Abstract

Liquid–liquid phase separation (LLPS) in organic aerosol particles can impact several properties of atmospheric particulate matter, such as cloud condensation nuclei (CCN) properties, optical properties, and gas-to-particle partitioning. Yet, our understanding of LLPS in organic aerosols is far from complete.

20 Here, we report on LLPS of one-component and two-component organic particles consisting of α -pinene- and β -caryophyllene-derived ozonolysis products and commercially-available organic compounds of relevance to atmospheric organic particles. In the experiments involving single-component organic particles, LLPS was observed in 8 out of 11 particle types studied. LLPS almost always occurred when the oxygen-to-carbon elemental ratio (O:C) was ≤ 0.44 , but did not occur when O:C was > 0.44 . The
25 phase separation occurred by spinodal decomposition and nucleation and growth mechanism, and when LLPS occurred, two liquid phases co-existed up to $\sim 100\%$ relative humidity (RH). In the experiments

involving two-component organic particles, LLPS was observed in 23 out of 25 particles types studied. LLPS almost always occurred when the average was $O:C \leq 0.67$, but never occurred when the average $O:C$ was > 0.67 . The phase separation occurred by spinodal decomposition and nucleation and growth mechanisms. When LLPS occurred, two liquid phases co-existed up to $\sim 100\%$. These results provide further evidence that LLPS is likely a frequent occurrence in organic aerosol particles in the troposphere, even in the absence of inorganic salts.

1. Introduction

Secondary organic aerosols (SOA) are ubiquitous in the atmosphere, comprising up to approximately 80% of the mass of submicrometer particles (Kanakidou et al., 2005; Jimenez et al., 2009; Heald et al., 2010). SOA particles are produced when OH, NO_3 , and O_3 oxidize volatile organic compounds (VOC) in the atmosphere. Depending on the VOC type, oxidant type, and reaction time, the oxygen-to-carbon elemental ratio ($O:C$) of SOA can vary from 0.2 to 1.0 (Zhang et al., 2007; Hallquist et al., 2009; Jimenez et al., 2009; Heald et al., 2010; Ng et al., 2010). SOA particles are important because they play critical roles in air quality, cloud formation, and the Earth's radiative properties (Seaton et al., 1995; Xiaohong and Jian, 2010; Pöschl and Shiraiwa, 2015; Sanchez et al., 2017; Shiraiwa et al., 2017).

SOA can undergo phase transitions as relative humidity (RH) changes in the atmosphere (Hänel, 1976; Martin, 2000; Krieger et al., 2012; You et al., 2014; Freedman, 2017). One possible phase transition is liquid–liquid phase separation (LLPS) (Pankow, 2003; Marcolli and Krieger, 2006; Ciobanu et al., 2009; Bertram et al., 2011; Krieger et al., 2012; Song et al., 2012a; Zuend and Seinfeld, 2012; Veghte et al., 2014; You et al., 2014; O'Brien et al., 2015; Freedman, 2017; Zhang et al., 2018, 2019; Olson et al., 2019; Riva et al., 2019). The occurrence of LLPS has implications for the optical properties (Brunamonti et al., 2015; Fard et al., 2018), gas-particle partitioning (Zuend et al., 2010; Zuend and Seinfeld, 2012; Shiraiwa et al., 2013), hygroscopic properties (Hodas et al., 2016), and cloud condensation nuclei (CCN) properties (Ovadnevaite et al., 2017; Liu et al. 2018) of atmospheric particles.

Many researchers have focused on LLPS in particles containing organic material mixed with inorganic salts. They found that LLPS can occur when the $O:C$ of the organic material is smaller than 0.8 (Bertram et al., 2011; Krieger et al., 2012; Song et al., 2012a, 2012b; Schill and Tolbert, 2013; You et al., 2013,

55 2014). More recently, studies on LLPS in organic aerosol particles free of inorganic salts have shown that
LLPS occurs in SOA generated in environmental chambers when the average O:C of the organic material
is smaller than roughly 0.5 across the RH range of ~95% to ~100% (Renbaum-Wolff et al., 2016; Rastak
et al., 2017; Song et al., 2017; Ham et al., 2019) with implications for the CCN properties of the SOA
(Petters et al., 2006; Hodas et al., 2016; Renbaum-Wolff et al., 2016; Ovadnevaite et al., 2017; Rastak et
60 al., 2017; Liu et al., 2018; Ham et al., 2019). In addition, Song et al. (2018) showed that LLPS occurs in
organic particles containing one commercially-available organic compound when the O:C is smaller than
0.44 while LLPS occurs in organic particles containing two commercially available organic species when
the average the O:C is smaller than ≤ 0.58 .

