**Abstract.** Atmospheric high viscosity organic particles (HVOP) were observed in samples of ambient aerosol collected on April and May 2016 in the Southern Great Plains of the United States. These particles were apportioned as either airborne soil organic particles (ASOP) or tar balls (TB) from biomass burning based on spectro-microscopic imaging and assessment of meteorological records of smoke and precipitation data. Regardless of their apportionment, the number fractions of HVOP were positively correlated ( $R^2 = 0.85$ ) with increased values of Ångström absorption exponent (AAE) measured *in-situ* for ambient aerosol at the site. Extending this correlation to 100% HVOP yields an AAE of 2.6, similar to previous literature reports of the class of light absorbing organic particles known as brown carbon (BrC). Although there are chemical similarities between ASOP and TB, they can be distinguished based on composition inferred from near edge absorption X-ray fine structure (NEXAFS) spectroscopy. ASOP were distinguished from TB based on their average  $-\text{COOH}/\text{C}=\text{C}$  and  $-\text{COOH}/\text{COH}$  peak ratios, with ASOP having lower ratios. NEXAFS spectra of filtered soil organic brine particles nebulized from field samples of standing water deposited after rain were consistent with ASOP when laboratory particles were generated by bubble bursting at the air-organic brine interface. However, particles generated by nebulizing the bulk volume of soil organic brine had particle composition different from ASOP. These observations are consistent with the raindrop generation mechanism responsible for ASOP emissions in the area of study. In contrast, nebulized samples carry with them higher fractions soil inorganics dissolved in the bulk volume of soil brine that are not aerosolized by the raindrop mechanism. Our results support the bubble bursting mechanism of particle generation during rainfall resulting in the ejection of soil organics into the atmosphere.

## 1 Introduction:

Regional and global atmospheric transport models are commonly used to predict the impact of aerosols on radiative forcing (Feng et al., 2013). The efficacy of these models relies on estimates of the types, number concentrations, spatial distribution, and emission sources of aerosols. One challenge of continued scientific discussion is how (and to what extent) industry and other anthropogenic activities contribute to climate forcing. Emissions of soot, one of the most well-studied anthropogenic aerosols emitted by fossil fuel combustion, have been shown to have a strong a climate warming factor comparable to carbon dioxide (Bond et al., 2013). However, soot is not the only light absorbing carbon containing aerosol of concern. Less absorbing, but often more abundant light absorbing organic aerosol carbon aerosol, known as brown carbon (BrC), has been the subject of increased investigation, with studies showing that BrC may account for a substantial fraction of the total aerosol radiative forcing (Feng et al., 2013;Zhang et al., 2017). These particles exhibit a wavelength dependent light absorption, absorbing stronger at shorter wavelengths, giving them a brown appearance. Ongoing research on the role of BrC in global radiative forcing suggests it is insufficiently represented in models (Feng et al., 2013;Laskin et al., 2015;Bond and Bergstrom, 2006).

BrC particles are defined in very general terms of their chemical composition and optical properties (Bond et al., 2013;Laskin et al., 2015). BrC refers to a broad category of organic particles comprised of many different chromophores originating from a variety of sources (Andreae and Gelencsér, 2006). Sources of BrC include, but are not limited to: biomass burning (Rizzo et al., 2013;Laskin et al., 2015), biogenic fungi, humic like substances (Andreae and Gelencsér, 2006;Wang et al., 2016), and secondary organics (Laskin et al., 2015). One example of BrC particles are tar balls (TB) which are most commonly found in biomass burning emissions downwind of smoldering fires (Chakrabarty et al., 2010). TB of 50-300 nm in size have a characteristic spherical morphology observed in many studies, indicative of their highly viscous or “glassy” phase state. Recently, larger spherical organic particles (~500 nm) of a different BrC type (Veghte et al., 2017) have been also observed in rural Oklahoma, with their composition consistent with soil organic matter (SOM). These newly discovered BrC particles have been termed airborne soil organic particles (ASOP) (Wang et al., 2016). The study reported formation of highly viscous submicron particles following the impaction of rain droplets on the soil surfaces which eject ASOP into the ambient air(Wang et al., 2016). Mechanism of plausible ASOP emissions was further corroborated by laboratory experiments with water droplets falling onto surfaces of soil proxies (Joung and Buie, 2015). As falling water droplets make contact with the porous surface, air is trapped beneath the rapidly expanding droplet. These bubbles rise to the surface of the droplet bringing soil organics with them where a cavity forms and then ruptures producing film and jet droplets (Joung and Buie, 2015).

A defining characteristic of BrC particles is the spectral dependence of light absorption in the visible wavelengths. One way of quantifying this dependence is to measure the absorption coefficient ( $\sigma_{ap}$ ) as a function of wavelength, to calculate the absorption Ångström exponent (AAE) (Backman et al., 2014). The AAE value is essentially the slope of a log-log plot of absorption coefficient and wavelength, with higher values corresponding to enhanced absorption in shorter wavelengths. Because soot absorbs nearly equally across the entire visible spectrum, it has an AAE value of approximately 1. In contrast,

70

reported AAE values for BrC are substantially higher, typically in a range of 2.5-6 (Rizzo et al., 2013; Lawless et al., 2004; Hoffer et al., 2006) but could be as high as 9-11 (Andreae and Gelencsér, 2006; Lin et al., 2017). An AAE value of 2.5 has been used as a lower limit to attribute absorption, at least in part, to BrC (Lack and Langridge, 2013). In addition to the AAE, absorption due to BrC has also been investigated through calculation of the complex refractive index (Veghte et al., 2017).

