10 **Abstract.** We investigate Arctic polar atmospheric ozone responses to Solar Proton Events (SPEs) using MLS
11 satellite measurements (2004-now) and WACCM-D simulations (1989-2012). Special focus is on lower strato-
12 spheric ozone depletion that has been proposed earlier based on superposed epoch analysis of ozonesonde anom-
13 alies (up to 10% ozone decrease). Superposed Epoch Analysis (SEA) of the satellite dataset provides no evidence
14 of any average SPE impact on the lower stratospheric ozone, although at the mesospheric altitudes a statistically
15 significant ozone depletion is present. In the individual case studies, we find only one potential case (January
16 2005) in which the lower stratospheric ozone level was significantly decreased after the SPE onset. However,
17 similar decreases could not be identified in other SPEs of similar or larger magnitude. We find a very good overall
18 consistency between SPE-driven ozone anomalies derived from the WACCM-D model simulations and the Aura
19 MLS data. The simulation results before the Aura MLS era indicate no significant effect on the lower stratospheric
20 ozone either. As a conclusion, the SPE has a zero direct impact on the lower stratospheric ozone.

1 **1 Introduction**

2 In the near-Earth space, solar wind charged particles are guided by the Earth's magnetic field and are able to
3 precipitate into the middle and upper atmosphere in the polar regions. Such kind of precipitation creates the spec-
4 tacular aurora, but also produces considerable amounts of HO_x (H, OH, HO₂) and NO_x (N, NO, NO₂) through
5 ion-neutral chemistry (e.g. Verronen and Lehmann, 2013). HO_x and NO_x increases lead to ozone loss through
6 catalytic reactions in the mesosphere and upper stratosphere, respectively (Sinnhuber et al., 2012). Moreover, in
7 polar winter, NO_x has a long chemical lifetime due to limited photodissociation by solar radiation. NO_x produced
8 by energetic particle precipitation (EPP) in the mesosphere-lower thermosphere is transported down to the strat-
9 osphere by the Brewer-Dobson circulation inside the polar vortex (Funke et al., 2014), causing depletion of upper
10 stratospheric ozone (Damiani et al., 2016). A number of studies have confirmed EPP's remarkable role in ozone
11 depletion directly during large EPP events (e.g. Funke et al., 2011) and in-directly due to descending NO_x (e.g.,
12 Randall et al., 2007). Thus, most advanced climate models are now including EPP forcing, in order to correctly
13 represent the ozone distribution in the polar stratosphere and mesosphere (Matthes et al., 2017; Stone et al., 2018).

14 Solar proton events (SPE) are one of the main types of EPP. During SPE, particles (mainly protons, ~10% alpha)
15 with energies from tens to hundreds of MeV precipitate into the atmosphere at geomagnetic latitudes larger than
16 60° for days. Such high-energy particles mainly deposit their energy at altitudes of 35-90 km, providing direct
17 ionization forcing on the polar middle atmosphere. Large SPEs have been studied since the 1960s until today
18 using satellite observations and model simulation. In addition to tens of percent of ozone loss observed at many
19 altitudes (Jackman 2001, Seppälä et al. 2004, Verronen et al. 2006), a strong SPE can reduce total ozone by 1-3%
20 for months after the event (Jackman 2011, 2014).

21 Recently, Denton et al. (2018 a, b) presented statistical studies of average ozone changes from 191 SPEs between
22 1989-2016 using ozonesonde measurements. Superposed epoch analysis of ozone anomalies at polar stations (So-
23 dankylä, Ny-Ålesund, and Lerwick) indicated that SPEs occurring during winter are causing ozone decrease by
24 5-10%, on average, at 20 km altitude. This effect is not produced in the current models because SPE-induced
25 ionisation rates are insignificant at this altitude even during largest events (Jackman et al., 2011), and Denton et
26 al. included also a large number of very small SPEs in their analysis. Such ozone decreases has not been observed
27 in the case studies of very extreme SPEs, e.g., the 2003 'Halloween' event, from either simulation or satellite
28 observation (Funke et al. 2011, and references therein). Recently, statistical analysis based on simulations has
29 found no evidence of such low-altitude ozone impact (Kalakoski et al. 2020).

