Abstract

Despite the numerous studies investigating haze formation mechanism in China, it is still puzzling that intensive haze episodes could form within hours directly following relatively clean periods. Haze has been suggested to be initiated by the variation of meteorological parameters and then to be substantially enhanced by aerosol-radiation-boundary layer feedback. However, knowledge on the detailed chemical processes and the driving factors for extensive aerosol mass accumulation during the feedback is still scarce. Here, the dependency of the aerosol number size distribution, mass concentration and chemical composition on the daytime mixing layer height (MLH) in urban Beijing is investigated. The size distribution and chemical composition-resolved dry aerosol light extinction is also explored. The results indicate that the aerosol mass concentration and fraction of nitrate increased dramatically when the MLH decreased from high to low conditions, corresponding to relatively clean and polluted conditions, respectively. Particles having their dry diameters in the size of ~400-700 nm, and especially particle-phase ammonium nitrate and liquid water, contributed greatly to visibility degradation during the winter haze periods. The dependency of aerosol composition on the MLH revealed that ammonium nitrate and aerosol water content increased the most during low MLH conditions, which may have further triggered enhanced formation of sulphate and organic aerosol via heterogeneous reactions. As a result, more sulphate, nitrate and water soluble organics were formed, leading to an enhanced water uptake ability and increased light extinction by the aerosols. The results of this study contribute towards a more detailed understanding of the aerosol-chemistry-radiation-boundary layer feedback that is likely to be responsible for explosive aerosol mass growth events in urban Beijing.

55 1. Introduction

56 Despite the recent reduction of air pollutants and their precursors in China between 2013 and 2017,
57 the current emission and air pollution levels are still substantially high (Wang et al., 2020b; Zheng et
58 al., 2018). Such high emissions, combined with specific meteorological conditions, frequently lead
59 to severe haze episodes (An et al., 2019; Wang et al., 2019). Particulate matter, a major air pollutant,
60 has considerable effects on climate, human health and visibility degradation (Che et al., 2007;
61 Lelieveld et al., 2015; Spracklen et al., 2008; Wang et al., 2015).

62
63 During winter haze episodes, a rapid growth of the aerosol mass concentration has commonly been
64 observed, and this phenomenon seems to be directly affected by meteorological factors (Li et al.,
65 2018b; Liu et al., 2018, 2019b; Wang et al., 2018a, 2014a). The meteorological conditions and
66 increased aerosol concentrations are proposed to be interlinked by a feedback loop, called the aerosol-
67 chemistry-boundary layer feedback, in which aerosol particles reduce both solar radiation reaching
68 the surface and turbulent kinetic energy (TKE) of the near-surface air (Ding et al., 2016; Petäjä et al.,
69 2016; Wang et al., 2020d). The reduced TKE owing to aerosol reduce the entrainment of relatively
70 dry air into the mixing layer from above, which makes the air more humid within the mixing layer.
71 The increased relative humidity due to decreased surface temperature enhance the aerosol water
72 uptake ability and promote secondary aerosol formation via aqueous-phase reactions, enhancing light
73 scattering and causing further reduction of solar radiation reaching the surface. All of these factors
74 lead to increased stability of mixing layer height and enhanced air pollution in the mixed layer, which
75 further suppresses the development of boundary layer. As a consequence, concentrations of primary
76 aerosol particles, water vapor and relative humidity increase, creating more favourable conditions for
77 homogeneous and heterogeneous reactions on aerosol surfaces or inside them (Cheng et al., 2016a;
78 Wang et al., 2016; Wu et al., 2018). Such reactions cause rapid formation of secondary aerosol matter
79 and enhanced light extinction during severe winter haze episodes. However, more detailed
80 information on the aerosol and reactive gas chemistry during the aerosol-chemistry-boundary layer
81 feedback and related rapid aerosol mass growth events is still needed (Liu et al., 2019). For instance,
82 it is still unclear which chemical reactions and which compounds in the particulate matter play key

roles during such rapid mass growth events.

The particle number size distribution and chemical composition are considered to be the most important variables influencing the light extinction by aerosol particles. In the atmosphere, the highest contribution to aerosol light extinction comes from organic compounds, nitrate and sulphate in particles with diameters of 100-1000 nm. This is due to the dominant mass fractions of the aforementioned compounds in aerosols that correspond to the peak intensity of solar radiation at wavelengths around 550 nm (Jimenez et al., 2009; Swietlicki et al., 2008). In addition, light scattering which contributes the most to the light extinction by atmospheric aerosols, can be substantially enhanced by the presence of liquid water in the aerosol (Chen et al., 2014; Liu et al., 2019a; Pan et al., 2009; Wang et al., 2020). Hence, quantifying the response of light extinction to different chemical compounds would be helpful in evaluating the feedbacks associated with secondary aerosol production.

In this study, we focus on the physical and chemical properties of aerosols in Beijing during the winter heating season from October 2018 to February 2019 using state-of-the-art instrumentation. The variation of aerosol chemical composition and the associated light extinction coefficient as a function of the varying mixing layer height are discussed. Our aim is to identify the key chemical components which contribute to the aerosol-chemistry-radiation-boundary layer feedback loop in Beijing.