75

To better characterize highly viscous organic particles (HVOP) appearing as solid spheres, samples of ambient particles were collected at the atmospheric radiation measurement (ARM) facility in Lamont, Oklahoma located in the southern great plains (SGP) as part of the Holistic Interactions of Shallow Clouds, Aerosols, and Land-Ecosystems (HI-SCALE) field campaign (Fast et al., 2019). To compare the spectroscopic signatures of atmospheric particles with SOM typical for the area of study, aquatic samples of the surface layer of muddy puddles were also collected around the sampling site. These aquatic samples were then filtered, nebulized, and the resulting particles were impacted onto microscopy substrates. The purpose of collecting these samples was to use them to compare particle morphology and composition when AAE was high, as indicated by online measurements performed at the site (Stephen Springston, 2011). The particle samples were analyzed with both scanning electron microscopy (SEM) and scanning transmission X-ray microscopy coupled with near-edge X-ray absorption fine structure (STXM-NEXAFS) spectroscopy. SEM images were taken at a 75° tilted angle with respect to the surface normal to identify HVOP suspected to be either ASOP or TB. STXM was then used to obtain chemical images of particles at the C K-edge spectral range to distinguish ASOP and TB based on their carbon NEXAFS spectra (Wang et al., 2016).

80

85

The present work evaluates the appearance of ASOP following rain events and determines their particle-specific spectroscopic characteristics that would enable distinguishing them from biomass burning TB, SOA, or other anthropogenic sources (Parworth et al., 2015; Sheridan et al., 2001). Characterizing the properties and emission sources of unaccounted BrC particles like ASOP is vital to ensure the proper representation of BrC in local and regional climate models. Multiple experimental records (both real-time and spectro-microscopic) were used here to assess the underreported ASOP. Using these techniques in tandem with longstanding atmospheric measurements will also help in advancing our knowledge of how ASOPs fit into the broader class of BrC and how ASOP may affect radiative forcing by aerosols.

90

## 2 Experimental:

### 2.1 Sample Collection

95

Samples of atmospheric particles were collected at the ARM SGP field site located in north central Oklahoma [36° 36' 18.0" N, 97° 29' 6.0" W], at an altitude of 320 meters (Ferrare et al., 2006). Sampling was performed before forecasted and after observed rain events during the rainy season from April 26<sup>th</sup> through May 17<sup>th</sup>, during day and night periods separately. Within this timeframe, samples were collected on 17 days with each sampling period beginning between 8:00 to 21:00 local time. The total sampling time was approximately eight hours (unless interrupted by a major rain event) with samplers operated using a 30/30 min on/ off duty cycle. Similarly, 4 nighttime samples were collected between the hours of

18:00 and 6:00 local time with a duty cycle of 60/30 min on/off. Rain events interrupted two sampling days (May 8<sup>th</sup> and May 16<sup>th</sup>) in which no sampling took place. The primary objective was to observe particle types during sunny days following major rain events, where a threshold precipitation rate of 5 mm/hr was used to define a rain event, when enhanced ASOP concentration would be likely. Note that ASOP may be present during some periods without a recent local rain event due to transport from elsewhere.

Particles were collected by impaction using a Micro-Orifice Uniform Deposit Impactor (MOUDI, MSP 100) attached to a rotating motor that rotates the eight impaction surfaces (known as stages) to facilitate uniform particle deposition. The impactor was connected to a ¾ max horsepower (0.56 kW) vacuum pump (General Electric Motors & Industrial Systems, 10 PSI rating). With a 30 L/min sampling flow rate, the micro-orifice nozzles reduce jet velocity, pressure drop, particle bounce and re-entrainment. This MOUDI was connected to a mesh covered sampling inlet which was tilted downward, avoiding unwanted collection of descending debris, insects, and other sources of contamination, and was positioned ~6 meters above the ground.

Samples for analysis were selected from two stages with the following particle size cutoff ranges: stage 7 (0.32 to 0.56 µm) and stage 8 (0.18 to 0.32 µm). These stages were chosen to cover part of the size ranges for TB (50 to 300 nm) (Tóth et al., 2014) and ASOP (300 to 800 nm) (Wang et al., 2016) while also constraining the number of samples to analyze. Substrates of Si<sub>3</sub>N<sub>4</sub> film supported by a silicon wafer (0.5 X 0.5 mm<sup>2</sup> Si<sub>3</sub>N<sub>4</sub> window, 100 nm membrane thickness, 5 X 5 mm<sup>2</sup> Si frame; Silson, Inc.) and filmed TEM copper grids (Carbon type B film, Copper 400 mesh grids; Ted Pella, Inc.) were used as impaction substrates.