30 Here we investigate the proposed SPE-induced direct depletion on lower stratospheric ozone using ozone data
31 from the Microwave Limb Sounder (MLS) instrument aboard the Aura satellite and the Whole Atmosphere Com-
32 munity Climate Model (WACCM-D) simulations. We proceed to evaluate ozone changes at altitudes 10-70 km
33 caused by SPEs both statistically (superposed epoch analysis) and individually (case by case). The MLS ozone
34 data, WACCM-D atmospheric simulation, and SPE data sets are presented in Sect. 2. In order to cross-check
35 ozone depletion at 20 km reported based on the ozonesonde data, statistical ozone responses from MLS satellite
36 measurements are firstly provided in Sect. 3. Following that, ozone changes after individual SPEs are given in
37 Sect. 4. Finally we summarize our results and conclusions in Sect. 5.

1 2 **Data sets**

2 2.1 **O₃ profile measurements by MLS**

3 The Microwave Limb Sounder (MLS) onboard the Earth Observing System (EOS) Aura satellite measures ozone
4 emission at 240 GHz, providing ozone volume mixing ratios at 55 pressure levels since 15 July 2004 (Waters et
5 al., 2006). Vertical profiles are retrieved from the MLS observations with a 165 km horizontal spacing at altitudes
6 between 8 and 90 km, a spatial resolution of 500 km × 500 km (along-track × across-track), and a vertical resolu-
7 tion of ~3.2 km. In this work, we use version 4.2 ozone data measured at 261 - 0.02 hPa (~10 - 70 km) to calculate
8 the daily averaged ozone density profile at northern high latitudes (60°-90°N). Readers who are interested in the
9 MLS data quality are referred to Livesey et al. (2018).

10 2.2 **O₃ from WACCM-D simulations**

11 WACCM is a global circulation model, including fully coupled dynamics and chemistry. Here, we use version 4
12 of the WACCM with resolution of 1.9° latitude by 2.5° longitude, with 88 vertical levels reaching from surface
13 to 6×10⁻⁶ hPa (≈140 km). Overview of the model and the description of climate and variability in long-term
14 simulation was presented by Marsh et al. (2013), with details of model physics in MLT (mesosphere - lower
15 thermosphere region) and the response of the model to radiative and geomagnetic forcing during solar maximum
16 and minimum described by Marsh et al. (2007). The simulation results presented here are from WACCM-D, a
17 variant of WACCM with more detailed set of lower ionospheric chemical reactions, aimed at better reproduction
18 of observed effects of EPP on MLT neutral composition (Verronen et al. 2016, Andersson et al. 2016).

