## Abstract

In this paper, we exploit the first 10-year data-record (2008-2017) of nitric acid (HNO<sub>3</sub>) total columns measured by the IASI-A/Metop infrared sounder, characterized by an exceptional daily sampling and a good vertical sensitivity in the mid-stratosphere (around 50 hPa), to monitor the causal relationship between the temperature decrease and the observed HNO<sub>3</sub> loss that occurs each year in the Antarctic stratosphere during the polar night. Since the HNO<sub>3</sub> depletion results from the formation of polar stratospheric clouds (PSCs) which trigger the development of the ozone (O<sub>3</sub>) hole, its continuous monitoring is of high importance. We verify here, from the 10-year time evolution of the pair HNO<sub>3</sub>-temperature (taken from reanalysis at 50 hPa), the recurrence of specific regimes in the cycle of IASI HNO<sub>3</sub> and identify, for each year, the day and the 50 hPa temperature ("drop temperature") corresponding to the onset of strong HNO<sub>3</sub> depletion in the Antarctic winter. Although the measured HNO<sub>3</sub> total column does not allow differentiating the uptake of HNO<sub>3</sub> by different types of PSC particles along the vertical profile, an average drop temperature of  $194.2 \pm 3.8$  K, close to the nitric acid trihydrate (NAT) existence threshold ( $\sim 195$  K at 50 hPa), is found in the region of potential vorticity lower than  $-10 \times 10^{-5}$  K.m<sup>2</sup>.kg<sup>-1</sup>.s<sup>-1</sup> (similar to the 70° – 90° S Eqlat region during winter). The spatial distribution and inter-annual variability of the drop temperature are investigated and discussed. This paper highlights the capability of the IASI sounder to monitor the long-term evolution of the polar stratospheric composition and processes involved in the depletion of stratospheric O<sub>3</sub>.

## 1 Introduction

The cold and isolated air masses found within the polar vortex during winter are associated with a strong denitrification of the stratosphere due to the formation of PSCs (composed of HNO<sub>3</sub>, sulphuric acid (H<sub>2</sub>SO<sub>4</sub>) and water ice (H<sub>2</sub>O)) (Peter, 1997; Voigt et al., 2000; von König, 2002; Schreiner et al., 2003; Peter and Groß, 2012). These clouds strongly affect the polar chemistry by (1) acting as surfaces for the heterogeneous activation of chlorine and bromine compounds, in turn leading to enhanced O<sub>3</sub> destruction (Solomon, 1999; Wang and Michelangeli, 2006; Harris et al., 2010; Wegner et al., 2012) and by (2) removing gas-phase HNO<sub>3</sub> temporarily or permanently through uptake by PSCs and sedimentation of large PSC particles to lower altitudes. The denitrification of the polar stratosphere during winter delays the reformation of chlorine reservoirs and, hence, intensifies the O<sub>3</sub> hole (Solomon, 1999; Harris et al., 2010). The heterogeneous reaction rates on PSCs surface and the uptake of HNO<sub>3</sub> strongly depend on the temperature and on the PSCs particle type. The PSCs are classified into three different types based on their composition and optical properties: type Ia solid nitric acid trihydrate -