In addition to impaction samples of ambient particles, aquatic samples containing SOM brine were collected in 50-200 mL aliquots via syringes from mud puddles surrounding the SGP field site. This was performed to evaluate a connection between organics from terrestrial aquatic samples, the hypothesized source of ASOP, and ambient ASOP. Four SOM aquatic samples were collected on May 17<sup>th</sup> 2016. The obtained samples were then nebulized in laboratory experiments using a Collision nebulizer (3 jet MRE, CH Technologies USA) and collected on stage 8 of a 10-stage impactor (110-R, MSP, Inc.) to produce 300-500 nm diameter particles, where ASOP comprised up to 80% of the particles by number. In addition, a portion of one SOM sample was used to generate particles by bubbling N<sub>2</sub> gas through the liquid using a fritted glass bubbler and then collected on substrates to mimic the hypothesized mechanism of ASOP formation.

## 2.2 STXM Measurements and Image Processing.

The STXM instruments (beamline 5.3.2.2 ALS, Berkeley, CA, USA, and the SM1 beamline CLS, Saskatoon, SK, Canada) used in this work are located in the Advanced Light Source (ALS) at the Lawrence Berkley National Laboratory and at the Canadian Light Source (CLS) at the university of Saskatchewan (Kilcoyne et al., 2003; Regier et al., 2007). Briefly, monochromatic soft X-rays are focused down to a spot size ranging from 20 to 40 nm in diameter. The sample is raster scanned after a region of sufficient particle concentration is found and individual images are captured at selected photon energies. Maps were collected in addition to spectra, which are images consisting of 8 energies around the elemental absorption k-edges, four

energies corresponding to C absorption at 278.0 eV, 285.4 eV, 288.6 eV, and 320.0 eV, two for N absorption at 398.0 eV and 430.0 eV, and 2 for O absorption at 525.0 eV and 550.0 eV. These energies are used to identify and characterize the basic chemical composition maps of particles on a pixel-by-pixel basis (Fraund et al., 2017). The two C energies at 285.4 and 288.6 eV are used for the identification of soot or elemental carbon (EC). The absorption peak at 285.4 eV occurs due to the excitation of the  $C\ 1s \rightarrow \pi^*_{C=C}$  transition (\* indicating the excited state) which is indicative of  $sp^2$  hybridized carbon-carbon bonds ( $C=C$ ). This excitation of  $sp^2$  hybridized carbon is prominent for soot (Bond and Bergstrom, 2006). To identify soot, the intensity of the  $sp^2$  peak (relative to the pre-edge at 278 eV after normalization to 320 eV) must be equal to or exceed 35% of that of highly ordered pyrolytic graphite (Moffet et al., 2010). Absorption at 288.6 eV is representative of the  $C\ 1s \rightarrow \pi^*_{R(C^*O)OH}$  transition characteristic of carboxylic acid groups (COOH) that are very common in atmospheric organic carbon. These photon energies aid in differentiating individual particles based on the molecular speciation of carbon, making this method convenient for analysis of the field collected particles (Moffet et al., 2010). Spatial displacement between images within a stack does occur and, whenever needed, it has been corrected for by utilizing the image registration algorithm developed by Guizar-Sicarios' (Fraund et al., 2017; Guizar-Sicarios et al., 2008).

### 2.3 SEM Measurements

The SEM analysis of particle samples was performed at the Environmental Molecular Sciences Laboratory (EMSL) located at Pacific Northwest National Laboratory (PNNL). Particles were imaged using a computer-controlled scanning electron microscope (FEI, Quanta 3D FEG, Hillsboro, AL, USA). SEM images were initially taken orthogonally to the substrate until a particle laden region on the substrate was identified. The substrate mount was then tilted by  $75^\circ$  in order to identify spherical particles. Based on the tilted images, particles which had an aspect ratio (height divided by width) greater than 0.8 were identified as spherical HVOP. The SEM images were categorized based on aspect ratio to determine the fraction of HVOP (high aspect ratio) compared to flat, non-spherical particles (low aspect ratio) for ensembles of approximately 400 total particles. This counting was performed manually for both ambient and lab-generated samples.

### 2.4 PSAP Measurements.

The Particle Soot Absorption Photometer ( $3\text{-}\lambda$  PSAP) instrument measures light transmission through aerosol filter samples at three wavelengths: red (660 nm), green (522 nm) and blue (470 nm) (Springston, 2016). PSAP measurement taken at the SGP ARM facility is a standard data product (ARM, 2019). Equation (1) shows how absorption coefficients  $\sigma_{ap}$  are calculated from raw PSAP data using spot size ( $A$ ), sample volume ( $V$ ), and average filter transmittances for incident ( $I_0$ ) and transmitted ( $I$ ) light through particle laden filter.

$$\sigma_{ap} = \frac{A}{V} \ln \left[ \frac{I_0}{I} \right] \quad (1)$$

Implementing corrections specified in Bond *et al.* (1999), as shown in Eq. (2), minimizes noise present in the PSAP data, which is a result of inherent unit-to-unit variability in field instrumentation. Additionally, these corrections mitigate

systematic error from filter loading. The absorption reported by the PSAP instrument ( $\sigma_{PSAP}$ ) includes an inherent calibration for a given measurement period which monitors the change in transmission by using the previous sample as a blank.