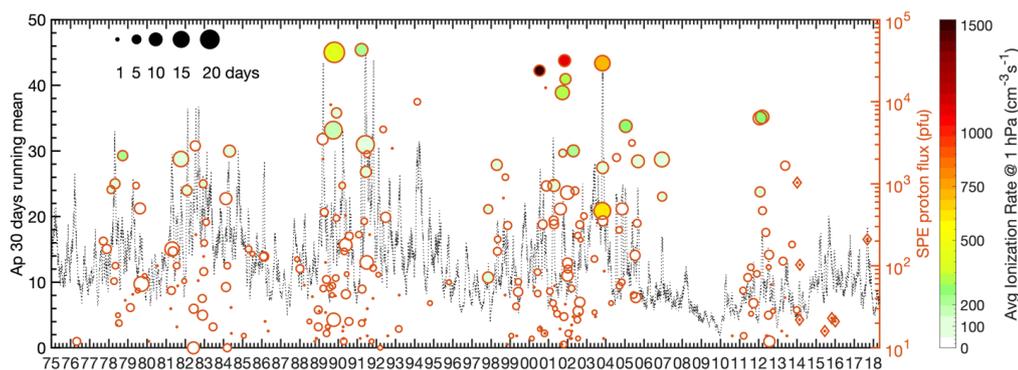

19 We use SD-WACCM-D specified dynamics configuration, with Modern-Era Retrospective Analysis for Research
20 and Applications (MERRA) (Rienecker et al., 2011) meteorological fields to force dynamics at every time step
21 up to about 50 km. Simulation covers years 1989-2012, and uses forcings from auroral electrons (E<10keV),
22 solar protons (< 300 MeV), and galactic cosmic rays for energetic particle precipitation. The SPE ionization rates
23 are based on proton flux measurements from the Geostationary Operational Environmental Satellites (GOES) (see
24 e.g. Jackman et al., 2011, for the calculation method). The WACCM-D SPE effects on neutral species are com-
25 pared to satellite observations in Andersson et al. (2016). Note that WACCM-D has not been validated below 20
26 km. Nevertheless, in Andersson et al (2016) the HNO₃ response above 15 km to single SPE onset was reasonable
27 comparing to MLS data. We also stress that protons >300 MeV are not included in the simulation, as the contri-
28 bution of >300 MeV protons to direct ozone loss in the lower stratosphere would likely be negligible due to the
29 relatively small fluxes at such high energies (Jackman et al., 2011). For more details of the simulation setup, see
30 Kalakoski et al. (2020).

31 2.3 **Solar proton events**

32 The data of solar proton events (SPEs) used in this study is based on NOAA GOES (Geostationary Operational
33 Environmental Satellite) proton flux observations. Fig. 1 presents 261 SPEs recorded from 1975 to date, including
34 their onset time, fluxes detected in space, approximated time of duration, and ionization rates to the atmosphere.
35 Here, the onset of a SPE is defined as the time when 5-min average proton fluxes with energies >10MeV are
36 greater than 10 Particle Flux Units (1 pfu = 1 particle /cm²/s/sr) at the geosynchronous orbit. For the estimation

1 of SPE duration and its impact on the atmosphere, we use the daily average ion pair production rates at ~ 1 hPa.
2 These ionization rates are calculated from GOES proton flux observations using the energy deposition methodol-
3 ogy described in, e.g., Jackman et al. (2011). Our study uses 49 events that occurred after the launch of Aura
4 MLS (July 2004 - now) and 177 events that occurred in WACCM-D simulation period (Jan 1989 - Dec 2012) to
5 evaluate the ozone changes following SPEs. It is clearly demonstrated in Fig. 1 that these SPEs are more frequent
6 near solar maximum years. Majority of the events are with flux less than 400 pfu, and their impacts to the atmos-
7 phere below 1 hPa (~ 50 km) are small. It is worth to mention that although these SPEs seem to have no preference
8 in occurring season, their seasonal distribution varies by months and should be considered during the interpreta-
9 tion (Fig. A1).

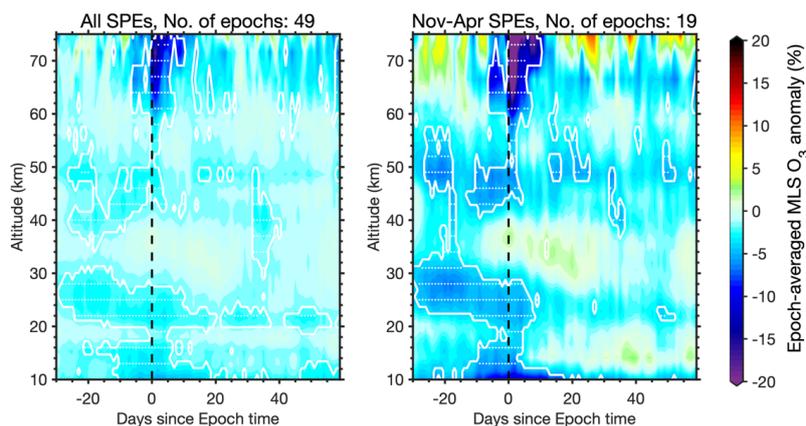

10

11 **Figure 1. Onset time of SPEs and their proton fluxes since 1975. The filled colors are the averaged ionization rate**
12 **during each SPE at 1hPa, while the size of the markers represents the approximate duration time of the SPEs obtained**
13 **from the 1hPa daily mean ionization rate. Diamonds mark the events without ionization information. The black dotted**
14 **line in the background is the 30-day mean of the daily geomagnetic activity Ap-index.**

