 to -3.2 % yr⁻¹) at TR, UB, and RB sites, respectively.

These studies reported higher absolute trends compared to the absolute trends observed at our study, which was probably due
420 to lower eBC concentrations in southern Finland. However, the relative trends were rather similar. Similarly to this study,
other studies also observed steeper absolute trends at TR and UB sites than at RB sites. Sun et al. (2020) observed similar
diurnal eBC trends at TR and UB site as we did so that the decreasing trends were the highest during the morning rush hour.

In addition to eBC, Krecl et al. (2017) studied also the trend of NO_x , and Font and Fuller (2016) studied the trend of $\text{PM}_{2.5}$. Contradictory to our study, Krecl et al. (2017) did not observe a decreasing trend for NO_x and Font and Fuller (2016) reported decreasing trends for $\text{PM}_{2.5}$ concentration, which were relatively similar to the trends of eBC concentration.

The abovementioned studies, which were conducted in urban environments, suggested that the dominant reason for the decreased BC concentrations were traffic regulations. Krecl et al. (2017) drew a connection between the decreasing eBC concentration and the renewal of the vehicle fleet. Sun et al. (2020), Singh et al. (2018), and Kutzner et al. (2018) proposed that the reductions in eBC were linked to the local and national air quality policies. Font and Fuller (2016) suspected that the eBC concentration decreased due to effective filters in diesel vehicles.

3.2.2 Seasonal, weekly and diurnal variation of BC

The diurnal variation of eBC was investigated separately for the cold and the warm seasons. According to Fig. S1, the coldest 5 months typically extended from November to March and the warmest 5 months from May to September. April and October were omitted from this analysis as transition months. The seasonal dependencies for each station separately are presented in Figs. S11 and S12.

The seasonal and diurnal variations of eBC were rather similar between the stations that belong in the same category (Fig. S13). Instead of studying the variation at each station separately, we determined a mean diurnal variation for different station categories to study the variation more generally. The figures were plotted by calculating the mean concentration each hour of each day of the week for the cold and the warm seasons separately. All the available data were taken into account when the diurnal variation from different stations were averaged together.

The mean seasonal, weekly and diurnal variation of eBC for different station categories are presented in Fig. 6. At the TR1, TR2, TR3, and TR4 (i.e., TR1–4) the seasonal and diurnal variation was different from TR5 and TR6 (i.e., TR5–6) and therefore the mean diurnal variations for these sets of stations were plotted separately in Figs. 6a and 6b. Fig. 6c presents the mean diurnal variation averaged over all the DH sites. Since UB1 had a notably longer time series compared to UB2, these two time series were not combined and only the diurnal variation from UB1 is used in Fig. 6d. The diurnal variation at RB1 was also presented without combining it with RB2 data in Fig. 6e.

Fig. 6 shows two common traits observed at all of the TR, DH, and UB sites during both seasons: 1) eBC concentration peak appeared each weekday morning around 8 a.m. because of the morning rush hour; and 2) the lowest eBC concentrations were measured each day during the night around 3 a.m. when there were not much anthropogenic activities. In addition to these common trends, each station category had their own traits in the seasonal, weekly, and diurnal variation. We also did a similar

455 variation analysis for the eBC/PM_{2.5} ratio presented in Fig. S14. In general the eBC/PM_{2.5} ratio seemed to follow the variation
of eBC (i.e., the eBC varies relatively more than PM_{2.5}).

At the TR1–4, the seasonal variation of eBC was not strong and in Fig. 6a the lines for the cold and the warm season follow
each other. The lack of seasonal variation in traffic environment was also observed previously in the HMA (Helin et al., 2018;
460 Teinilä et al., 2019) and elsewhere (Kutzner et al., 2018; Reche et al., 2011). During weekdays, the morning concentration
peak of eBC occurred around 8 a.m. and the afternoon peak around 4 p.m. The variation of eBC concentration correlated with
the diurnal variation of the traffic counts (examples of traffic rates from Mannerheimintie and Mäkeläncatu in Fig. S10). eBC
concentration was notably lower during weekend, when the traffic rates were also lower. Järvi et al. (2008) also reported that
the close by traffic rates are the most important factors explaining the variation in eBC concentration at a TR site.