$$\sigma_{PSAP} = \frac{\sigma_{ap}}{2(0.5398\tau + 0.355)} \quad (2)$$

165 The raw absorption coefficient of a sample ( $\sigma_{ap}$ ) at a given time is normalized by filter transmission ( $\tau$ ), which is reset after the installation of a new filter ( $\tau = 1$  for an unloaded filter) (Springston, 2016). The corrected absorption coefficients were used to calculate the AAE values. Backman *et al.* (2014) introduced the following equation relating Ångström Exponent (AE) to the wavelength ( $\lambda$ ) dependent extinction (Backman *et al.*, 2014):

$$\ln [\sigma_E(\lambda)] = -AE \ln[\lambda] + C \quad (3)$$

170 here,  $\sigma_E$  refers to the extinction coefficient at wavelength  $\lambda$ . While the AE represents the spectral dependence of combined scattering and absorption, the AAE is specific to absorption and is obtained by substituting  $\sigma_{ap}$  for  $\sigma_E$  (Backman *et al.*, 2014). By taking Eq. (3) at a given wavelength and subtracting Eq. (1) at another wavelength, the constant C can be removed, resulting in a more practical equation:

$$AAE = \frac{-\ln\left[\frac{\sigma_{ap}(\lambda_1)}{\sigma_{ap}(\lambda_2)}\right]}{\ln\left[\frac{\lambda_1}{\lambda_2}\right]} \quad (4)$$

175 Using Eq. (4), PSAP data was used to calculate the AAE of ambient aerosols. Appearance of BrC was then inferred from PSAP time records based on elevated values of AAE >1.7 (Kirchstetter *et al.*, 2004).

### 3 Results:

#### 3.1 Optical Properties of Spherical Particles (SP)

180 Spherical HVOP have similar spectral characteristics to BrC regardless of their origin. Both TB and ASOP show characteristic increased absorption for shorter wavelengths of visible light compared to longer wavelengths (Alexander *et al.*, 2008; Veghte *et al.*, 2017). During periods when they are prevalent, overall aerosol optical properties should start to resemble those of BrC. To investigate the presence of BrC with this wavelength dependence, PSAP data was utilized to determine time records of AAE as shown in Fig. 1 alongside the corrected absorption coefficients. Time records of CO mixing ratios and particle number concentrations are also shown in Fig. 1 to provide further information on the composition of air mass. Figure  
185 1 shows how both red and blue absorption coefficients and AAE change over the course of this study. Rain events were defined as periods of time where rainfall exceeded 10 mm/hr. If two rain events were observed less than 30 minutes apart, they were considered one event. The vertical gray bars show sampling periods when aerosol with BrC properties was detected and which particle samples were imaged with STXM and SEM.

Both the absorption coefficient and AAE time series data were collected with minute time resolution; the data has  
190 been averaged over 30-minute time windows to emphasize longer term data trends instead of short-term fluctuations. The AAE  
sometimes shows an increase after rain events, though it is not consistent; because aerosol production from rain is more  
complex than rainfall amounts (depending on droplet size and impact velocity) it is difficult to see a correlation between rain  
and AAE or particle concentration. From this time record, a few samples stand out: the night of April 28<sup>th</sup>, May 5<sup>th</sup>, and May  
14<sup>th</sup> as these samples had elevated AAE >1.7. On May 5<sup>th</sup> and April 28<sup>th</sup> measured AAE values were above 2, warranting  
195 analysis of particle samples (Lack and Langridge, 2013). While the May 14<sup>th</sup> sample doesn't show particularly high AAE  
values, compared to the entire time series, it was collected after a heavy rain storm passed through the area. Also, the particle  
concentration immediately following the rain event on May 14<sup>th</sup> shows a significant level of precipitation scavenging, reducing  
the number of particles other than ASOP present during sampling (Hegg et al., 2011). Of note, the lower the  $\sigma_{ap}$  drops, due to  
rain or otherwise, the more pronounced the effect PSAP noise has on the calculated AAE. In addition to having high AAE  
200 values, both the April 28<sup>th</sup> and May 5<sup>th</sup> periods showed elevated particle and CO concentrations indicating plausible  
anthropogenic activity or biomass burning plumes. Figure S1 shows the time series of four trace gasses (N<sub>2</sub>O, CO, O<sub>3</sub> and SO<sub>2</sub>)  
which can be used to identify anthropogenically influenced air plumes. In addition to elevated CO levels, the April 28<sup>th</sup> and  
May 5<sup>th</sup> samples show elevated SO<sub>2</sub> and N<sub>2</sub>O concentrations while some of the highest O<sub>3</sub> concentrations seen over the  
sampling periods were observed during May 5<sup>th</sup>. In contrast, the May 14<sup>th</sup> period exhibits low or fairly average concentrations  
205 of these trace gasses.

### 3.2 Chemical Imaging of High Viscosity Organic Particles

Bulk optical properties, like an elevated AAE, can suggest the presence of spherical HVOP, therefore these  
measurements were used to select samples for detailed chemical imaging of particles. First, tilted SEM images were taken and  
HVOP fractions were observed in individual samples, ranging from 5% to near 70% by number. Figure 2 shows representative  
210 microscopy and spectro-microscopy images for three days where HVOP fractions were high. The top row shows the tilted  
SEM images used to identify HVOP. Magenta arrows point to a few identified HVOP to highlight how much they stick out  
above the substrate compared to the others. Of note, the SEM images also show presence of what looks like fractal soot  
particles in the April 28<sup>th</sup> and May 5<sup>th</sup> samples.