15

16 3 Statistical O₃ response from MLS

17 Similar to the method used by Denton et al. (2018 b), we applied a superposed epoch analysis to the MLS daily
18 ozone anomalies. The superposed epoch analysis, also referred to as compositing in geophysics, is used to acquire
19 variation of a time series before and after an event or a chain of certain kind of events. The point of time when the
20 event begins is the epoch time. In this case, the epoch times are the onset times of individual SPEs during MLS
21 operating period. All available ozone data were binned as a function of epoch time and altitude, with temporal
22 resolution of one day. The pre- and post-epoch spans used here are 30 and 60 days, respectively. For the selected
23 sets of SPEs, all the binned ozone data sets were averaged to represent the effect of the SPEs. This method ex-
24 cludes natural ozone variations that are larger than the span-scale. Since SPE-driven effects are expected to take
25 place on daily to monthly time scales, variations caused by e.g. QBO can be excluded. However, seasonal varia-
26 tions, must be excluded before using superposed epoch. Thus, the daily profile climatology calculated from the
27 ozone data was subtracted from the daily ozone data.

1

2 **Figure 2. Epoch-averaged MLS ozone anomalies in the northern polar region (60°-90°N) (relative in %) along with**
3 **geopotential altitude for a total of 49 SPE epochs (left panel) and 19 winter SPE epochs (right panel). The black dashed**
4 **line represents the epoch time, i.e., onset of SPEs. The white thick line area corresponds to the epoch-averaged anomalies**
5 **with >95% confidence after the Monte Carlo test.**

6

7 In order to test the statistical significance of the obtained results, a Monte Carlo test was implemented. Instead of
8 using SPE onset as epoch times, the analysis was rerun using 2000 random sets of epoch times. SPE-epoch aver-
9 aged variations larger than 95% of the 2000 randomized results are considered significant and robust (reported as
10 >95% confidence), suggesting that these extracted signatures are likely related to SPE.

11 Fig. 2 shows the superposed epoch of MLS northern polar ozone anomalies for all 49 SPEs (left panel) and for
12 the ones occurred in winter (Nov-Apr) (right panel) within the instrument's operational period. Robust averaged
13 anomalies (>95% confidence) are presented within the white thick lines. Spatial distribution of statistically robust
14 anomalies is similar in all-SPE epochs and winter-SPE epochs. The depletion is more pronounced for winter
15 epochs due to two facts: 1) ozone recovery is slower due to less production from O₂ photodissociation; 2) Largest
16 SPEs with flux >1000 pfu that cause more ozone depletion happen to occur in NH wintertime. Among all the SPEs
17 during MLS measurement period, ~3/4 of big SPEs are in NH wintertime (see Fig. A1). In both panels, closely
18 following the SPE onset, very pronounced ozone depletion appears above 50 km for over 5 days. This is the direct
19 ozone loss caused by the SPE-induced HO_x enhancement. The number of extreme SPEs is relatively small, which
20 explains the absence of the long-lasting ozone depletion that would be expected between 40-50 km from enhanced
21 amounts of NO_x. While the upper stratospheric ozone depletion signature is not seen in the statistical average, 5-
22 10% decrease of ozone is present below 30 km, including ozone loss around 20 km similar to that reported by
23 Denton et al. However, although the decrease of ozone at 20 km does appear after the epoch time, the signatures
24 above and below are not related to the epoch times. This suggests that the whole robust variation in the stratosphere
25 is more related to other phenomena in the northern polar cap, e.g. to changes in the strength of polar vortex or
26 related chemical effects. We will discuss this in more detail in Sect. 4.