465

During the warm season at TR1–4 sites, the morning eBC concentration peak was higher during the cold season. Since seasonal
variation in the traffic rates were not expected, the observation was probably explained by the variation in WS and MH. When
the MH and WS are higher, the concentrations of air pollutants decrease due to more effective dilution (Järvi et al., 2008;
Teinilä et al., 2019). Fig. S2 shows that the MH and WS in the morning (before 9 a.m.) during the cool season were lower than
470 in the warm season. WS and MH had a clear diurnal cycle in the warm season, but in the cool season the WS or MH had no
variation whatsoever. The lower MH and WS in morning during the warm season could explain why the eBC concentrations
peak during the warm season mornings.

The seasonal variation of eBC was the most pronounced at the DH sites, where the lowest concentrations occurred in June and
475 July and the highest concentrations in December and January (Figs. S12g–k), which is likely explained by the residential wood
combustion during the cold season. At the DH sites, the highest concentrations were measured during the evening (Fig. 6c),
when people returned back home and started to warm up their houses and saunas. This was different to other station categories,
where the morning concentration peak was higher or similar compared to the afternoon peak. Domestic wood combustion also
increased the concentrations during the weekend and unlike at the TR and UB sites, the eBC concentration at the DH sites
480 were rather similar compared to the weekdays.

The effect of wood combustion at DH sites was studied by Helin et al. (2018), who applied AE33 data measured at TR2, DH3,
and DH4 (note different names of the sites between our study and the study by Helin et al., 2018) in a source apportionment
model suggested by Sandradewi et al. (2008). They reported that on average about 41 and 46 % of the eBC observed at the
485 DH4 and DH5, respectively, originated from wood combustion. The fractions were notably higher than observed at the TR2
(about 15 %). They also observed higher eBC fractions from wood combustion in the cool season: for example, eBC fractions
from wood combustion were 46 and 35 % at DH3 in winter and summer, respectively. The effect of wood combustion in
evenings was also evident in the data by Helin et al. (2018), who observed that eBC from wood combustion increased towards

the evening at the DH3 and DH4. A comparison between weekdays and weekends at DH3 showed similar eBC concentrations
490 originating from traffic, but slightly increased eBC concentrations from wood combustion in the weekend.

The effect of residential wood combustion on the diurnal variation was also observed at TR5–6 (Fig. 6b), which were closer
to the detached housing areas than the other TR sites (see Fig. 1). The temporal variation at TR5–6 was a mix between the
variation observed at the other traffic sites (TR1–4) and at the DH sites. At TR5–6, the concentration of eBC was notably
495 higher in the evenings during the cold season compared to the warm season, which is similar to the DH stations. In addition,
the maximum of the afternoon concentration peak occurred around the same time as at the DH sites. However, the effect of
traffic is seen in the afternoon peaks, since the peaks grew more rapidly around the afternoon rush hour. The traffic also
affected the morning concentration peak, which is similar to the afternoon concentration peak, whereas at the DH sites, the
morning peak was notably lower. At TR5–6, the eBC concentration during weekend was lower than in weekdays, which was
500 observed at the other TR sites as well. However, the difference was not as pronounced, which is again due to the effect of
wood combustion (e.g., increased eBC concentration during Saturday evening).

In the cold season, the diurnal variation of eBC at the UB1 was rather similar to the diurnal variation at the TR1–4, with the
rush hour peaks occurring in the morning and afternoon (Fig. 6d). During the warm season, however, the afternoon rush hour
505 peak was missing. Also in weekends, the concentrations during the warm season were considerably lower. Since the UB1 was
not in vicinity to pollution sources, the effect of dilution, which is governed by meteorological parameters, became more
important. In the daytime during the warm season, the pollutants were diluted in the convective and more windy (Fig. S2)
boundary layer effectively, whereas during the cold season the pollutants accumulated in the boundary layer, if it is shallower
and does not grow during the day as much as in the warm season (Pohjola et al., 2004). Also, the transported wood combustion
510 emissions from the DH areas can slightly increase the concentrations during the cool season even closer to the city center
(Helin et al., 2018).

At the RB sites, there was a notable seasonal variation as the eBC concentrations are higher during the cold season (Fig. S13n–
o), since regional wood combustion emissions and long-range transported pollutants also elevates eBC concentrations at
515 background sites in winter (Luoma et al., 2019). The diurnal and weekly variation, however, were not as clear (e.g., Fig. 6e)
as there were no anthropogenic activities nearby. Diurnal variation was mainly caused by the variation in the convective
boundary layer height that caused mixing and dilution and not by local anthropogenic sources, which is expected for a regional
background station.