Second, the same samples were later imaged by the STXM spectro-microscopy. The middle and bottom row of images  
215 shown in Fig. 2 are STXM chemical maps and total carbon absorbance (TCA) maps, respectively. In the chemical speciation  
maps each pixel is assigned as either inorganic dominant, organic dominant, or as a region with high C=C bonding in following  
procedure describe in Moffet, et al. 2010 (Moffet et al., 2010). The TCA maps indicate the thickness of each of the particles  
(as calculated using previously published thickness equations (Fraund et al., 2019; O'Brien et al., 2015)) normalized by the  
individual area equivalent diameter. Values close to 0 represent flat particles, while values closer to 1 represent taller, nearly  
220 spherical particles. As was suggested in the SEM images, soot is present in both the April 28<sup>th</sup> and May 5<sup>th</sup> samples, while the  
May 14<sup>th</sup> sample has only organic and inorganic particles. In the April 28<sup>th</sup> and May 5<sup>th</sup> samples, circular soot-containing

particles are associated with the highest TCA. In contrast, the May 14<sup>th</sup> sample contained high TCA spherical particles comprised of organic dominant material only.

Sample collection information from the 7 samples where the fractions of HVOP were calculated is presented in Table 1 below. The highest HVOP fraction was observed with the samples taken on May 5<sup>th</sup>. The prevalence of these particles can be seen in Fig. 2 in the top row. Elevated fractions of HVOP were also found for the April 28<sup>th</sup> night sample taken at 18:30 and for the May 14<sup>th</sup> sample. While the April 28<sup>th</sup> and May 5<sup>th</sup> sample showed elevated HVOP fractions for both stage 7 and 8 samples, the May 14<sup>th</sup> sample is unique in that a higher HVOP fraction was only found for the smaller stage. In addition, the April 28<sup>th</sup> and the May 5<sup>th</sup> sample both have elevated particle concentrations and CO mixing ratios, suggesting more polluted conditions possibly due to anthropogenic activity or biomass burning events. In contrast, the time period corresponding to May 14<sup>th</sup> sample shows the lowest particle concentration and CO mixing ratio. Also of note is that the April 28<sup>th</sup> and May 5<sup>th</sup> samples were both taken long after the last rain, with May 5<sup>th</sup> being taken multiple days afterwards whereas the May 14<sup>th</sup> sample was taken 10 hours after the last rain.

Optical properties of individual HVOP from this same data set have been investigated in our previous work, Veghte, *et al.* in 2017 (Veghte *et al.*, 2017). There, the complex refractive index from 200 to 1200 nm was calculated for HVOP found in the April 28<sup>th</sup> sample using electron energy loss spectroscopy (EELS). The imaginary part (*k*) of the refractive index is related to light absorption and can be related to the absorption coefficient using  $\sigma_{ap} = 4\pi k/\lambda$  (Jennings *et al.*, 1979). Absorption coefficients over the 200 – 1200 nm wavelength range were calculated from the published imaginary refractive index plot (Veghte *et al.*, 2017). From this plot published in Veghte, *et al.* (Veghte *et al.*, 2017), the AAE was calculated using the  $\sigma_{ap}$  values for 660 and 470 nm and a value of 1.41. This is close to the value calculated in the present work (1.42, Table 1) for the April 28<sup>th</sup> sample (a difference of only 0.01) showing that the two methods agree, at least for one sample.

**Table 1. Ambient samples collected during IOPI. Stage 8 values in parentheses where available.**

<sup>1</sup>Central Daylight Time (UTC -5) <sup>2</sup>Particle Soot Absorption Photometer (PSAP) <sup>3</sup>Video Disdrometer <sup>4</sup>Condensation Particle Counter (CPC) <sup>5</sup>ARM/Aerosol Observatory System (AOS)

From Table 1 a correlation plot was made between the AAE values and the HVOP fractions and a strong correlation was found ( $R^2 = 0.85$ ) as seen in Fig. S2. Extrapolating this linear correlation to 100% HVOP yields an AAE value of 2.6, consistent with previously reported AAE values for BrC (Lack and Langridge, 2013). This not only suggests that the HVOP

found here are BrC, but that they warrant consideration by models due to their measurable effect on bulk aerosol-radiation interactions as they can occupy a significant fractions of the aerosol fine mode.

250 The appearance of viscous HVOP at the SGP site has been reported earlier by Wang *et al.* in 2016 (Wang *et al.*, 2016). There, they showed that the viscous HVOP at SGP had an elevated total carbon absorption (TCA, defined by the pre-edge OD subtracted from the post-edge OD) compared to other carbonaceous particles of similar sizes. High TCA values indicate particles that were not deformed upon impaction suggesting a high viscosity. Figure 3 shows TCA values of individual particles plotted against circular equivalent diameter (CED) for four samples reported in this work. The April 28<sup>th</sup>,  
255 May 5<sup>th</sup>, and May 14<sup>th</sup> samples all have elevated TCA whereas the May 2<sup>nd</sup> sample shows lower carbon absorption, in line with the TCA values characteristic of lab-generated SOA particles. Note that the May 5<sup>th</sup> sample, where the highest HVOP fraction was identified, has the smallest particles with TCA values above the ambient organic particle regions. Contrast this with the May 2<sup>nd</sup> sample, which shows very few particles with high TCA values and a correspondingly low HVOP fraction.