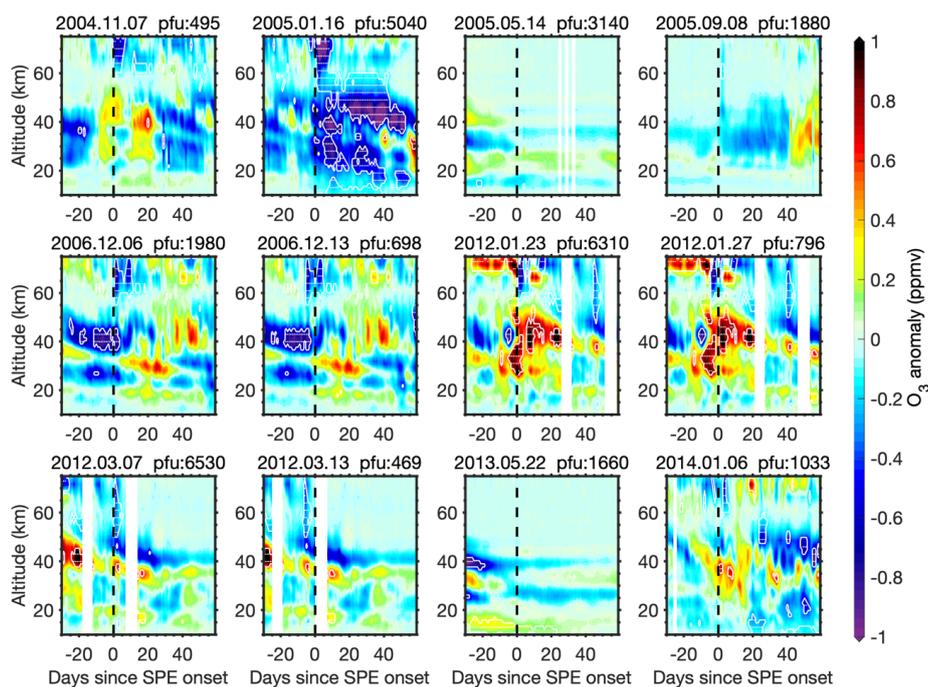

27 A superposed epoch analysis of WACCM-D ozone anomalies from SPEs during 1989-2012 has been reported by
28 Kalakoski et al. (2020), thus we will not repeat it here. In their results, the epoch-averaged WACCM-D ozone

1 anomalies showed the same robust depletion at above 50 km. Since their analysis included also the very large
2 SPEs that occurred 1989-2004 (see Fig. 1 in this study and list of largest 15 SPEs in Tab. 1, Jackman et al., 2008),
3 long-term ozone depletion in the upper stratosphere was clearly detected as well. However, there was no robust
4 ozone loss below 30 km found in the WACCM-D simulations.

5 4 O₃ response to individual SPEs

6 Despite the fact that our WACCM-D epoch analysis includes most of the major SPEs in the space age, there is a
7 chance that ozone loss around 20 km may occur following individual large SPE in MLS data but the signal is
8 buried in all-event statistics, like in the case of upper stratospheric ozone depletion signatures. To exclude such a
9 possibility, in this section we analyse ozone responses to individual SPEs.

10

11 **Figure 3. MLS ozone anomalies (in ppmv) along with altitude at 30 days before and 60 days after individual big SPEs**
12 **(proton fluxes >400 pfu) since July 2004. The white thick line area demonstrates ozone anomalies with >95% confidence**
13 **after the Monte Carlo test.**