49 NAT ( $\text{HNO}_3 \cdot (\text{H}_2\text{O})_3$ ), type Ib liquid supercooled ternary solution - STS ( $\text{HNO}_3/\text{H}_2\text{SO}_4/\text{H}_2\text{O}$  with  
50 variable composition) and type II, crystalline water-ice particles (likely composed of a combination of  
51 different chemical phases) (Toon et al., 1986; Koop et al., 2000; Voigt et al., 2000; Lowe and  
52 MacKenzie, 2008). In the stratosphere, they mostly consist of mixtures of liquid/solid STS/NAT  
53 particles in varying number densities, with  $\text{HNO}_3$  being the major constituent of these particles. The  
54 large-size NAT particles of low number density are the principal cause of sedimentation (Lambert et al.,  
55 2012; Pitts et al., 2013; Molleker et al., 2014; Lambert et al., 2016). The formation temperature of STS  
56 ( $T_{\text{STS}}$ ) and the thermodynamic equilibrium temperatures of NAT ( $T_{\text{NAT}}$ ) and ice ( $T_{\text{ice}}$ ), have been  
57 determined, respectively, as:  $\sim 192$  K (Carslaw et al., 1995),  $\sim 195.7$  K (Hanson and Mauersberger, 1988)  
58 and  $\sim 188$  K (Murphy and Koop, 2005) for typical 50 hPa atmospheric conditions (5 ppmv  $\text{H}_2\text{O}$  and 10  
59 ppbv  $\text{HNO}_3$ ). While the NAT nucleation was thought to require temperatures below  $T_{\text{ice}}$  and pre-existing  
60 ice particles, recent observational and modelling studies have shown that  $\text{HNO}_3$  starts to condense in  
61 early PSC season in liquid NAT mixtures well above  $T_{\text{ice}}$  ( $\sim 4$  K below  $T_{\text{NAT}}$ , close to  $T_{\text{STS}}$ ) even after a  
62 very short temperature threshold exposure (TTE) to these temperatures but also slightly below  $T_{\text{NAT}}$  after  
63 a long TTE, whereas the NAT existence persists up to  $T_{\text{NAT}}$  (Pitts et al., 2013; Hoyle et al., 2013; Lambert  
64 et al., 2016; Pitts et al., 2018). It has been recently proposed that the higher temperature condensation  
65 results from heterogeneous nucleation of NAT on meteoritic dust in liquid aerosol (Hoyle et al., 2013;  
66 Groöb et al., 2014; James et al., 2018). Further cooling below  $T_{\text{STS}}$  and  $T_{\text{ice}}$  leads to nucleation of liquid  
67 STS, of solid NAT onto ice and of ice particles mainly from STS (type II PSCs) (Lowe and MacKenzie,  
68 2008). The formation of NAT and ice has also been shown to be triggered by stratospheric mountain-  
69 waves (Carslaw et al., 1998; Hoffmann et al., 2017). Although the formation mechanisms and  
70 composition of STS droplets in stratospheric conditions are well described (Toon et al., 1986; Carslaw  
71 et al., 1995; Lowe and MacKenzie, 2008), the NAT and ice nucleation processes still require further  
72 investigation. This could be important as the chemistry-climate models (CCMs) generally oversimplify  
73 the heterogeneous nucleation schemes for the PSCs formation (Zhu et al., 2015; Spang et al., 2018; Snels  
74 et al., 2019) preventing an accurate estimation of  $\text{O}_3$  levels. The influence of  $\text{HNO}_3$  in modulating  $\text{O}_3$   
75 abundances in the stratosphere is furthermore underrepresented in CCMs (Kvissel et al., 2012).

76  
77 Several satellite instruments measure stratospheric  $\text{HNO}_3$  (e.g. MLS/UARS (Santee et al., 1999),  
78 MLS/Aura (Santee et al., 2007), MIPAS/ENVISAT (Piccolo and Dudhia, 2007), ACE-FTS/SCISAT  
79 (Sheese et al., 2017) and SMR/Odin (Urban et al., 2009)). The spaceborne lidars CALIOP/CALIPSO  
80 and the infrared instrument MIPAS/Envisat) are capable to detect and classify the PSC types, and to  
81 follow their formation mechanisms (Lambert et al., 2016; Pitts et al., 2018; Spang et al., 2018) and  
82 references therein, which complements in situ measurements (Voigt et al., 2005) and ground-based lidar  
83 (Snels et al., 2019). From these available observational datasets, the  $\text{HNO}_3$  depletion has been linked to  
84 the PSCs formation and detected below the  $T_{\text{NAT}}$  threshold (Santee et al., 1999; Urban et al., 2009;  
85 Lambert et al., 2016; Ronsmans et al., 2018), but its relationship to PSCs still needs further investigation  
86 given the complexity of the nucleation mechanisms that depends on a series of parameters (e.g.  
87 atmospheric temperature, water and  $\text{HNO}_3$  vapour pressure, time exposure to temperatures, temperature  
88 history).