So far, the above analysis applies to a general class of HVOP, which can include both ASOP and TB particles.  
260 Additional considerations are necessary, however, before any conclusions are tied to ASOP exclusively. The two samples, with the highest HVOP fractions and AAE values, were those collected more than 39 hours after a rain event. Because emission of ASOP is associated with bursting of bubbles at flooded soil surfaces after rain, the HVOP found in the April 28<sup>th</sup> and May 5<sup>th</sup> samples are likely not locally emitted ASOP, while ASOP might be present in the sample of May 14<sup>th</sup>.

To investigate the nature and source of HVOP and determine which can be confidently classified as ASOP, smoke  
265 and fire from biomass burning sources (NOAA:OSPO, 2019) and precipitation data (NWS, 2019), were used along with the calculations of air backward trajectories using a hybrid single particle Lagrangian integrated trajectory model (HYSPLIT) (Stein *et al.*, 2015; Rolph *et al.*, 2017). This data for the events when the three samples had elevated HVOP fractions are shown in Fig. 4 below: Apr 28<sup>th</sup>, May 5<sup>th</sup>, and May 14<sup>th</sup>. Additional information about the HYSPLIT trajectory conditions, as well as trajectories calculated from multiple starting altitudes, is available in Fig. S3.

270 April 28<sup>th</sup> had a moderate fraction of HVOP ( $25 \pm 0.6\%$ ) along with the second highest AAE over the sampling periods studied here. This sample was also taken about 39 hours after the last rain, which makes ASOP less likely to be found. Figure 4 shows that the corresponding air mass trajectories passed over a few burning fires. Smoke was present in some of the fires surrounding the sampling site but air mass trajectories did not pass through these regions. Precipitation data shows rainfall in some of the surrounding states but none close to the sampling site. The storm surrounding Oklahoma may have produced  
275 some ASOP which could have been transported to the sampling site, although elevated particle concentration and slightly enhanced CO, SO<sub>4</sub>, and N<sub>2</sub>O concentration at the time of sampling suggested biomass burning as more likely emission source (Koppmann *et al.*, 2005). ASOP may make up a small fraction of the HVOP seen during this sampling period, however. Immediately east of the sampling site are a coal-fired power plant, an oil refinery, and natural gas power plants. As seen in Fig. 4 (as well as in more detail in Fig. S3) the April 28<sup>th</sup> sample has an initial eastward direction.

280 May 5<sup>th</sup> has the highest HVOP fraction and the highest average AAE but it also had been days (140 hours) since the last rain event, making ASOP unlikely. There were many fires surrounding the sampling site compared to the other sampling

periods and the back trajectories show air masses passing directly over some of these fires suggesting the presence of associated smoke emissions. Precipitation data shows that no rainfall was observed anywhere near the sampling site. Figure 1 also shows that this sampling date coincided with a slight particle concentration enhancement and the highest CO mixing ratios observed  
285 over this period of the field campaign. Figure S1 also shows enhancement in O<sub>3</sub> and SO<sub>2</sub> concentrations. Because TB are found within smoke plumes, the high HVOP fraction observed in the April 28<sup>th</sup> and May 5<sup>th</sup> samples may be primarily (or exclusively) due to TB (Pósfai et al., 2004). The presence of combustion byproducts like TB and soot is supported by the STXM carbon speciation maps shown in Fig. 2, where particles with elevated C=C bonding constituents are often attributed to soot.

The last sample date shown (May 14<sup>th</sup>) has regions of smoke away from the sampling site with backward trajectories  
290 heading from just outside the smoke filled region. However, because a rain event was recorded 10 hours prior to sampling where significant precipitation scavenging was observed (see the particle concentration decrease in Fig. 1), no influence from biomass burning was observed in this sample. The precipitation map shows that precipitation was observed over the sampling site as well as many of the surrounding areas (Radke et al., 1980). Because the microscopy samples were taken shortly after it had rained, the 35 ± 1.3% fraction of HVOP observed at that time may likely be related to ASOP. With the HVOP observed  
295 in the microscopy images being around 0.6 μm in diameter, it is expected that they would be aloft and present for the sampling period for at least 10 hours after the rain event (Williams et al., 2002). Any particles of this size travelling from further away, such as ASOP produced elsewhere, through some of the surrounding storm are less likely to be scavenged due to the lowered precipitation scavenging efficiency (Greenfield scavenging gap) at approximately 0.1 μm (Radke et al., 1980). This could have effectively concentrated ASOP particles as the air mass travelled through the surrounding storm.