In the following, we investigated LLPS in particles containing one and two organic species generated
65 from ozonolysis products of α -pinene and β -caryophyllene, which are atmospherically relevant, and
commercially-available organic compounds. α -pinene and β -caryophyllene are the most abundant types
of monoterpene ($C_{10}H_{16}$) and sesquiterpenes ($C_{15}H_{24}$) in the atmosphere, respectively (Guenther, 1995;
Sakulyanontvittaya et al., 2008; Henrot et al., 2017). However, the studies of LLPS and morphologies for
 α -pinene and β -caryophyllene oxidation products are still rare. Our results can provide additional insight
70 into the O:C range required for LLPS in organic particles free of inorganic salts. Moreover, our results
can provide that the chemical complexity of organic particles effects on LLPS. These observations should
improve our understanding of LLPS behavior and provide more accurate constrained the value of the O:C
ratio for LLPS. The results from these studies should also improve the understanding and modelling of
CCN activity of SOA free of inorganic salts.

75

2. Experimental

2.1 Materials

Table 1 presents the physical properties of the organic compounds investigated. In this study, 11 organic
species were used, including seven products from the ozonolysis of α -pinene and β -caryophyllene and
80 four commercially-available organic compounds. These species covered an O:C range of 0.13 - 1.00
(Table 1). All species were liquid at room temperature.

Seven of the products from the ozonolysis of α -pinene and β -caryophyllene were synthesized. The detailed synthesis methods for these species are described in Bé et al. (2017). Using ^1H NMR, ^{13}C NMR, and IR spectroscopy, the ozonolysis products were characterized to confirm their identity and purity. The
85 purity of all synthesized compounds was $> 95\%$. All products contained a carboxylic acid, ketone, and/or aldehyde, which are abundant organic functional groups in the atmosphere (Hallquist et al., 2009; Nozière et al., 2015). The O:C range of the ozonolysis products was between 0.13 and 0.44 (Table 1). To achieve O:C ratios up to 1.00, we used commercially-available organic compounds (Sigma-Aldrich, purities $\geq 97\%$) (Table 1).

90

2.2 Preparation of particles consisting of one and two organic species

Particles consisting of either one or two organic compounds were prepared at room temperature without the addition of a solvent. Particles consisting of the commercially-available organic compounds were nebulized directly on siliconized hydrophobic glass slides (Hampton Research, Canada). Particles
95 consisting of ozonolysis products were slightly viscous. To form particles on a substrate, these ozonolysis products were picked up with the tip of a pipette, and the pipette was then flicked towards a hydrophobic glass slide.

Particles consisting of two organic compounds were prepared using mixtures (1:1 mass ratio) of pure organic species without addition of a solvent. To prepare the mixtures with 1:1 mass ratio, each organic
100 species was weighed in a vial and then combined. After mixing, the solutions were homogenous based on visual inspection. Particles were generated from these mixtures and deposited on hydrophobic slides either by nebulization (for the mixtures involving commercially-available organic compounds) or by the flicking method via the tip of a pipette as described above (for the ozonolysis products). This method of producing two-component organic particles did not work for α -pinene ozonolysis products and β -
105 caryophyllinic acid due to the stickiness of these material. Hence, these materials were not included in the systems used to generate two-component organic particles.

2.3 Optical microscopy for observation of liquid–liquid phase separation

The organic particles on hydrophobic glass slides were placed into a RH and temperature controlled flow-
110 cell coupled to an optical microscope (Olympus BX43, 40× objective, Japan) (Parsons et al., 2004; Pant
et al., 2006; Bertram et al., 2011; Song et al., 2012a, 2018; Ham et al., 2019). During all experiments, the
temperature inside the flow-cell was maintained at 291 ± 1 K. The RH was controlled by a continuous
flow of a wet and dry N_2 mixture with a total flow rate of 500 sccm. The temperature and RH were
monitored by a humidity and temperature sensor (Sensirion, SHT 71, Switzerland). RH inside the flow-
115 cell was calibrated by measuring the deliquescence RH of four different pure inorganic salts (potassium
carbonate, sodium chloride, ammonium sulfate, and potassium nitrate) (Winston and Bates, 1960). The
RH uncertainty from the calibration was $\pm 1.5\%$.