2. Methodology

2.1. Measurement location and instrumentations

Measurements were conducted between 1 October 2018 and 28 February 2019 at the roof top of the university building at the west campus of Beijing University of Chemical Technology (39.95°N, 116.31°E). This station is located about 150 m away from the nearest road (Zizhuyuan road) and 500 m away from the West Third Ring Road, and it is surrounded by commercial properties and residential

109 dwellings representative of an urban environment. More details on the location can be found in (Liu
110 et al., 2020; Zhou et al., 2020).

111

112 The meteorological data for this work include basic meteorological variables (relative humidity (RH),
113 temperature, wind speed, wind direction, and visibility) and mixing layer height (MLH) measured
114 using a weather station (Vaisala Inc., Finland) and a Ceilometer CL51 (Vaisala Inc., Finland),
115 respectively. The MLH is defined as the height above the surface, through which relatively vigorous
116 vertical mixing occurs (Holzworth, 1972), and its value is highly related to the vertical temperature
117 structure and, so some extent, to a mechanically-induced turbulence (Baxter, 1991). Here, we
118 followed the method introduced earlier by Munkel et al. (2007) and Eresmaa et al. (2012) in
119 determining the MLH.

120

121 The number size distributions of aerosol particles from 6 nm to 840 nm were measured by a
122 Differential Mobility Particle Sizer (DMPS) (Aalto et al., 2001). The mass concentration of fine
123 particulate matter (PM_{2.5}) was measured using a Tapered Element Oscillating Microbalance
124 Dichotomous Ambient Particulate Monitor (TEOM 1405-DF, Thermo Fisher Scientific Inc, USA)
125 with a total flow rate of 16.67 L/min (Wang et al., 2014).

126

127 A time-of-flight aerosol chemical speciation monitor (ToF-ACSM, Aerodyne Research Inc.) was used
128 to measure the concentrations of non-refractory (NR) components, including sulfate, nitrate,
129 ammonium, chloride and organics of PM_{2.5} (Fröhlich et al., 2013). A PM_{2.5} cyclone was deployed on
130 the rooftop with a flow rate of 3 L /min. [The correlation coefficient of PM_{2.5} measured by TEOM and
131 ToF-ACSM is around 0.9, which indicates the consistence of the two datasets.](#) Aerosol was dried
132 though a Nafion dryer (MD-700-24F-3, PERMA PURE) before entering the ToF- ACSM. The inlet
133 flow was set at 1.4 cm³/s. The particle beam passed through the chamber and reached the heated
134 porous tungsten surface (T≈600°C). There, the non-refractory PM_{2.5} constituents were vaporized and
135 then ionized by electrons (E_{kin}=70eV, emitted by a tungsten filament). The ions were measured by a
136 detector and the data was analyzed using Tofware ver. 2.5.13 within IgorPro ver. 6.3.7.2

(WaveMetrics). The relative ionization efficiencies (RIE) for sulfate, nitrate, ammonium, chloride and organics applied were 0.86, 1.05, 4.0, 1.5 and 1.4, respectively. Besides RIE correction, the data also did CO₂+/- NO₃ artifact correction (Pieber et al., 2016) and collection efficiency (CE) correction (Middlebrook et al., 2012). Mass concentrations of ammonium nitrate, ammonium sulfate and ammonium chloride were determined according to the method introduced by Gysel et al. (2007). The aerosol liquid water content (AWC) was calculated by the thermodynamic equilibrium model ISORROPIA II using ToF-ACSM data (Fountoukis and Nenes, 2007).

Highly-oxygenated organic molecules (HOMs) were measured by a chemical ionization long time-of-flight mass spectrometer equipped with a nitrate chemical ionization source (LToF-CIMS, Aerodyne Research, Inc. USA) (Jokinen et al., 2012) similar to gas-phase sulfuric acid. The ambient air was drawn into the ionization source through a stainless-steel tube with a length of ~1.6 m and a diameter of 3/4 inch at a flowrate of ~ 8 L/min. A 30-40 L/min purified air flow and a 4-8 mL/min ultrahigh purity nitrogen flow containing nitric acid were mixed together as the sheath flow, which is guided through a PhotoIonizer (Model L9491, Hamamatsu, Japan) to produce nitrate reagent ions. This sheath flow is then introduced into a co-axial laminar flow reactor concentric to the sample flow. Nitrate ions are pushed to the sample flow layer by an electric field and subsequently charge analytical molecules. Organic carbon (OC) and element carbon (EC) concentrations were measured semi-continuously with a 1-hour time resolution using an OC/EC Analyzer (Model-4, Sunset Lab. Inc.) and time series of ACSM Org and Sunset OC as shown in Fig S6.

The ammonia is measured by Trace Ammonia analyzer (Los Gatos Research, Inc.) at atmospheric ambient levels with high precision (0.2 ppb in 1s) and ultra-fast response (5 Hz).

The air mass history was studied by calculating particle retroplumes using a Lagrangian particle dispersion model FLEXPART (FLEXible PARTicle dispersion model) ver. 9.02 (Stohl et al., 2005). The ECMWF (European Centre for Medium-Range Weather Forecast) operational forecast (with 0.15° horizontal and 1 h temporal resolution) was used as the meteorological input into the model. During the measurement period, a new release of 50 000 test particles, distributed evenly between 0 and 100 m above the measurement site, occurred every 1 hour. The released particles were traced backwards

165 in time for 72 h, unless they exceeded the model boundary (20–60°N, 95–135°E).