The influence of smoke shown in Fig. 4 may account for the enhancement of HVOP fractions without rainfall in the April 28<sup>th</sup> and May 5<sup>th</sup> samples, likely due to TB. The carbon STXM/NEXAFS spectra of TB have been recorded previously and its characteristic features are shown in Fig. 5 (Tivanski et al., 2007). The same figure compares the STXM/NEXAFS spectra for both ambient particles collected during this study and lab generated ASOP proxies. The right panel of Fig. 5 also includes three characteristic spectra of HVOP particles from the April 28<sup>th</sup>, May 5<sup>th</sup> and May 14<sup>th</sup> samples. Even though May  
305 5<sup>th</sup> and April 28<sup>th</sup> had the highest AAE values and the highest HVOP fractions, many hours since the last rain along with the presence of smoke suggest they might be TB, consistent with their NEXAFS spectral features. Three apparent peaks are common for these spectra: the C=C peak at 285.3 eV, the COH peak at 286.7 eV, and the R-(C=O)OH peak at 288.6 eV, all of which are present in the previously reported TB spectra (Tivanski et al., 2007). May 5<sup>th</sup> spectra also show a small feature around 289.5 eV which is present (and more prominent) in the TB spectra, a peak which is associated with alkyl carbon bonded to oxygen, often alcohols. This similarity reinforces the assumption that May 5<sup>th</sup> contains a large amount (70%) of HVOP  
310 attributable to TB.

Upon comparison with the April 28<sup>th</sup> and May 5<sup>th</sup> samples, NEXAFS spectra of HVOP particles from the May 14<sup>th</sup> sample (taken 10 hours after raining) show a slightly enhanced C=C peak and an almost absent COH peak. These same features can be seen in the previously reported NEXAFS spectra of ASOP (Wang et al., 2016; Veghte et al., 2017) and “free light” SOM  
315 isolated in that work for comparison. One reason for the difference in COH peak intensity may be due to the presence of

levoglucosan or other plant derived products such as polysaccharides, tannins, or lignin fragments (Marín-Spiotta et al., 2008) (which contains multiple –OH groups) in the samples affected by smoke plumes, a common product of biomass burning from the pyrolysis of carbohydrates (Lakshmanan and Hoelscher, 1970). Another differentiating factor is the ratio of intensities between the –COOH peak at 288.6 eV and the C=C peak at 285.3 eV. In the TB spectrum, the –COOH peak is much higher than the C=C peak compared to the ASOP spectrum (Wang et al., 2016) and this difference is borne out in the spectra collected for the current study as well. Also shown is a spectrum of organic particles not associated with HVOP. This spectrum is characterized by small C=C and COH absorptions with an intense –COOH peak. The large –COOH peak seen in non-SP organics is indicative much higher contributions of carboxylic functional groups which define solubility of the organic particles. This increased solubility would lower the viscosity of the non-viscous organic particles due to their substantial water content and thus these particles would be deformed and flatten upon impactation.

The left-panel of Fig. 5 shows STXM/NEXAFS spectra of ASOP proxies generated from the SOM brine. The top four spectra from the puddle water samples all show a fairly strong carbonate signal at around 290.1 eV along with two broad potassium peaks ( $L_2$  and  $L_3$ ) at about 298 eV. Also, the corresponding inset carbon speciation map shows a large, inorganic dominant region (teal blue). The presence of large inorganic regions is not consistent with the mainly organic particles seen previously. However, because these samples were nebulized from bulk solutions to begin with, water soluble carbonates from the soil must have been present upon nebulization. To better model the bubble bursting mechanism of generating ASOP, dry  $N_2$  gas was bubbled through puddle water samples and particles resulted from the bubble bursting at the air-solution interface were collected. In these experiments, generated particles showed almost a complete reduction of the carbonate peak and a small reduction in the potassium peaks, plus the carbon speciation map (Fig. 5 inset) showed an entirely organic dominant particle. Comparison between the spectra of ASOP proxies generated in the ‘bubbling experiment’ with the ambient spectra of HVOP from May 14th shown in the right panel indicates substantial similarities between their spectral features. This includes the diminished –COOH/C=C peak ratio and the relative absence of a COH peak.

For more quantitative comparison two sets of peak ratios were calculated. The first between the –COOH and C=C absorptions and another between the –COOH and COH peaks. The peak ratios are plotted in Fig. 6 below for all of the ambient samples, the proxy particles from the “bubbling” experiment, and the two literature spectra. As noted above, the TB spectra have higher –COOH/C=C and –COOH/COH peak ratios. The separation between these two ratios is also the largest for the TB spectrum. While the April 28<sup>th</sup> and May 5<sup>th</sup> peak ratios are not quite as high, they all bear a strong resemblance to the TB spectrum. Perhaps alone the similarity would not be enough to define these ambient samples as TB; however, coupled with the other data presented here the peak ratios support the SP seen in the May 5<sup>th</sup> sample as being TB. The April 28<sup>th</sup> peak ratios are further separated than the literature ASOP peak ratios are, but closer together than the TB literature peak ratios. With the possibility of ASOP travelling from surrounding states (with active rainfall) as well as the proximity of smoke plumes it is likely that the HVOP observed on April 28<sup>th</sup> are comprised of both TB and ASOP. The May 14<sup>th</sup> sample peak ratios however, are much different and are more comparable to the ASOP peak ratios. The –COOH/C=C ratio is much lower in both cases and the –COOH/COH ratio is of the same value. From the lab generated aerosols, the bubbling sample peak ratios are also similar

350 to the ASOP peak ratios, suggesting that bubbling reproduces the mechanism of ASOP generation. Another noteworthy observation is the difference between the April 28<sup>th</sup> or May 5<sup>th</sup> peak ratios and the May 14<sup>th</sup> peak ratios. Although each of these samples showed the presence of HVOP and each sample's AAE suggested that these HVOP were BrC, there is a stark contrast between the smoke influenced samples (Apr 28<sup>th</sup> and May 5<sup>th</sup>) and the rainfall influence samples (May 14<sup>th</sup>), suggesting different sources of SP in these two cases.