520 It is important to note that the measured variation in the eBC concentration was affected by both: the BC emissions, and the
atmospheric processes determining the dilution of the BC. For instance, the diurnal variation of the eBC concentration at a
traffic site is affected by traffic rate at the nearby streets, roads and highways, but it is affected also by changes of local weather

conditions possibly having a diurnal variation. Such atmospheric parameters are e.g., ambient temperature, prevailing wind direction, wind speed, and height of the boundary layer. Furthermore, especially the ambient temperature can directly affect the emissions also; e.g., slightly higher wintertime morning concentrations in detached housing areas can be due to the effects of ambient temperature to the cold start emissions of passenger cars.

Conclusions

This study analyzed the time series of atmospheric eBC concentrations in traffic, detached house, urban background and regional background environments measured in years 2007–2018 in the Helsinki metropolitan area (HMA) and at one background site outside the HMA. The overall mean eBC concentration varied in the range from 0.77 to 2.08 $\mu\text{g m}^{-3}$ at TR stations, from 0.64 to 0.80 $\mu\text{g m}^{-3}$ at DH stations, and from 0.51 to 0.53 $\mu\text{g m}^{-3}$ at UB stations. At the RB sites the mean eBC concentrations were the lowest, about 0.28 $\mu\text{g m}^{-3}$.

The study highlights the importance of local sources in respect of urban air quality; it shows that the local traffic and residential wood combustion in residential areas formed the main sources of atmospheric eBC in the urban area studied here. The influence of traffic was clearly seen at the traffic stations (TR) and the effect of domestic wood combustion at the detached housing sites (DH). At the TR sites, which located closer to residential areas (TR5–6), the diurnal variation showed signs that the air quality in the area was heavily affected both by traffic and domestic wood burning emissions. The concentrations at the TR sites reached their peak in the weekday mornings and stayed elevated until the afternoon rush hour had passed. In the evening, after the workday, the eBC concentrations reached their maxima at the DH sites, where the residents warmed up their houses partly by wood combustion. At the DH sites, the eBC concentrations did not decrease during the weekend like at the TR sites.

The trend analysis conducted in this study showed statistically significant decreasing trends for atmospheric BC. Decreasing eBC concentration has two positive effects: 1) improved air quality and 2) decreased warming effect on the global climate by light absorbing aerosols. The absolute trends of eBC concentration were most notable at the TR sites, where the trends varied from -0.04 to -0.09 $\mu\text{g m}^{-3} \text{ yr}^{-1}$. At an UB station and at an RB station, the absolute trends were -0.02 and -0.01 $\mu\text{g m}^{-3} \text{ yr}^{-1}$, respectively. The relative trends of eBC concentration varied from -10.6 to -5.7 % yr^{-1} , which was rather similar to the relative trends of NO_x concentration, which varied from -19.7 to -4.0 % yr^{-1} . The relative trends of $\text{PM}_{2.5}$, which varied from -3.9 to -2.7 % yr^{-1} , did not decrease as rapidly as the trends of eBC and NO_x . For the eBC and NO_x the most notable decrease was observed for the hours of morning rush hour, when traffic has the biggest effect on the air quality. The difference between the relative trends of eBC, NO_x and $\text{PM}_{2.5}$ concentrations, and the most notable decrease of eBC and NO_x concentrations during the morning rush hour indicated that especially the emissions from traffic have decreased.

This study suggests that the development in vehicle exhaust particle mitigation has been successful, at least from the viewpoint of BC and NO_x emissions. With the current development, the pollution concentrations are expected to decrease in the next years as well. In general, the vehicle fleet is renewing, electric and hybrid cars are gaining popularity, and vehicles that run with biofuels or gas are becoming more common. The operator of public traffic in the HMA (HSL) aims to cut more than 90 % of their bus emissions (NO_x, PM, CO₂) by the year 2025 compared to the year 2010, which will improve the air quality especially at the main roads in the HMA, where several bus lines operate.

560

This study also shows the need for regulation and mitigation of emissions from residential wood combustion, which is, according to the emission inventories, actually the most significant BC source in Finland (Rautalahti and Kupiainen, 2016). The research material of this study did not allow the assessment of long-term trends in DH areas but, in principle, any similar technology changes have not been observed in wood combustion than has been in vehicles.