89  
90 In contrast to the limb satellite instruments mentioned above, the infrared nadir sounder IASI offers a  
91 dense spatial sampling of the entire globe, twice a day (Section 2). While it cannot provide a vertical  
92 profile of  $\text{HNO}_3$  similar to the limb sounders, IASI provides reliable total column measurements of  
93  $\text{HNO}_3$  characterized by a maximum sensitivity in the low-middle stratosphere around 50 hPa (20 km)  
94 during the dark Antarctic winter (Ronsmans et al., 2016, 2018) where the PSCs cloud form (Voigt et al.,  
95 2005; Lambert et al., 2012; Spang et al., 2016, 2018). This study aims to explore the 10-years continuous  
96  $\text{HNO}_3$  measurements from IASI for providing a long-term global picture of depletion and of its  
97 dependence to temperatures during polar winter (Section 3). The temperature corresponding to the onset

98 of the strong depletion in HNO<sub>3</sub> records (here referred to as ‘drop temperature’) is identified in Section  
99 4 for each observed year and discussed in the context of previous studies.

## 101 2 Data

102  
103 The HNO<sub>3</sub> data used in the present study are obtained from measurements of the Infrared Atmospheric  
104 Sounding Interferometer (IASI) embarked on the Metop-A satellite. IASI measures the Earth’s and  
105 atmosphere’s radiation in the thermal infrared spectral range (645 - 2760 cm<sup>-1</sup>), with a 0.5 cm<sup>-1</sup> apodized  
106 resolution and a low radiometric noise (Clerbaux et al., 2009; Hilton et al., 2012). Thanks to its polar  
107 sun-synchronous orbit with more than 14 orbits a day and a field of view of four simultaneous footprints  
108 of 12 km at nadir, IASI provides global coverage twice a day (9.30 AM and PM mean local solar time).  
109 That extensive spatial and temporal sampling in the polar regions is key to this study.

110  
111 The HNO<sub>3</sub> vertical profiles are retrieved on a uniform vertical 1 km grid of 41 layers (from the surface  
112 to 40 km with an extra layer above to 60 km) in near-real-time by the Fast Optimal Retrieval on Layers  
113 for IASI (FORLI) software, using the optimal estimation method (Rodgers, 2000). Detailed information  
114 on the FORLI algorithm and retrieval parameters specific to HNO<sub>3</sub> can be found in previous papers  
115 (Hurtmans et al., 2012; Ronsmans et al., 2016). For this study, only the total columns (v20151001) are  
116 used, considering (1) the low vertical resolution of IASI with only one independent piece of information  
117 (FWHM of the averaging kernels of ~30 km), (2) the limited sensitivity of IASI to tropospheric HNO<sub>3</sub>,  
118 (3) the dominant contribution of the stratosphere to the HNO<sub>3</sub> total column and (4) the largest sensitivity  
119 of IASI in the region of interest, i.e. in the low and mid-stratosphere (from ~70 to ~30 hPa), where the  
120 HNO<sub>3</sub> abundance is the highest (Ronsmans et al., 2016). The IASI measurements capture the expected  
121 variations of HNO<sub>3</sub> within the polar night, as illustrated in Fig. 1 that shows examples of vertical HNO<sub>3</sub>  
122 profiles retrieved within the dark Antarctic vortex (above Arrival Height) and outside the vortex (above  
123 Lauder). The retrieved profiles are shown along with their associated total retrieval error and averaging  
124 kernels (the total column averaging kernels and the so-called “sensitivity profile” are also represented;  
125 see Ronsmans et al., 2016 for more details). Above Arrival Height during the dark Antarctic winter, we  
126 clearly see depleted HNO<sub>3</sub> levels in the low and mid-stratosphere and the altitude of maximum  
127 sensitivity (at around 30 hPa for this case). At Lauder on the contrary, HNO<sub>3</sub> levels larger than the a  
128 priori are observed in the stratosphere with a larger range of maximum sensitivity. The total columns are  
129 associated with a total retrieval error ranging from around 3% at mid- and polar latitudes to 25% above  
130 cold Antarctic surface during winter (due to a weaker sensitivity above very cold surface with a DOFS  
131 of 0.95 and to a poor knowledge of the seasonally and wavenumber-dependent emissivity above ice  
132 surfaces which induces larger forward model errors), and a low bias (lower than 12%) in polar regions  
133 over the altitude range where the IASI sensitivity is the largest, when compared to ground-based FTIR  
134 measurements (see Hurtmans et al., 2012 and Ronsmans et al., 2016 for more details). In order to expand  
135 on the comparisons against FTIR measurements which is not possible during the polar night, Fig. 2 (top  
136 panel) presents the time series of daily IASI total HNO<sub>3</sub> columns co-located with MLS measurements  
137 within 2.5x2.5 grid boxes, averaged in the 70°S–90°S equivalent latitude band. In order to account for  
138 the vertical sensitivity of IASI, the averaging kernels associated with each co-located IASI retrieved  
139 profiles were considered for this cross-comparison. The MLS profiles were first interpolated to the  
140 FORLI pressure grids, then converted into column profiles. They were also extended down to the surface  
141 by considering the FORLI-HNO<sub>3</sub> a priori profile. Similar variations in the HNO<sub>3</sub> column are captured  
142 by the two instruments, with an excellent agreement in particular for the timing of the strong HNO<sub>3</sub>  
143 depletion within the inner vortex core. Note that a similar good agreement between the two satellite  
144 datasets is obtained in other latitude bands (see Fig. 2 bottom panel for the 50°S–70°S equivalent latitude  
145 band; the other bands are not shown).