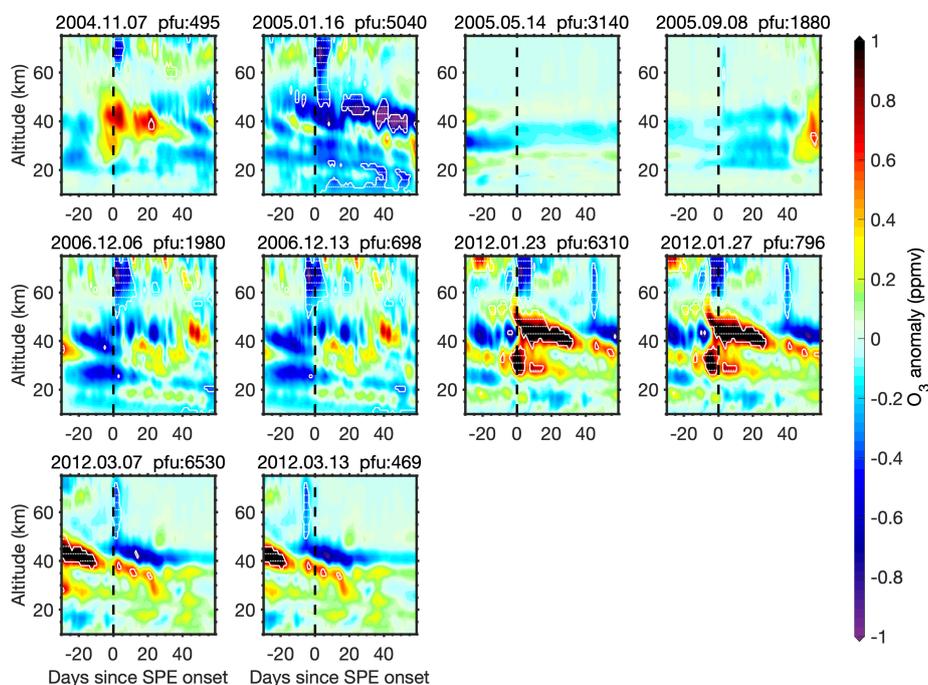

14

15 Similar to the analysis presented in Sect. 3, ozone anomalies presented here were calculated by subtracting daily
16 climatology from daily averaged ozone data from MLS and WACCM-D. Note that the subtracted daily mean
17 climatology from MLS and WACCM-D were derived from the MLS data period and the WACCM-D simulation
18 period, respectively. Then, instead of applying superposed epoch analysis on multiple SPEs, ozone anomalies are
19 presented 30 days before and 60 days after onset of individual SPE. For estimating the statistical significance of

1 the ozone anomalies found in the individual SPEs, we applied a similar Monte Carlo approach as in the case of
2 SEA, i.e., the variance of 6000 random ‘onset’ times was used as a measure for a significant anomaly. It is worth
3 noting, however, that this method recognizes ‘statistically significant’ all anomalies larger than the random back-
4 ground variation, whether the anomaly is due to SPE or, for instance, due to exceptional dynamical/chemical
5 anomalies, which have a similar occurrence probability as SPEs.

6 Anomalies following all individual SPEs can be found in Figs. A2 and A3. In general, SPEs with proton fluxes <
7 400 pfu cause neither visible daily ozone depletion in the mesosphere (below 75 km), nor in other altitudes. Ozone
8 changes following individual SPEs are more pronounced during winter. Figs. 3 and 4 demonstrate MLS and
9 WACCM-D ozone variations following SPEs with proton fluxes > 400 pfu since July 2004. Both the ozone vari-
10 ations and the robust signatures from these two different data sets are very consistent. After year 2004, three large
11 winter SPEs, i.e., January 2005, September 2005 and March 2012, produced clear upper stratospheric ozone loss.
12 Ozone depletion is most pronounced following the January 2005 event. For this event, we also observe a robust
13 lower stratospheric ozone loss from MLS following SPE for the first time: ozone is depleted by ~1 ppmv (~15%)
14 at 20 – 35 km and by ~0.15 ppmv (> 20%) below 15km 5 days after SPE onset.