166

167 **2.2. Aerosol light extinction calculation**

168 The aerosol light extinction coefficient was calculated with the Mie-Model, which uses particle
169 number size distribution, mass concentrations of different aerosol compounds and their refractive
170 index as inputs (Seinfeld and Pandis, 2006). We introduced a series of assumptions into the Mie-
171 Model, including 1) “internal mixture” which considers each chemical component in a particle as
172 homogeneously mixed with each other; 2) all particles are spherical; and 3) particles of different sizes
173 have the same chemical composition.

174

175 The practical method introduced under those assumptions in previous studies were found to be
176 capable of estimating a variation trend of optical property of PM_{0.5–20} with a relatively good accuracy
177 (Lin et al., 2013).

178

179 Table 1. Summary of the parameters for calculating the average optical refractive index.

180

Species	$\rho_i(\text{g cm}^{-3})$	n_i	k_i
(NH ₄) ₂ SO ₄	1.760	1.530	0.000
NH ₄ NO ₃	1.725	1.554	0.000
NH ₄ Cl	1.527	1.639	0.000
Organics	1.400	1.550	0.001
EC	1.500	1.800	0.540

181

182 The average optical refractive index (AORI) of an internally-mixed particle can be calculated from
183 the optical refractive indices (ORI) of each chemical component by following a mixing rule of
184 volume-averaged chemical components as $\text{AORI} = n_{\text{eff}} + k_{\text{eff}} \times i$, where the real part (n_{eff}) and
185 imaginary part (k_{eff}) are given by:

$$n_{eff} = \left(\sum_i n_i \cdot m_i / \rho_i \right) / \left(\sum_i m_i / \rho_i \right) \quad (1)$$

$$k_{eff} = \left(\sum_i k_i \cdot m_i / \rho_i \right) / \left(\sum_i m_i / \rho_i \right) \quad (2)$$

Here m_i and ρ_i are the mass concentration and density of the component i in particles, respectively, and n_i and k_i are the real and imaginary parts of ORI of this component, respectively. The parameters for calculating the AORI are summarised in Table 1. The values of n_i and k_i in Table 1 are referenced to the light wavelength of 550 nm.

$Q_{sp,j}$ represents light scattering efficiency of a single particle with diameter D_j , while $Q_{ep,j}$ represents light absorption efficiency. Theoretically, $Q_{sp,j}$ and $Q_{ep,j}$ are both the function of D_j and the $AORI_j$ (the AORI of the particle with diameter D_j) at a given light wavelength λ , for which the complicated calculations were referenced to a previous publication (Lin et al., 2013). Regarding the limitations of measurement techniques, the $AORI_j$ was assumed to be equal to the $AORI_{PM2.5}$, which was determined based on chemical composition of $PM_{2.5}$. It is possible to derive expressions for the cross sections of a spherical particle exactly. The formulas for $Q_{sp,j}$ and $Q_{ep,j}$ are:

$$Q_{sp,j}(D_j, \lambda, AORI_j) = \frac{2}{\alpha^2} \sum_{k=1}^{\infty} (2k+1) \cdot [|a_k|^2 + |b_k|^2] \quad (3)$$

$$Q_{ep,j}(D_j, \lambda, AORI_j) = \frac{2}{\alpha^2} \sum_{k=1}^{\infty} (2k+1) \cdot Re[a_k + b_k] \quad (4)$$

where

$$a_k = \frac{\alpha \psi'_k(y) \psi_k(\alpha) - y \psi'_k(\alpha) \psi_k(y)}{\alpha \psi'_k(y) \xi_k(\alpha) - y \xi'_k(\alpha) \psi_k(y)}$$

$$b_k = \frac{y \psi'_k(y) \psi_k(\alpha) - \alpha \psi'_k(\alpha) \psi_k(y)}{y \psi'_k(y) \xi_k(\alpha) - \alpha \xi'_k(\alpha) \psi_k(y)}$$

206 with $y = \alpha m$.

207

$$208 \quad m = n_{eff} + i \cdot k_{eff}$$

209

$$210 \quad \alpha = \frac{\pi D_j}{\lambda}$$

211

212 with $\lambda = 550$ nm.

213

214 where complex number m stands for $AORI_j$, while α is the size of the particle, usually expressed as

215 a dimensionless size parameter. The functions $\psi_k(z)$ and $\xi_k(z)$ are the Riccati–Bessel functions:

$$\psi_k(z) = \left(\frac{\pi z}{2}\right)^{1/2} J_{k+1/2}(z) \quad (5)$$

$$\xi_k(z) = \left(\frac{\pi z}{2}\right)^{1/2} [J_{k+1/2}(z) + i(-1)^k J_{-k-1/2}(z)] \quad (6)$$

216

217 where $J_{k+1/2}$ and $J_{-k-1/2}$ are the Bessel functions of the first kind and their footnotes indicate the

218 order of Bessel functions. The Mie theory can serve as the basis of a computational procedure to

219 calculate the scattering and absorption of light by any sphere as a function of wavelength.