At the beginning of LLPS experiments, organic particles inside the flow-cell were equilibrated at $\sim 100\%$
RH for 15–20 min. If LLPS was observed, the RH was decreased from $\sim 100\%$ to $\sim 5\text{--}10\%$ lower than the
120 RH at which the two liquid phases merged into one phase followed by an increase in RH to $\sim 100\%$. If
LLPS was not observed, the RH was decreased from $\sim 100\%$ to $\sim 0\%$ RH, followed by an increase to $\sim 100\%$
RH. During all experiments, the RH was adjusted at a rate of $0.1 - 0.2\% \text{ RH min}^{-1}$. The optical images
during experiments were recorded every 5 s using a CMOS (complementary metal–oxide–semiconductor)
detector (DigiRetina 16, Tucsen, China). Organic particles were selected in the diameter range of 30–100
125 μm , which was required for LLPS experiments. Each one and two organic species was measured 4–5
times within this size range.

3. Results and discussion

3.1 Liquid–liquid phase separation in particles containing one organic species

130 Eleven different types of particles containing one organic species were investigated for LLPS at 291 ± 1
K. Out of the eleven different types of one-component organic particles studied, eight underwent LLPS
during humidity cycles (Table S1). LLPS occurred in all one-component organic particles containing α -
pinene and β -caryophyllene ozonolysis products.

Shown in Figure 1 and Movies S1–S7 are optical images recorded while the RH was decreased for all
135 the cases where LLPS was observed in one-component organic particles. For these cases, two liquid
phases were always observed at $\sim 100\%$ RH. As the RH was decreased, the two liquid phases merged into

one liquid phase at ~95% RH, except for particles of β -caryophyllinic acid (Fig. 1e and Movie S5). For β -caryophyllinic acid particles, the two liquid phases merged into one liquid phase at 82.1% RH (Fig. 1e and Movie S5).

140 Shown in Figure 2 and Movies S8-S14 are optical images of the same seven particles shown in Fig. 1 and Movies S1-S7, except the images were recorded while the RH was increased, rather than decreased. At low RH-values, the particles contained one phase. As the RH increased, LLPS occurred at ~95% RH for all cases exception for β -caryophyllinic acid particles, which underwent LLPS at 82.9% RH (Fig. 2e and Movie S12). At the onset of LLPS, many small inclusions formed in the particles. As the RH was
145 further increased, the small inclusions coagulated and coalesced, and the particles continued to grow (Fig. 2 and Movies S8-S14). At ~100% RH, all particles contained two liquid phases. These results for LLPS occurrence in the organic particles was consistent within the studied size ranges (~30-100 μm in diameter).

LLPS in the single component organic particles occurred by nucleation and growth, and spinodal decomposition with RH increasing. Particles of β -nocaryophyllonic acid and suberic acid monomethyl
150 ester (Song et al. 2018) had two liquid phases with inclusions by nucleation and growth mechanism (Fig. 2d and Movies S11) while the other single component organic particles had a core-shell morphology by spinodal decomposition (Fig. 2a, b, c, e, f, g and Movies S8, 9, 10, 12, 13, 14). Nucleation and growth mechanism is a phase transition which has to be overcome an energy barrier to form stable nuclei of the second phase within a liquid (Shelby, 1995; Papon et al., 1999; Ciobanu et al., 2009; Song et al., 2012a).
155 Spinodal decomposition is a phase transition that occurs within a liquid without an energy barrier (Shelby, 1995; Papon et al., 1999; Ciobanu et al., 2009; Song et al., 2012a). Previous studies also observed LLPS by spinodal decomposition in α -pinene-derived SOA, β -caryophyllene-derived SOA, and limonene-derived SOA (Renbaum-Wolff et al., 2016; Song et al., 2017; Ham et al., 2019). We expect that the inner phase consisted mainly of water while the outer phase consisted mainly of organic molecules because the
160 amount of the inner phase reduced in size as the RH was decreased (Renbaum-Wolff et al., 2016; Song et al., 2017, 2018). This assumption has also been reported in several other studies (Renbaum-Wolff et al., 2016; Song et al. 2017, 2018; Ham et al. 2019). The surface tension of water and the surface tensions of organics are consistent with this assumption (Jasper, 1972).