Table 1: Annual mean values of eBC concentration for each station in units of $\mu\text{g m}^{-3}$. Color-coding indicates the magnitude of the mean concentration; darker color refers to higher concentration. The annual means at UB2 in 2016–2017 are bracketed, since there was less than 50 % of valid data.

Station	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016	2017	2018

Table 2: The traffic counts for working days at the nearest streets to the TR sites. The traffic counts and the fraction of the heavy-duty are from the yearly Helsinki traffic reports. The streets and roads mentioned here are marked in Fig. S3.

Station	Street name	Traffic count (vehicles/weekday)	Heavy-duty (%)	Distance to street edge (m)	Reference year
TR1	Mannerheimintie	15 800	11	3	2017
	Kaivokatu	20 100	8	40	2017
TR2	Mäkelänkatu	28 100	11	0.5	2017
TR3	Mannerheimintie	44 400	14	0.5	2010
	Reijolankatu	19 400	-	25	2010
TR4	Kehä I	69 200	8	5	2012
	Tattariharjuntie	13 700	13	120	2012
TR5	Tikkurilantie	9 500	-	7	2016
TR6	Turuntie	29 300	4	20	2017
	Lintuvaarantie	15 400	5	30	2017
	Kehä I	68 900	4	250	2017

Table 3: Results of the trend analysis of the eBC, PM_{2.5}, and NO_x concentrations. The values without brackets are the absolute trends in units of $\mu\text{g m}^{-3} \text{yr}^{-1}$, the values in the square brackets are the 5th and 95th uncertainty limits of the trend in units of $\mu\text{g m}^{-3} \text{yr}^{-1}$, and the bracketed values are the relative trends in units of $\% \text{yr}^{-1}$. The values for PM_{2.5} at TR2 are italicized, since they were statistically not significant (p-value = 0.05).

Station	eBC ($\mu\text{g m}^{-3} \text{yr}^{-1}$)	PM _{2.5} ($\mu\text{g m}^{-3} \text{yr}^{-1}$)	NO _x ($\mu\text{g m}^{-3} \text{yr}^{-1}$)	Measurement years
TR1	-0.04	-0.24	-3.11	2011, 2013–2018
	[-0.06; -0.02]	[-0.38; -0.01]	[-4.18; -1.87]	
	(-6.5 % yr ⁻¹)	(-3.7 % yr ⁻¹)	(-7.1 % yr ⁻¹)	
TR2	-0.09	<i>-0.46</i>	-11.00	2015–2018
	[-0.11; -0.05]	<i>[-0.71; 0.02]</i>	[-12.47; -8.70]	
	(-10.6 % yr ⁻¹)	<i>(-7.1 % yr⁻¹)</i>	(-19.7 % yr ⁻¹)	
UB1	-0.02	-0.20	-0.80	2012–2018
	[-0.03; -0.01]	[-0.34; -0.05]	[-1.08; -0.50]	
	(-5.7 % yr ⁻¹)	(-3.9 % yr ⁻¹)	(-5.0 % yr ⁻¹)	
RB2	-0.01	-0.10	-0.05	2006–2018
	[-0.02; -0.01]	[-0.20; -0.03]	[-0.08; -0.03]	
	(-7.6 % yr ⁻¹)	(-2.7 % yr ⁻¹)	(-4.0 % yr ⁻¹)	