147 Quality flags similar to those developed for O<sub>3</sub> in previous IASI studies (Wespes et al., 2017) were  
148 applied a posteriori to exclude data (i) with a corresponding poor spectral fit (e.g. based on quality flags  
149 rejecting biased or sloped residuals, fits with maximum number of iteration exceeded), (ii) with less  
150 reliability (e.g. based on quality flags rejecting suspect averaging kernels, data with less sensitivity  
151 characterized by a DOFS lower than 0.9) or (iii) with tropospheric cloud contamination (defined by a  
152 fractional cloud cover  $\geq 25\%$ ). Note that the HNO<sub>3</sub> total column distributions illustrated in sections  
153 below use the median as a statistical average since it is more robust against the outliers than the mean.

154  
155 Temperature and potential vorticity (PV) fields are taken from the ECMWF ERA Interim Reanalysis  
156 dataset, respectively at 50 hPa and at the potential temperature of 530 K (corresponding to ~20 km  
157 altitude where the IASI sensitivity to HNO<sub>3</sub> is the highest during the Southern Hemisphere (S.H.) winter  
158 (Ronsmans et al., 2016). Because the HNO<sub>3</sub> uptake by PSCs starts a few degrees or slightly below  $T_{NAT}$   
159 (~195.7 K at 50 hPa (Hanson and Mauersberger, 1988)) depending on the meteorological conditions  
160 (Pitts et al., 2013; Hoyle et al., 2013; Lambert et al., 2016; Pitts et al., 2018), a threshold temperature of  
161 195 K is considered in the sections below to identify the PSCs-containing regions. The potential vorticity  
162 is used to delimit dynamically consistent areas in the polar regions. In what follows, we use either the  
163 equivalent latitudes ("eqlat", calculated from PV fields at 530 K) or the PV values to characterize the  
164 relationship between HNO<sub>3</sub> and temperatures in the cold polar regions. Uncertainties in ERA-Interim  
165 temperatures will also be discussed below.

### 166 167 **3 Annual cycle of HNO<sub>3</sub> vs temperatures**

168  
169 Figure 3a shows the yearly HNO<sub>3</sub> cycle (solid lines, left axis) in the southernmost equivalent latitudes  
170 (70° - 90° S), as measured by IASI over the whole period of measurements (2008–2017). The total HNO<sub>3</sub>  
171 variability in such equivalent latitudes has already been discussed in a previous IASI study (Ronsmans  
172 et al., 2018) where the contribution of the PSCs into the HNO<sub>3</sub> variations was highlighted. The  
173 temperature time series, taken at 50 hPa, is here represented as well (dashed lines, right axis). From this  
174 figure, different regimes of HNO<sub>3</sub> total columns vs temperature can be observed throughout the year and  
175 from one year to another. In particular, we define here three main regimes (R1, R2 and R3) along the  
176 HNO<sub>3</sub>/temperature cycle. The full cycle and the main regimes in the 70° - 90° S eqlat region are further  
177 represented in Fig. 3b that shows a histogram of the HNO<sub>3</sub> total columns as a function of temperature  
178 for the year 2011. Similar histograms are observed for the ten years of IASI measurements (not shown).  
179 The red horizontal and vertical lines in Fig. 3a and Fig. 3b, respectively, represent the 195 K threshold  
180 temperature used to identify the onset of HNO<sub>3</sub> uptake by PSCs (see Section 2). The three identified  
181 regimes correspond to:

- 182
- 183 - R1 is defined by the maxima in the total HNO<sub>3</sub> abundances covering the months of April and  
184 May ( $\sim 3 \times 10^{16}$  molec.cm<sup>-2</sup>, R1 in Figures 3a and b), when the 50 hPa temperature strongly  
185 decreases (from ~220 to ~195 K). These high HNO<sub>3</sub> levels result from low sunlight, preventing  
186 photodissociation, along with the heterogeneous hydrolysis of N<sub>2</sub>O<sub>5</sub> to HNO<sub>3</sub> during autumn  
187 before the formation of polar stratospheric clouds (Keys et al., 1993; Santee et al., 1999; Urban  
188 et al., 2009; de Zafra and Smyshlyaev, 2001). This period also corresponds to the onset of the  
189 deployment of the southern polar vortex which is characterized by strong diabatic descent with  
190 weak latitudinal mixing across its boundary, isolating polar HNO<sub>3</sub>-rich air from lower latitudinal  
191 airmasses.
  - 192
  - 193 - R2 which extends from June to October is characterized by the onset of the strong decrease in  
194 HNO<sub>3</sub> total columns at the beginning of June, when the temperatures fall below 195 K, followed

195 by a plateau of total HNO<sub>3</sub> minima. In this regime, the HNO<sub>3</sub> total columns average below  $2 \times 10^{16}$   
196 molec.cm<sup>-2</sup> and the 50 hPa temperatures range mostly between 180 and 190 K.

197

198 - R3 starts in October when sunlight returns and the 50 hPa temperatures rise above 195 K. Despite  
199 the stratospheric warming with 50 hPa temperatures up to 240 K in summer, the HNO<sub>3</sub> total  
200 columns stagnate at the R2 plateau levels (around  $1.5 \times 10^{16}$  molec.cm<sup>-2</sup>). This regime likely  
201 reflects the photolysis of NO<sub>3</sub> and HNO<sub>3</sub> itself (Ronsmans et al., 2018) as well as the permanent  
202 denitrification of the mid-stratosphere, caused by the PSCs sedimentation. The likely  
203 renitrification of the lowermost stratosphere (Braun et al., 2019; Lambert et al., 2012) where the  
204 HNO<sub>3</sub> concentrations and the IASI sensitivity to HNO<sub>3</sub> are lower (Ronsmans et al., 2016) can  
205 hardly be inferred from the IASI total column measurements. The plateau lasts until  
206 approximately February, where HNO<sub>3</sub> total column slowly starts increasing, reaching the April-  
207 May maximum in R1.

208

209 As illustrated in Fig. 3a, the three regimes are observed each year with, however, some interannual  
210 variations. For instance, the sudden stratospheric warming (SSW) that occurs in 2010 (see the  
211 temperature time series at 20 hPa for the year 2010; green dotted line) yielded higher HNO<sub>3</sub> total columns  
212 (see green solid line in July and August) (de Laat and van Weele, 2011; Klekociuk et al., 2011; WMO,  
213 2014; Ronsmans et al., 2018).