220

221 According to the Mie-Model, b_{sp} (light scattering coefficient) and b_{ep} (light extinction coefficient)

222 can be quantified with Eqs. (5) and (6), respectively. b_{ap} (light absorption coefficient) is the

223 difference between b_{ep} and b_{sp} , which equals zero, when k_i equals zero or very small. Optical

224 properties including b_{ep} , b_{sp} and b_{ap} to be discussed later are all referenced to light wavelength of

225 550 nm.

$$b_{sp} = \sum_j b_{sp,j} = \sum_j \frac{\pi D_j^2}{4} \cdot Q_{sp,j}(D_j, \lambda, AORI_j) \cdot N_j \quad (7)$$

$$b_{ep} = \sum_j b_{ep,j} = \sum_j \frac{\pi D_j^2}{4} \cdot Q_{ep,j}(D_j, \lambda, AORI_j) \cdot N_j \quad (8)$$

226

227

228 In Eqs. (7) and (8), D_j stands for the median Stokes diameter in the j -th particle size range and N_j is
229 the number concentration of particles with diameter, D_j .

230

231 3. Results and discussion

3.1. An over of the measurement campaign

The time series particle number size distribution from 6 nm to 840 nm, mass concentrations of nitrate, organics, sulfate, ammonium and chloride in NR-PM_{2.5} (non-refractory PM_{2.5}) and PM_{2.5}, concentration of HOMs and OC are shown in Figure 1(a), (b) and (c). The statistics of these compounds are summarized in Table S1. In general, they showed similar variation patterns (Figure S2 and S3). These concentrations showed high values during haze event than clean days and increased significantly during night time. As shown in Figure 1(b), the rapid mass growth during the heating season in Beijing is related to the rapid growth in nitrate concentration. At the same time, the haze events (PM_{2.5} concentration $\geq 75 \mu\text{g}/\text{m}^3$ and lasting more than one day) are accompanied by particle size growth (Figure 1(a)). To further study which particle size possesses the highest light extinction efficiency during the haze events, and to what extent nitrates contribute to light extinction with the variation of MLH, a case of rapid rapid aerosol mass growth event is selected for further study.

232 3.2. Typical case of rapid aerosol mass growth episodes affected by aerosol-chemistry- 233 boundary layer interactions

234 An example of rapid aerosol mass growth in urban wintertime Beijing is illustrated in Figure 2, where
235 the haze accumulation was associated with a rapid PM_{2.5} mass concentration increase from $8.5 \mu\text{g}/\text{m}^3$
236 to more than $100 \mu\text{g}/\text{m}^3$ in less than 7 hours. A haze episode started on afternoon 20 February 2019
237 under stagnant meteorological conditions with low wind speeds and elevated ambient relative
238 humidity (Figure S4). The polluted periods during this case occurred under southerly wind transport
239 conditions, whereas clean air masses originated from the north-westerly regions (as shown in Figure

240 S5, S6). These are typical features for a haze evolution process in Beijing (Wang et al., 2020b). During
241 the haze periods marked by the shaded areas in Figure 2, an obvious increase of chemical mass
242 concentration was observed by the ToF-ACSM, characterised by high concentrations of secondary
243 aerosol components (nitrate, organics and sulphate) and typically a shallow boundary layer. The mass
244 concentrations of organics, sulphate and nitrate increased dramatically with a decreasing MLH,
245 accounting for 88.5% of NR-PM_{2.5} during the rapid aerosol mass growth period. The aerosol mass
246 growth was the fastest for nitrate. The mass concentrations of organic and elemental carbon followed
247 that of NR-PM_{2.5}.

248
249 The MLH reached its maximum at around 14:00 in the afternoon of 20 February, after which the
250 development of the mixing layer was suppressed and MLH decreased with the arrival of pollution
251 (Figure 2a). Previous studies have shown that the aerosol-radiation-boundary layer feedback
252 contributes to a rapid enhancement of air pollution (Petäjä et al., 2016; Wang et al., 2020d). High
253 concentrations of aerosol particles obscure downward radiation, as a result of which the surface
254 temperature and sensitive heat flux decrease and the development of mixing layer height is suppressed.
255 Recent studies have gradually realized that the facilitation of various chemical processes play a non-
256 negligible role in the aerosol-radiation-boundary layer feedback (Liu.Q et al., 2018; Liu. Z et al., 2019).
257 Therefore, it is important to identify and quantify the role of different specific chemical species and
258 particle size ranges in reducing atmospheric radiation and extinction.

259
260 Figure 3 shows the contributions of size and chemical composition-resolved dry aerosol to light
261 extinction during the investigated period. As the pollution intensified and MLH decreased (Fig 2c),
262 the light extinction of atmospheric aerosols increased significantly. Assuming that particles of
263 different sizes have the same chemical composition as PM_{2.5} (organics, NH₄NO₃, EC, (NH₄)₂SO₄,
264 NH₄Cl), the light extinction of particles in the size range of 300-700 nm increased significantly from
265 the relative clean period to the polluted period (namely from 12:00 to 16:00). During relatively clean
266 conditions, the contributions of organics, NH₄NO₃, EC, (NH₄)₂SO₄ and NH₄Cl to the total aerosol
267 light extinction were 42%, 23%, 18%, 11% and 7%, respectively. The contribution of NH₄NO₃ to

aerosol light extinction reached 40% during the heavily polluted period. Based on the observation it is likely that the increased light extinction by aerosols reduced solar radiation reaching the surface, so that the development of the boundary layer was suppressed.