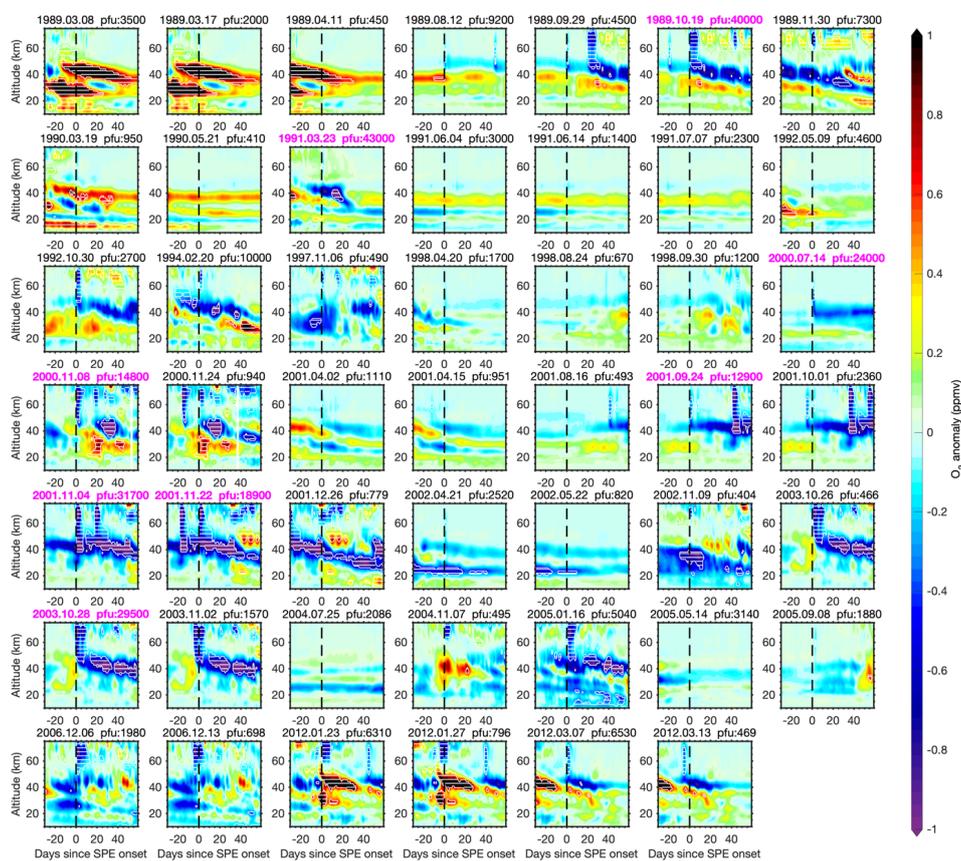

15
16 **Figure 4. Same as Fig. 3 but for WACCM-D ozone anomalies.**

17
18 Overall, wintertime ozone variation below 35 km is rather complicated. Year-to-year variability of stratospheric
19 polar ozone is mostly controlled by dynamical and chemical processes, both are essentially coupled to temperature
20 changes. Factors that modify polar temperature, e.g., sudden stratospheric warming (SSW) and El Niño–Southern

1 Oscillation (ENSO), are essentially planetary wave perturbations that modulate the strength of polar vortex. The
2 probabilities of major SSWs and, on the other hand, springs with extremely strong polar vortex are at similar
3 levels as the one of SPEs. Thus, ozone variations by these events will be seen as robust signatures in our study as
4 well, yet they do not necessarily coincide with onsets of SPEs with proton fluxes >400 pfu and >10000 pfu,
5 respectively. The large SPE in January 2012 (Figs. 3 and 4) is severe enough to destroy stratospheric ozone.
6 However, the stratospheric ozone anomalies at that time were dominated by dynamical ozone enhancement from
7 SSW in 17th Jan 2012 (Päivärinta et al., 2016). One of the most pronounced examples of extreme strong polar
8 vortex impact is the well-reported ozone depletion during spring of 2011, which can be observed in ozone anom-
9 alies around the two small SPEs that occurred in March 2011 (see Fig. A2). The lower stratospheric polar vortex
10 was the strongest (in either hemisphere) in the previous 32 years (Manney et al., 2011). Large volume of polar
11 stratospheric clouds (PSCs) converted chlorine reservoirs to ozone-destroying species, leading to extraordinary
12 low ozone in the stratosphere (Pommereau et al., 2018). Similarly, robust anomaly seen after January 2016 SPE
13 can be explained by cold 2015–2016 winter anomaly. We are confident to exclude SPE's influence on the anomaly
14 in both cases because: firstly, the signal is not following SPE onset, secondly these SPEs are such small events
15 that ozone loss was not observed, not even in the mesosphere. These robust non-SPE signals are included in the
16 superposed-epoch analysis performed in Sect. 3, contributing to the robust anomalies below 30 km in Fig. 2.

1 **Figure 5. Same as Fig. 4 but for WACCM-D ozone anomalies before and after individual big SPEs (proton fluxes >400**
2 **pfu) since 1989. Extreme SPEs (proton fluxes >10000 pfu) are marked with bold magenta titles.**