214

215 Figure 3c shows the evolution of the relationship between the daily averaged HNO<sub>3</sub> (calculated from a  
216 7-day moving average) with the highest occurrence (in bins of  $0.1 \times 10^{16}$  molec.cm<sup>-2</sup> and of 2K) and the  
217 50 hPa temperature, over the 10 years of IASI. The red vertical line represents the 195 K threshold  
218 temperature. Figure 3c clearly illustrates the slow increase in HNO<sub>3</sub> columns as the temperatures  
219 decrease (February to May, i.e. R3 to R1), the strong and rapid HNO<sub>3</sub> depletion occurring in June (R2),  
220 the plateau of low HNO<sub>3</sub> abundances in winter and spring (from August to November; R2 to R3). Figure  
221 3c also highlights the interannual variability in total HNO<sub>3</sub>, which is found to be the largest in R3, and  
222 shows a strong consistency in the onset of the depletion between each year (beginning of June when the  
223 temperatures fall below 195 K as indicated by the red vertical line). Given the span of PSCs formation  
224 over a large range of altitudes (typically between 10 and 30 km) (Höpfner et al., 2006, 2009; Spang  
225 et al., 2018; Pitts et al., 2018) and that of maximum IASI sensitivity to HNO<sub>3</sub> around 50 hPa (Hurtmans  
226 et al., 2012; Ronsmans et al., 2016), the temperatures at two other pressure levels, namely 70 and 30 hPa  
227 (i.e. ~15 and ~25 km), have also been tested to investigate the relationship between HNO<sub>3</sub> and  
228 temperature in the low and mid-stratosphere. The results (not shown here) exhibit a similar HNO<sub>3</sub>-  
229 temperature behavior at the different levels with, as expected, lower and larger temperatures in R2,  
230 respectively, at 30 hPa (down to ~180 K) and at 70 hPa (down to ~185 K), but still below the NAT  
231 formation threshold at these pressure levels ( $T_{NAT} \sim 193$  K at 30 hPa and  $\sim 197$  K at 70 hPa) (Lambert et  
232 al., 2016). Therefore, the altitude range of maximum IASI sensitivity to HNO<sub>3</sub> (see Section 2) is  
233 characterized by temperatures that are below the NAT formation threshold at these pressure levels,  
234 enabling the PSCs formation and the denitrification process. Furthermore, the consistency between the  
235 195 K threshold temperature taken at 50 hPa and the onset of the strong total HNO<sub>3</sub> depletion seen in  
236 IASI data (see Fig. 3a and Fig. 3c) is in agreement with the largest NAT area that starts to develop in  
237 June around 20 km (Spang et al., 2018), which justifies the use of the 195 K temperature at that single  
238 representative level in this study.

239

#### 240 **4 Onset of HNO<sub>3</sub> depletion and drop temperature detection**

241

242 To identify the spatial and temporal variability of the onset of the depletion phase, the daily time  
243 evolution of HNO<sub>3</sub> during the first 10 years of IASI measurements and the temperatures at 50 hPa are

244 explored. In particular, the second derivative of HNO<sub>3</sub> total column with respect to time is calculated to  
245 detect the strongest rate of decrease seen in the HNO<sub>3</sub> time series and to identify its associated day and  
246 50 hPa temperature.

247

#### 248 **4.1 HNO<sub>3</sub> vs temperature time series**

249

250 Figure 4 shows the time series of the second derivative of HNO<sub>3</sub> total column with respect to time (blue)  
251 and of the temperature (red) averaged in the areas of potential vorticity smaller than  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$   
252 to encompass the regions inside the inner polar vortex where the temperatures are the coldest and  
253 the total HNO<sub>3</sub> depletion occurs (Ronsmans et al., 2018). The use of that PV threshold value explains  
254 the gaps in the time series during the summer when the PV does not reach such low levels, while the  
255 time series averaged in the 70°- 90° S Eqlat band (dashed blue for the second derivative of HNO<sub>3</sub> and  
256 grey for the temperature) covers the full year. Note that the HNO<sub>3</sub> time series has been smoothed with a  
257 simple spline data interpolation function to avoid gaps in order to calculate the second derivative of  
258 HNO<sub>3</sub> total column with respect to time as the daily second-difference HNO<sub>3</sub> total column. The  
259 horizontal red line shows the 195 K threshold.