271

3.3. Connection between the aerosol chemical composition, light extinction, size distribution and MLH during the heating season

274

To better characterize the effect of the chemical composition of dry aerosols and the PNSD (particle number size distribution) light extinction under different MLH conditions, the daytime (8:00 – 16:00 LT) measurement data from October 2018 to February 2019 were selected for further analysis. As shown by Figure 4 and consistent with other observations in Beijing (Tang et al., 2016; Wang et al., 2020c), there was a general tendency for the PM_{2.5} mass concentration to increase with a decreasing MLH. Organic compounds and nitrate were the most abundant fractions of the daytime aerosol mass composition, contributing together approximately 70% to total NR-PM_{2.5} mass concentration. With a decreasing MLH, the fraction of nitrate mass in NR-PM_{2.5} slightly increased while that of organics decreased. This feature makes the aerosol more hygroscopic under low MLH conditions typical for heavily polluted periods. The increased nitrate fraction in the aerosol could also enhance the formation of other secondary aerosol components (Xue et al., 2019). Note that some fraction of aerosol nitrate could consist of organic nitrate originating from reaction of peroxy radical with nitric oxide; however, it is difficult to distinguish organic nitrate from inorganic nitrate at the moment due to instrumental limitations (Fröhlich et al., 2013).

289

Figure 5 depicts the calculated daytime light extinction of the dry aerosol as a function of the MLH, separated by different size ranges and chemical components. We may see that in general, particles with dry diameters in the range of 300-700 nm explains more than 80% of the total aerosol light extinction (Figure 5b). Similar to their share in NR-PM_{2.5}, the fraction of light extinction by ammonium nitrate increased and that of organics decreased during the lowest MLH conditions

corresponding to the heavy pollution periods (Figure 5d). There are also apparent differences in the relative contribution of different particle size ranges to light extinction in different MLH conditions: with a decreasing MLH, the contribution of particles with dry dimeters larger than about 400-500 nm clearly increased while that of sub-300 nm particles notably decreased. This indicates that the enhanced light extinction by the dry aerosol at low MLH conditions was not only due the more abundant aerosol mass concentration, but also due to the growth of individual particles to optically more active sizes.

At relative humidity larger than about 70%, aerosol liquid water gives a significant contribution to the aerosol mass concentration and often a dominant contribution to the aerosol light extinction (Titos et al., 2016). This has important implications for the aerosol-chemistry-radiation-boundary layer feedback, when considering our findings listed above and further noting that heavy pollution periods are often accompanied by high values of RH in Beijing (Zhong et al., 2018). First, compared to clean or moderately-polluted conditions, the enhancement in the aerosol light extinction under polluted is probably much larger than that illustrated in Figure 5. Second, the high aerosol water content under polluted conditions promotes many kinds of chemical reactions taking place on the surface or inside aerosol particles.

3.4. Aerosol-chemistry-radiation-boundary layer interaction

In order to further investigate the interaction between MLH and chemical compounds (either observed or calculated), we divided the observed PM_{2.5} concentrations into highly polluted and less polluted conditions using a threshold value of 75 µg /m³ for PM_{2.5}. The organics, nitrate, ammonium, sulfate, chloride, HOM, aerosol water content (AWC) and PM_{2.5} as a function of the mixing layer height during both highly polluted and less polluted conditions are shown in Figure 6. The fitted relationships connecting the concentrations of different chemical compounds to the reduction of MLH under highly and less polluted conditions allowed us to estimate the net mass concentration increase of each

322 compound due to secondary formation and aerosol-chemical-boundary layer feedback under highly
323 polluted conditions (shaded areas in Figure 6). It is worth noting that AWC, nitrate and sulfate
324 increased the most as the MLH decreased, as represented by the large shaded areas in Figs. 6 (h), (b)
325 and (c). [The increases of these components are significant as tested \(Supplement information\)](#). The
326 day-time nitrate in aerosol is formed predominately via the reaction of nitric acid and ammonium,
327 while nitric acid is produced from gas phase reaction of nitrogen dioxide and hydroxy radical
328 (Seinfeld and Pandis, 2006). High concentrations of daytime nitrate aerosols indicate efficient
329 production of gas phase nitric acid, its partitioning into liquid aerosol and its fast neutralization by
330 abundant ammonia (Li et al., 2018a; Pan et al., 2016; Wang et al., 2020). A recent study shows that
331 condensation of nitric acid and ammonia could promote fast growth of newly formed particle in urban
332 environment condition (Wang et al., 2020d). Another possibility is that ammonium nitrate is formed
333 rapidly on particle surfaces due to the hydrolysis of dinitrogen pentoxide (N_2O_5) during daytime, as
334 the AWC increased significantly (Wang et al., 2014; Wang et al., 2020). However, a quantitative
335 distinction between the two formation pathways for nitrate formation is not possible in this study. The
336 dramatic increase of nitrate aerosol could also promote the formation of sulfate by heterogeneous
337 reactions (Cheng et al., 2016b; Wang et al., 2016). The concentration of HOMs showed a slight
338 increase as the MLH decreased, which suggests that also the formation of HOMs is enhanced with an
339 increased level of air pollution. This phenomenon should be further investigated as HOMs can
340 substantially contribute to the secondary organic aerosol formation.