3

4 Identify sources of the robust ozone anomaly below 35 km following the SPE beginning on 16th Jan 2005 is
5 difficult. With a moderate cold winter temperature causing more ozone loss, coincident of robust dynamical ozone
6 changes following the SPE exists. Meanwhile, an extremely large (over 270%) ground level enhancement (GLE)
7 of neutrons occurred during the SPE period on 20 January 2005 (Jackman et al., 2011). Ionization rate reached
8 500 cm⁻³s⁻¹ at 30 km for one day due to the very high energy protons (300-20 000 MeV) that caused the GLE
9 (Usoskin et al., 2011). Jackman et al. (2011) carried out a detailed study of January 2005 SPE's influence on the
10 northern polar atmosphere using WACCM3 simulation, and reported an ozone column decrease of less than 0.01%
11 by GLE protons, while the ozone changes below 50 km observed in MLS data are seasonal changes. Nonetheless,
12 in our study the robust MLS ozone destruction signature in the lower stratosphere following the January 2005
13 SPE is extremely unique, not only when compared to other SPEs cases after 2004, but also when large and extreme
14 SPEs before 2004 are included (see the WACCM-D simulation result presented in Fig. 5). Further research needs
15 to be done to confirm the dynamical/chemical factors that led to ozone destruction below 35 km in January 2005.

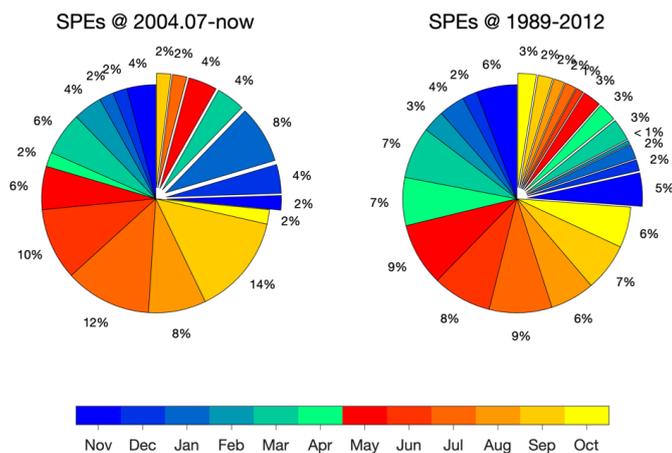

16 **5 Conclusions**

17 Recent studies have reported up to 10% average decrease of lower stratospheric ozone at 20 km altitude following
18 solar proton events (SPE). However, mechanisms which could cause such a large low-altitude impact are not
19 clear. We used the Aura MLS satellite ozone datasets from 2004 to date and WACCM-D model simulations from
20 1989 - 2012 to analyse SPE-driven ozone changes. In our approach, stratospheric and mesospheric daily ozone
21 anomalies (10-70 km) were examined over the epochs of SPEs by applying 1) a Superposed Epoch Analysis
22 (SEA) for all the cases and 2) a case-by-case analysis for individual events. Statistical significance of the anom-
23 alies found in the ozone levels was estimated by employing a Monte Carlo approach.

24 Arctic polar ozone destruction in the mesosphere and upper stratosphere can be directly observed from satellite
25 measurement anomaly, when following SPEs in September-April with proton fluxes >400 pfu and >1000 pfu,
26 respectively. We observe 5-10% ozone destruction below 30 km altitude in MLS SEA results. However, the de-
27 pletion appears before the epoch time, i.e. SPE onset. We argue that such lower stratospheric ozone losses are
28 rather caused by unusually stable and strong polar vortex, together with sufficient ozone depleting reservoirs of
29 chlorine. In the case by case study, we find a very good overall consistency between SPE-driven ozone anomalies
30 derived from the WACCM-D model simulations and the Aura MLS data. This enables us to generalise the study
31 also to the SPEs before the Aura MLS era. From 1989 to date, robust lower stratospheric ozone decrease after
32 SPEs was observed only once in MLS ozone anomaly, i.e. following the January 2005 SPE. Ozone was depleted
33 by ~1 ppmv (~15%) at 20 – 35 km and by ~0.15 ppmv (> 20%) below 15km 5 days after SPE onset. Nevertheless,
34 the exact mechanisms of the suggested lower stratosphere impact are currently unclear. The simulation results
35 indicate that even for the strongest SPEs in our record, there is no significant effect on the lower stratospheric
36 ozone as such. Although it remains unclear to what degree the lower ozone decrease in January 2005 was caused
37 by the SPE, and how much due to natural variability, we suspect that the observed, statistically significant lower
38 stratospheric ozone impact is most likely by chance coincident with the SPE epoch. Based on our analysis, we
39 argue that SPE do not cause direct lower stratospheric ozone anomalies.