#### 355 **4 Conclusion**

BrC particles like TB and ASOP and their place in the global aerosol budget are yet insufficiently understood. Here, it was shown that presence of HVOP is correlated with the BrC properties of overall aerosols, indicated by the elevated values of AAE. On multiple days HVOP were observed to comprise a significant fraction of the fine mode aerosols.

Tilted SEM was used to identify HVOP fractions in a number of samples taken during this study, and the fractions of HVOP present for each sample were determined based on the aspect ratios of individual particles. The HVOP fractions showed a strong correlation with the average AAE over the sampling periods, with an  $R^2$  of 0.85. When extrapolated to 100% fraction of HVOP an AAE of 2.6 was calculated, consistent with literature reported values of BrC (Lack and Langridge, 2013). These observed AAE values suggest that BrC relevant particles can be identified by methods of chemical imaging based on three dimensional morphology coupled with chemical composition. These samples were further classified into samples with TB and samples with ASOP based on their NEXAFS characteristics and by comparing smoke and precipitation data during corresponding collection periods.

Chemical imaging showing the differences between ASOP and TB laden samples was performed using STXM/NEXAFS spectromicroscopy. Samples unaffected by recent rain, collected while smoke plumes were present showed a higher  $-\text{COOH}/\text{C}=\text{C}$  peak ratio and an elevated  $-\text{COH}$  peak intensity. The elevated  $-\text{COH}$  peak is likely due to the presence of sugars such as levoglucosan or other less oxidized molecules. The sample from May 14<sup>th</sup> was collected 10 hours after a rain event and had less influence from smoke plumes. This sample showed a much more subdued  $-\text{COH}$  peak and a smaller  $-\text{COOH}/\text{C}=\text{C}$  peak ratio. Comparing the ambient spectra collected here with previously collected spectra supported the presence of TB in the smoke-affected samples and the presence of ASOP in the sample taken after a rain event. Peak ratios between  $-\text{COOH}$  and  $\text{C}=\text{C}$  and between  $-\text{COOH}$  and  $\text{COH}$  were calculated to serve as a quantitative metric that can be potentially used to differentiate between TB and ASOP, and, probably more generally, between the smoke-affected samples and the samples with particles induced by rainfall.

HVOP are a subclass of BrC particles which can define the nature of aerosol-radiation interactions during time periods when they are prevalent. Differentiating between types of HVOP like TB and ASOP has proven to be a challenging task that relies on subtle differences in chemical composition and atmospheric conditions at the time of sampling. Further questions still exist about ASOP specifically. How do soil characteristics affect the composition of ASOP? How are ASOP transformed as they travel through the atmosphere? What are the emissions factors of ASOP? Answering questions like these may improve

the quality of models in regions where large areas with open soils such as agricultural fields and grasslands are exposed to intensive rains, especially during rainy seasons when ASOP might be prevalent.

**Figure 4:** Smoke, fire, and precipitation data along with HYSPLIT back trajectories for three sample dates. The red circle represents the sampling site while the small red triangles represent fires. The gray overlays seen in the top row represent detected smoke particles (overlapping smoke plumes are shown in darker shades of gray). The bottom row shows the 24-hour average precipitation amount over the sampling date. The top row maps were obtained using the AirNow-Tech navigator using the Hazard Mapping System smoke product from NOAA, Source: U.S. EPA AirNow-Tech (SonomaTechnologiesInc., 2019). HYSPLIT trajectories for April 28<sup>th</sup> and May 5<sup>th</sup> are for 24 hours. The May 14<sup>th</sup> back trajectory was truncated at 10 hours due to a rain event with significant precipitation scavenging. Precipitation maps were made using the NWS AHPS (NWS, 2019).

**Figure 5:** Comparison of NEXAFS spectra between laboratory generated ASOP proxies (left) and four ambient ASOP samples (right). Inset carbon speciation maps are shown for representative particles with green representing organic dominant regions and teal representing inorganic dominant regions. TCA images, like the ones shown in Fig. 2 are shown as well. Only one image is shown for the ambient samples as they all look similar. The ASOP proxy spectra are show for particles generated by nebulizing aquatic samples collected at the site and by bubbling N<sub>2</sub> gas through one of the aquatic samples.

550 Figure 6: Plot of peak ratios for: (blue dots) carboxylic acid peak at 288.6 eV and the carbon double bond peak at 285.3 eV and (red dots) carboxylic acid peak and the COH peak at 286.7 eV. ASOP Proxies refers to particles generated via bubbling through the aquatic sample of SOM.