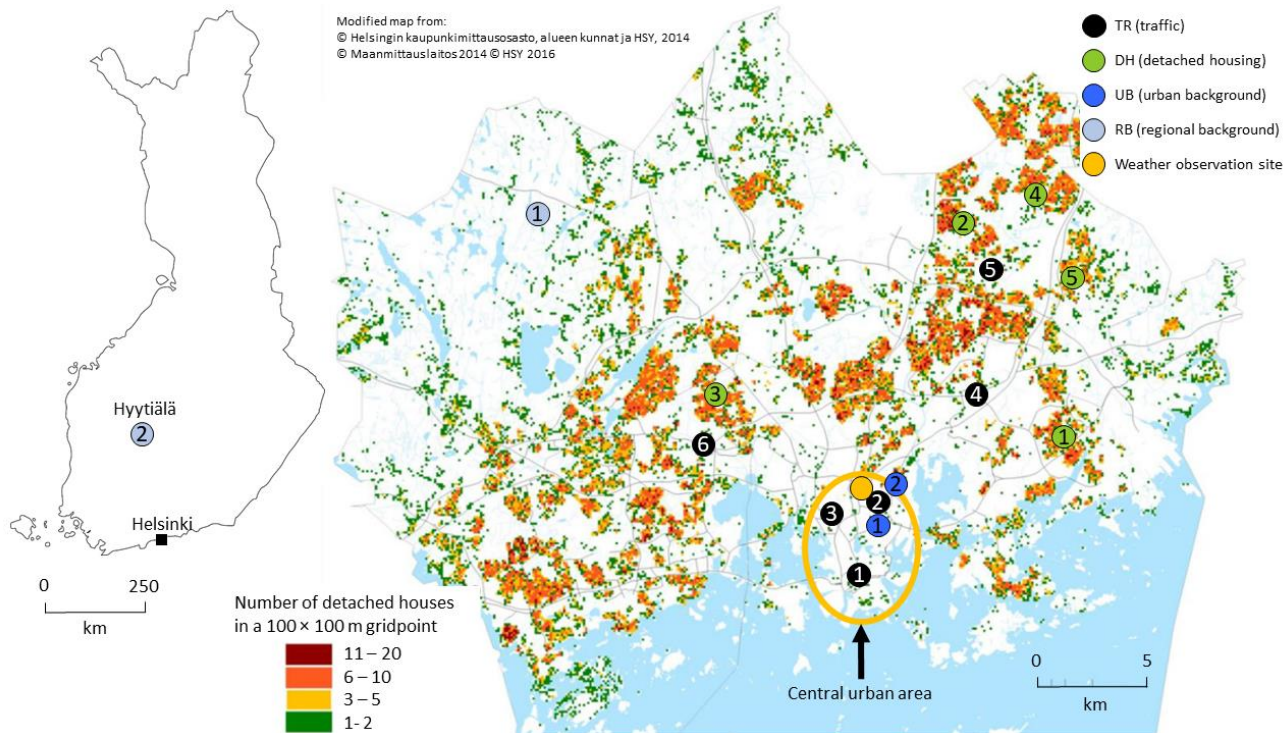

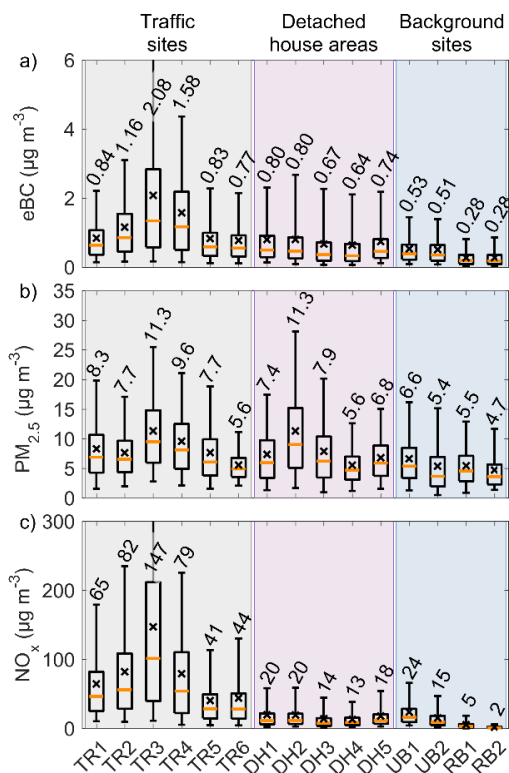

Figure 1: The locations of the stations and the density of the detached houses. Differently colored markers indicate different station categories. The central urban area is marked to the map with an orange circle.

775

Figure 2: The statistics of the a) eBC, b) PM_{2.5}, and c) NO_x concentrations at each station. The boxplots are presented for 1 h mean values. The orange line in the middle of each box represents the median, the edges of the boxes represent the 25th and 75th percentiles, and the whiskers represent the 5th and 95th percentiles. The black cross is the arithmetic mean, and its numerical value is reported above or below each box. The background color represents the station type: gray for traffic sites (TR), purple for the detached housing sites (DH), and blue for the background sites (UB for urban and RB for regional background). The 75th percentiles of eBC and NO_x concentration at TR3, which are not visible at the figure, were 6.7 and 440 µg m⁻³, respectively.

780

785

Figure 3: The statistics of eBC/PM_{2.5} fraction at each station. The explanation for the markers is the same as in Fig. 2, except here the values reported above each box are the median values.