341
342 Figure 7 displays the dry aerosol light extinction by different chemical compounds in the same way
343 as Figure 6 did for aerosol mass concentrations. The aerosol light extinction is directly related to the
344 reduction of solar radiation reaching the surface, assuming that aerosol chemical components are
345 vertically nearly homogeneously distributed. The light extinction from ammonium nitrate,
346 ammonium sulfate and organics showed significantly increased contributions under highly polluted
347 conditions (low MLH) as compared with less polluted conditions. To the contrary, no such
348 enhancement was observed for ammonium chloride or element carbon (Figs. 7 (d) and (e)). In case
349 of EC this is an expected result, as it originates solely from primary sources. The formation of particle

350 phase chloride have secondary sources from chlorine atom-initiated oxidation of volatile organic
351 compounds, so that the resulting oxidation products could contribute to the observed chloride (Wang
352 and Ruiz, 2017; Wang et al., 2019a).

353
354 To better illustrate the combined effects of secondary aerosol formation and associated feedback on
355 the daytime mass concentrations and light extinction due to different chemical components, we scaled
356 these quantities by either the total PM_{2.5} mass concentration or EC concentration and plotted them as
357 a function of MLH (Fig. 8). With the average level of PM_{2.5} measured by TEOM and ToF-ACSM,
358 the latter scaling minimizes the boundary layer accumulation effect on our analysis, as EC originates
359 from primary emission sources (Cao et al., 2006). As shown in Fig. 8a, organics with their mass
360 fraction of 61% were the most abundant component in PM_{2.5} under high MLH conditions, followed
361 by nitrate and ammonium with their mass fractions of 22% and 13%, respectively. The aerosol was
362 estimated to be rather dry under high MLH conditions ($AWC/PM_{2.5} = 0.03$). However, with the
363 decreasing MLH, the fraction of nitrate and the AWC to PM_{2.5} ratio increased up to 45% and 0.2,
364 respectively. This clearly indicates rapid nitrate formation and dramatic increase of the aerosol water
365 uptake from less polluted conditions to intensive haze pollution. Compared with EC (Fig.8c), the
366 concentrations of organic compounds, nitrate, sulfate and ammonium increased by factors of 1.5, 6.3,
367 4.8 and 4.9 respectively, from the highest to the lowest MLH conditions. Thus, although organics
368 remained as the second most abundant aerosol component after nitrate under haze conditions,
369 secondary formation and associated feedback from less to highly polluted conditions were clearly
370 stronger for both sulfate and ammonium. Efficient sulfate production associated with haze formation
371 has been reported in several studies conducted in China (Cheng et al., 2016; Xie et al., 2015; Xue et
372 al., 2016). Ammonium production during haze formation is tied with neutralization of acidic aerosol
373 by ammonia, which was apparently present abundantly in the gas phase. Compared with the EC
374 concentration, light extinction by (NH₄NO₃) increased the most from the highest MLH conditions
375 ($248 \text{ M m}^{-1}/\mu\text{g m}^{-3}$) to the lowest MLH conditions ($1150 \text{ M m}^{-1}/\mu\text{g m}^{-3}$) as shown by Figure 8b.
376 Overall, the rapid growth of nitrate aerosol mass, together with abundant concentration of organic
377 aerosol, were the main cause of the light extinction for dry aerosol under haze formation.

378

379 The mechanism governing the aerosol-chemistry-radiation-boundary layer feedback for the rapid
380 growth of atmospheric aerosol is illustrated in Fig. 9. As a result of reduction in solar radiation and
381 atmospheric heating, a variety of chemical reactions in the gas phase and on particle surfaces or inside
382 them are enhanced with an increased relative humidity and AWC. Such conditions are unfavorable
383 for the dispersion of pollutants, which further enhances atmospheric stability. The formation of
384 hydrophilic compounds, e.g., nitrate, sulfate and oxygenated organic compounds, result in enhanced
385 water uptake by aerosol particles, which will essentially increase heterogeneous reactions associated
386 with these particles. As a result, the aerosol mass and size increase, light extinction is enhanced, and
387 the development of the mixing layer is depressed. At the same time, aerosol precursors concentrated
388 within a shallower mixing layer lead to enhanced production rate of aerosol components in both gas
389 and aerosol phases, especially nitrate but also other secondary aerosol. The increased concentrations
390 of aerosol will further enhance this positive loop.

391

392 **4. Conclusions**

393

394 We investigated the synergetic variations of aerosol chemical composition and mixing layer height
395 during the daytime in urban Beijing. Significant dependency of the sharp increase of ammonium
396 nitrate and aerosol water content with the occurrence of the explosive aerosol mass growth events
397 were observed. We showed that these two components drove a positive aerosol-chemistry-radiation-
398 boundary layer feedback loop, which played an important role in the explosive aerosol mass growth
399 events. A plausible explanation is that the increased aerosol water content at low mixing layer heights
400 provides favorable conditions for heterogeneous reactions for nitrate and sulfate production and
401 neutralization by ammonia. The significant formation of secondary aerosol increases the
402 concentration of aerosol particles in the diameter range 300-700 nm, which effectively reduces the
403 solar radiation reaching the surface and further enhances the aerosol-chemistry-radiation-boundary
404 layer feedback loop. Our analysis connects the aerosol light extinction to a reduction in the mixing

405 layer height, which suppresses the volume into which air pollutants are emitted and leads to an
406 explosive aerosol mass growth. Our results indicate that reduction of ammonium and nitrate
407 concentration in aerosol could weaken the aerosol-radiation-chemistry-boundary layer feedback loop,
408 which could thereby reduce heavy haze episodes in Beijing.