165 Illustrated in Fig. 3a is the lower RH boundary for LLPS ($LLPS_{lower}$) and upper RH boundary for LLPS
($LLPS_{upper}$) determined for one-component organic particles (blue symbols). LLPS occurred in the one-
component organic particles when the O:C was ≤ 0.44 . Our results are consistent with the results from
Song et al. (2018), who observed LLPS in one-component organic particles when the O:C was ≤ 0.44
(Fig. 3a, grey symbols). Our results are also consistent with $LLPS_{lower}$ and $LLPS_{upper}$ determined for SOA
170 produced from α -pinene and β -caryophyllene (Renbaum-Wolff et al., 2016; Song et al., 2017; Ham et al.,
2019). In all cases, $LLPS_{upper}$ was $\sim 100\%$ RH.

The values of $LLPS_{lower}$ and $LLPS_{upper}$ determine in the current experiments using a decreasing RH was
within the uncertainty of $LLPS_{lower}$ and $LLPS_{upper}$ values determine in the experiments using an increasing
RH (Tables S1 and S2). In addition, no dependence on particle size was observed for $LLPS_{lower}$ and
 $LLPS_{upper}$ within the size range investigated (30–100 μm).

175

3.2 Liquid-liquid phase separation in particles containing two organic species

To better mimic the complexity of real aerosol compositions, we also studied LLPS in particles containing
two organic species. Table S2 lists the 25 different mixtures investigated using combinations of β -
caryophyllene ozonolysis products and commercially-available organic compounds. In total, 23 out of the
180 25 two-component organic particle types investigated underwent LLPS (Fig. 3b and Table S2). Shown in
Fig. 4 and Movies S15-S19 are examples of images of two-component organic particles that underwent
LLPS during a decrease in RH. Shown in Fig. 5 and Movies S20-S24 are the same five particles, but
images recorded as the RH was increased.

Out of the 23 particles types that underwent LLPS, 22 of the particle types formed a core-shell
185 morphology with decreasing RH. Only one particle type (β -caryophyllonic acid/ β -nocaryophyllonic acid)
was observed both core-shell and partially engulfed morphology with increasing RH (Fig. S1). As
discussed in Sect. 3.1, the inner phase is expected to be mainly water while the outer phase is expected to
be mainly organic material (Renbaum-Wolff et al., 2016; Song et al., 2017, 2018). As RH was decreased,
the two liquid phases merged into one phase. For example, particles of β -caryophyllene aldehyde/PEG-
190 400 merged into one phase at 39.9% RH (Fig. 4e and Movie S19).

195 Interestingly, particles showed different morphologies of core-shell, partially engulfed, and inclusions after LLPS occurred for RH increasing. These different morphologies have been also observed previously (Kwamena et al., 2010; Reid et al., 2011; Song et al., 2012a, 2013). The different morphologies could be resulted from the phase separation mechanisms, volume ratios and different functional groups (dicarboxylic acid vs carboxylic acid and ketone) which can result in different interfacial energies and spreading coefficients (Kwamena et al., 2010; Reid et al., 2011; Song et al., 2013; Stewart et al., 2015, Gorkowski et al. 2020).

200 In the experiments with two-component organic particles and increasing RH, in most cases (19 out of the 23 particle types that underwent LLPS), phase separation began with the abrupt formation of many small inclusions (e.g. Fig. 5a, b, e and Movies S20, 21, 24). This behavior suggests spinodal decomposition as the mechanism for LLPS. In contrast, the mechanism for LLPS in the particles containing ozonolysis products mixed with pyruvic acid was likely nucleation and growth mechanism based on the appearance of nucleation from the interior of the particles as the RH increased (Figs. 5c, d and Movies S22, 23).