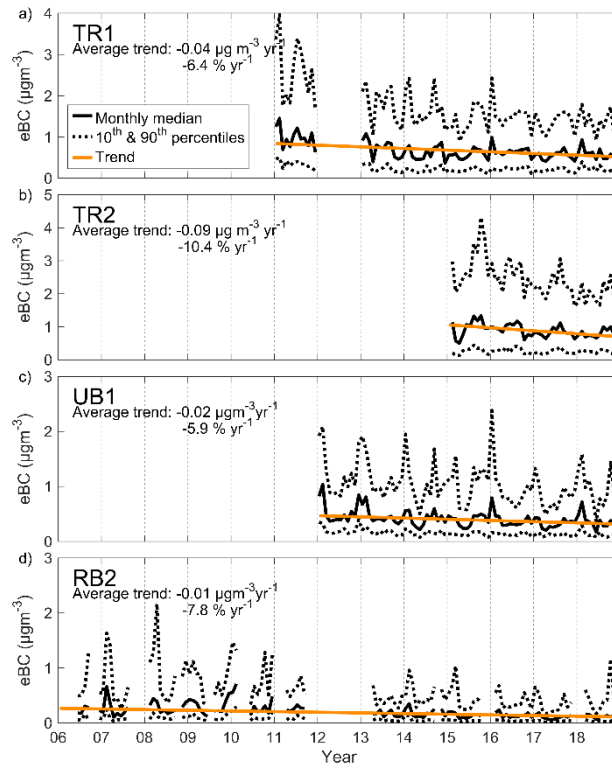

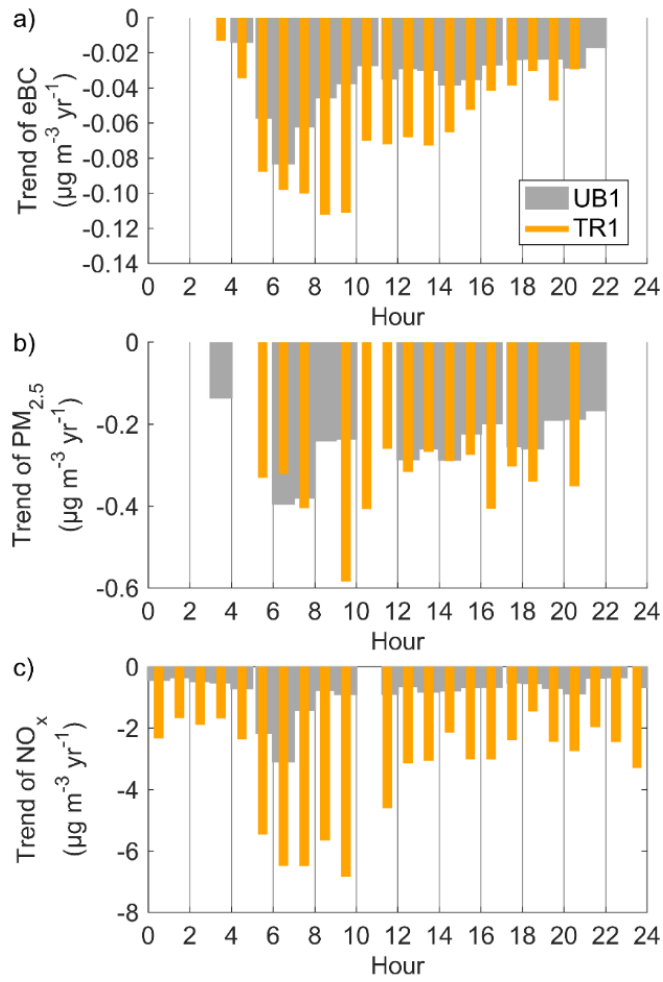

Figure 4: Time series and the trends of eBC concentration at TR1, TR2, UB1, and RB2. The solid black line represents the monthly medians, the dashed lines represent the 10th and 90th monthly percentiles, and the orange line is the fitted long-term trend.

790 **Figure 5: Annual trends for the hourly data. Here, only data from weekdays were used. None of the pollutants had a positive trend for any time of the day.**

795 **Figure 6: Diurnal variation of eBC for different station categories: a) traffic sites that were not influenced by wood burning (TR1–4), b) traffic sites that were influenced by wood burning (TR5–6), c) detached housing sites (DH1–5), d) urban background (UB1), and e) regional background (RB1). The diurnal variation is determined separately for the cold (from November to March) and warm (from May to September) periods.**