Figure caption

Figure 1. Time series of (a) particle number concentration distribution (PNSD) from 6 nm to 840 nm (b) chemical composition of NR_PM_{2.5} and PM_{2.5} mass concentrations (c) The concentrations of organic carbon (OC) and highly oxygenated organic molecules (HOM).

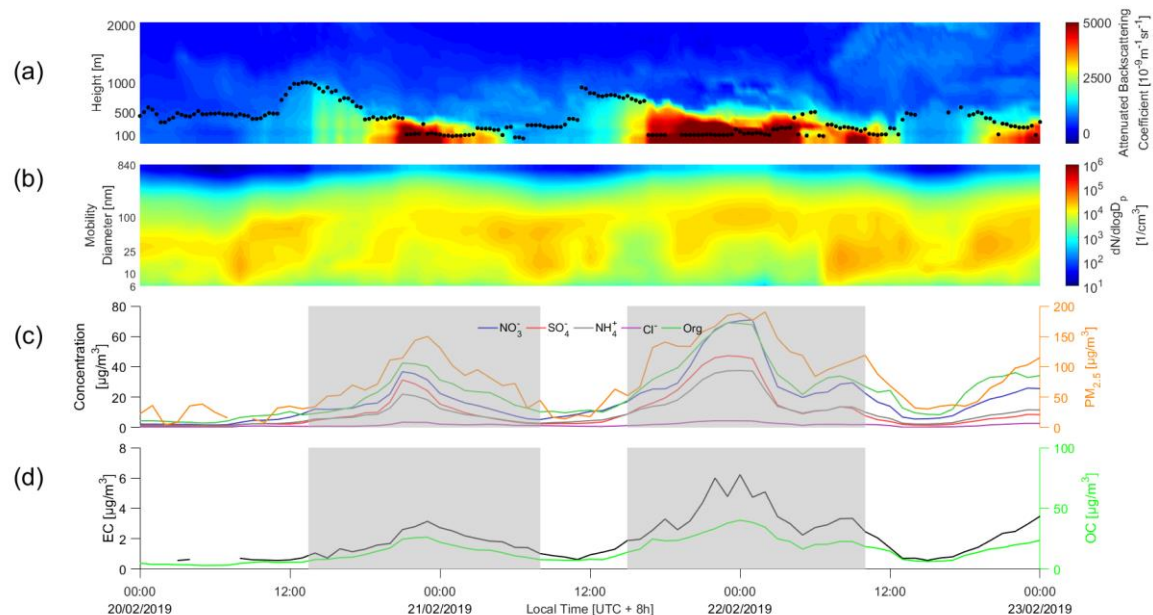

Figure 2. Time series of (a) attenuated backscattering coefficient and mixing layer height (b) particle number concentration distribution (PNSD), (c) chemical composition and PM_{2.5} mass concentrations and (d) elemental carbon (EC) and organic carbon (OC). The haze periods are marked by the shaded areas.

Figure 3. Time series of (a, b) variation of light extinction from different size aerosol and fractions, and (c, d) variation of light extinction from different aerosol species and fractions. The legends in the left side of figures are particle diameter and the right side are chemical compositions, respectively.

Figure 4. Statistical relationship between MLH and concentration (a) and fraction (b) of chemical composition species. Only daytime conditions determined by ceilometer from non-rainy periods (RH<95%) during the observation (~ 6 months) are considered.