205 Illustrated in Fig. 3b (blue symbols) is the lower RH boundary for LLPS ($LLPS_{lower}$) and upper RH boundary for LLPS ($LLPS_{upper}$) determined in the experiments with two-component organic particles. LLPS was observed in all cases when the average O:C ≤ 0.67 . When LLPS was observed, $LLPS_{upper}$ was $\sim 100\%$ RH. These results are similar to previous results from Song et al. (2018) (gray symbols in Fig. 3b), even though they studied different types of two-component organic particles. Figure 3b also presents Sigmoid-Boltzmann fits of all data points from Song et al. (2018) and the current study to parameterize $LLPS_{lower}$ (solid line) and $LLPS_{upper}$ (dashed line) as a function of O:C. The parametrizations of Sigmoid-Boltzmann fits are given in the Supplement Information (Sect. S3).

4. Atmospheric implications

215 O:C of organic materials has been used to interpret and parameterize hygroscopicity (Jimenez et al., 2009), oxidation (Heald et al., 2010; Kroll et al., 2011), and mixing thermodynamics of organic aerosol particles (Donahue et al., 2011; Hodas et al., 2016). Previous studies have shown LLPS in mixed organic and inorganic aerosol particles often occurs for O:C < 0.8 (Bertram et al., 2011; Krieger et al., 2012; Song

et al., 2012a, 2012b; Schill and Tolbert, 2013; You et al., 2013, 2014). Even in the absence of inorganic
220 salts, the occurrence of LLPS was dependent on the O:C of organic materials (Renbaum-Wolff et al.,
2016; Song et al., 2017; Song et al., 2018; Ham et al., 2019). Our results show that as compositional
complexity increased from one organic species to two organic species, LLPS occurred over a wider range
of average O:C values of organic materials (increasing from 0.44 to 0.67) (Figs. 3a and b). Considering
the chemical complexity and the O:C ratio of organic particles in the troposphere ($0.20 < \text{O:C} < 1.00$)
225 (Zhang et al., 2007; Hallquist et al., 2009; Jimenez et al., 2009; Heald et al., 2010; Ng et al., 2010), our
result provided additional evidence that LLPS is likely a common feature of organic aerosols free of
inorganic salts. A caveat is that the mixing ratio of 1:1 for two organic species and the chemical
complexity used in our experiments is rather simple compared to the chemical complexity found in the
atmosphere (Zhang et al., 2007; Hallquist et al., 2009; Jimenez et al., 2009). Further studies are needed
230 to confirm LLPS in organic aerosols comprising of more complex mixtures with different mixing ratios.
In addition to the O:C ratio, the types of organic functional groups present in the molecules are also likely
important for LLPS (Song et al., 2012b) because different functional groups lead to different strengths of
intermolecular interactions with water. Further studies are needed to elucidate the effect of functional
groups on the occurrence of LLPS in organic particles.

235 LLPS in aerosol particles has an impact on heterogeneous reactions (Folkers et al. 2003; Anttila et al.
2006; Cosman and Bertram, 2008; Cosman et al. 2008; McNeill et al., 2008; Lam et al., 2019) and CCN
(Petters et al., 2006; Hodas et al., 2016; Renbaum-Wolff et al., 2016; Ovadnevaite et al., 2017; Rastak et
al., 2017; Liu et al., 2018). The reactive uptake of gas-phase oxidants can differ depending on the number
of phases present in the particles (Folkers et al. 2003; Anttila et al. 2006; Cosman and Bertram, 2008;
240 Cosman et al. 2008; McNeill et al., 2008; Lam et al., 2019). For example, the effective OH uptake
coefficient of 3-methylglutaric acid/ammonium sulfate particle decreased with a factor of ~2.4 than the
particle of 3-methylglutaric acid (Lam et al., 2019). The occurrence of LLPS in organic aerosol particles
at high RH, as observed in the current studies, is important since LLPS at high RH can lower the barrier
to CCN activation by decreasing the surface tension of the particles (Ovadnevaite et al., 2017; Rastak et
245 al., 2017; Liu et al., 2018). A decrease in surface tension and lowering of the barrier to CCN, can lead to

an increase in cloud droplets numbers in the atmosphere, with implications for modelling the indirect effect of aerosols on climate (Ovadnevaite et al., 2017; Rastak et al., 2017).