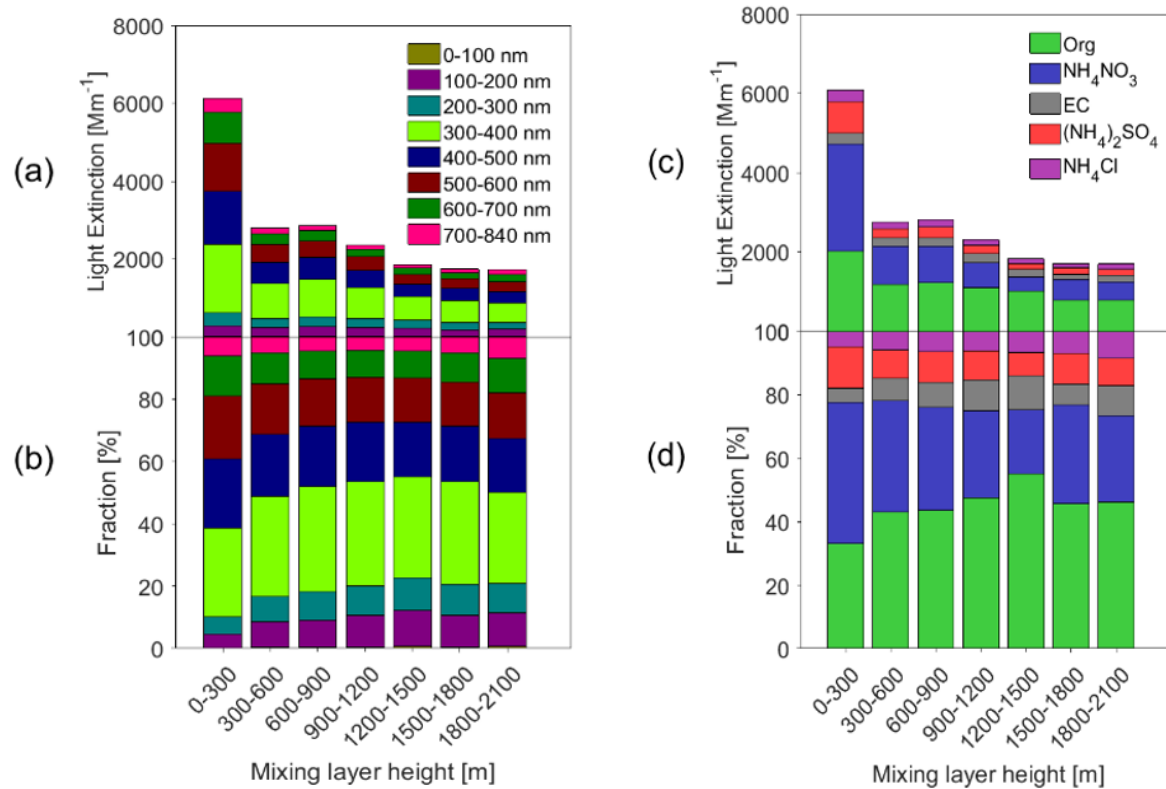

Figure 5. Statistical relationship between MLH and light extinction of different aerosol species. Only daytime conditions determined by the ceilometer from non-rainy periods ($\text{RH} < 95\%$) are considered.

524

Figure 6. Observed dependency of (organics (a), nitrate (b), ammonium (c), sulfate (d), chlorine (e), element carbon (f), HOMs (g), AWC (h) and PM_{2.5}(i) on the MLH during polluted and less-polluted conditions. The data related to the upper fitting line represents PM_{2.5} concentrations larger than 75 µg m⁻³, while the data related to the lower fitting line represents PM_{2.5} concentrations lower than 75 µg m⁻³. Only daytime conditions determined by the ceilometer from non-rainy periods (RH<95%) were considered. The solid cycles and hollow cycles denotes concentrations that are more than 75 µg m⁻³ and less than 75 µg m⁻³, respectively. The dark grey points and red lines in the boxes represent mean and median values, respectively. The shaded area between the upper solid and dotted lines corresponds to an increased amount of the specific compounds with decreased MLH, assuming that the compound has the same variation pattern under highly- polluted conditions as in less polluted time.

Figure 7. Observed dependency of the aerosol light extinction due to NH_4NO_3 (a) $(\text{NH}_4)_2\text{SO}_4$ (b), NH_4Cl (c) Org (d) and EC (e) on the MLH during polluted and non-polluted conditions. The data related to the upper fitting line represents $\text{PM}_{2.5}$ concentrations larger than $75 \mu\text{g m}^{-3}$, while the data related to the lower fitting line represents $\text{PM}_{2.5}$ concentrations less than $75 \mu\text{g m}^{-3}$. Only daytime conditions determined by ceilometer from non-rainy periods ($\text{RH} < 95\%$) are considered. The dark grey points and red lines in the boxes represent mean and median values, respectively. The shaded area between the upper solid and dashed line corresponds to an increased amount of $\text{PM}_{2.5}$ with a decreased MLH, assuming that $\text{PM}_{2.5}$ has the same variation pattern under highly- polluted conditions as in less polluted time

Figure 8. (a) the ratio of the mass concentration of different chemical components (nitrate, sulfate, organics, chlorine, ammonium) and AWC to the mass concentration of NR_PM_{2.5} as a function of MLH. (b) the ratio of dry aerosol light extinction by different chemical components (NH₄NO₃, (NH₄)₂SO₄, Org, NH₄Cl) to the mass concentration EC as a function of MLH (c) the ratio of the mass concentration of different chemical components (nitrate, sulfate, organics, chlorine, ammonium) and AWC to the mass concentration of EC as a function of MLH. All the data corresponds to polluted conditions (fine PM >75 µg m⁻³), and only daytime conditions determined by the ceilometer from non-rainy periods (RH<95%) were considered.

Figure 9. A schematic picture illustrating the process of rapid aerosol mass growth and enhanced light extinction in Beijing. The plus symbols represent the strengthening of a specific process. At the presence of aerosols during afternoon time in Beijing, the intensity of solar radiation reaching the surface will be decreased and relative humidity will be increased. As a result, the development of boundary layer will be suppressed, and the concentrations of aerosol precursors (e.g., SO_2 , NO_2 , VOC) will be increased. In turn, the secondary production of these sulfate, nitrate and oxygenated organic compounds will be enhanced due to increased concentrations and partitioning of these compounds into the aerosol phase. The increased formation of secondary aerosol mass will reduce solar radiation further and the haze formation increased, as shown in pie charts that the light extinction fraction of aerosol changed from organic to nitrate. Noting that during intensive haze periods, nitrate and its contribution to light extinction contribution increased dramatically.