260

261 As already illustrated in Fig. 3a and Fig. 3c, the strongest rate of HNO<sub>3</sub> depletion (i.e. the second  
262 derivative minimum) is found around the 195 K threshold temperature, within some days (4 to 23 days)  
263 after total HNO<sub>3</sub> reaches its maximum, i.e. typically between the 11th of May (2013) and the 8th of June  
264 (2009). Except for the year 2014, the 50 hPa drop temperatures are detected between 189.2 K and 198.6  
265 K ( $194.1 \text{ K} \pm 2.8 \text{ K}$  -  $1\sigma$  standard deviation - on average over the 10 years, excluding 2014 that stands  
266 out with a drop temperature of 202.8 K). Knowing that  $T_{\text{NAT}}$  can be higher or lower depending on the  
267 atmospheric conditions and that NAT starts to nucleate from  $\sim 2-4 \text{ K}$  below  $T_{\text{NAT}}$  (Pitts et al., 2011;  
268 Hoyle et al., 2013; Lambert et al., 2016), the results here tend to demonstrate the consistency between  
269 the 50 hPa drop temperature, i.e. the temperature associated with the strongest HNO<sub>3</sub> depletion detected  
270 from IASI, and the PSCs formation temperature in that altitude region. Note that the range observed in  
271 the 50 hPa drop temperature could reflect the preponderance by one type of PSCs over another from one  
272 year to the next. The results further justify the use of the single 50 hPa level for characterizing and  
273 investigating the onset of HNO<sub>3</sub> depletion from IASI. Nevertheless, given the range of maximum IASI  
274 sensitivity to HNO<sub>3</sub> around 50 hPa, typically between 70 and 30 hPa (Ronsmans et al., 2016), the drop  
275 temperatures are also calculated at these two other pressure levels (not shown here) to estimate the  
276 uncertainty of the calculated drop temperature defined in this study at 50 hPa. The 30 hPa and 70 hPa  
277 drop temperatures range respectively over  $185.7 \text{ K} - 194.9 \text{ K}$  and over  $194.8 \text{ K} - 203.7 \text{ K}$ , with an  
278 average of  $192.0 \pm 2.9 \text{ K}$  and  $198.0 \pm 3.2 \text{ K}$  ( $1\sigma$  standard deviation) over the ten years of IASI. The  
279 average values at 30 hPa and 70 hPa fall within the  $1\sigma$  standard deviation associated with the average  
280 drop temperature at 50 hPa. It is also worth noting the agreement between the drop temperatures and the  
281 NAT formation threshold at these two pressure levels ( $T_{\text{NAT}} \sim 193 \text{ K}$  at 30 hPa and  $\sim 197 \text{ K}$  at 70 hPa)  
282 (Lambert et al., 2016).

283

284 Figures 5a and b show the zonal distribution of HNO<sub>3</sub> total columns and of the temperature at 50 hPa,  
285 respectively, spanning 55° - 90° S over the whole IASI period, with, superimposed, three isocontour  
286 levels of potential vorticity ( $-10$ ,  $-8$  and  $-5 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  in blue, cyan and black, respectively) and  
287 one isocontour for the 50 hPa temperature. The PV isocontour of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  is clearly shown  
288 to separate well the region of strong depletion in total HNO<sub>3</sub> according to the latitude and the time. The  
289 red vertical dashed lines indicates the average date for the drop temperatures calculated in the area of  $\text{PV} \leq -$   
290  $10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  ( $194.2 \pm 3.8 \text{ K}$ ; see Fig. 4) over the IASI period. It shows that the strongest rate in  
291 HNO<sub>3</sub> depletion occurs on average a few days before June. The delay of some days between the  
292 maximum in total HNO<sub>3</sub> and the start of the depletion (see Fig. 4) is also visible in Fig. 5a. The yearly

293 zonally averaged time series over the ten years of IASI can be found in Fig. 6; it shows the reproducibility  
294 of the edge of the collar HNO<sub>3</sub> region and of the region of the strong HNO<sub>3</sub> depletion, respectively  
295 delimited by the PV isocontours of  $-5 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  and of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  at 50 hPa,  
296 measured by IASI from year to year.

## 298 4.2 Distribution of drop temperatures

300 To explore the capability of IASI to monitor the onset of HNO<sub>3</sub> depletion at a large scale from year to  
301 year, figure 7 shows the spatial distribution of the 50 hPa drop temperatures (based on the second  
302 derivative minima of total HNO<sub>3</sub> averaged in  $1^\circ \times 1^\circ$  grid cells) inside a region delimited by a PV value  
303 of  $-8 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$ , for each year of the IASI period. The green contour represents the PV isocontour  
304 of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$ , averaged over the period 10 May – 15 July for each year, which delimits our  
305 region of interest. The isocontours of 195 K for the average temperatures and the minimum temperatures,  
306 as well as the isocontour of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  for the minimum PV encountered at 50 hPa over the  
307 10 May to 15 July period are also represented. The calculated drop temperatures corresponding to the  
308 onset of HNO<sub>3</sub> depletion inside the averaged PV isocontour are found to vary between  $\sim 180$  and  $\sim 210$   
309 K and the corresponding dates range between  $\sim$ mid-May and mid-July (not shown here). Note that the  
310 high extremes in the drop temperature, which are found in some cases above eastern Antarctica, should  
311 be considered with caution: they correspond to specific regions above ice surface with emissivity  
312 features that are known to yield errors in the IASI retrievals (Hurtmans et al., 2012; Ronsmans et al.,  
313 2016). Indeed, bright land surface such as ice might in some cases lead to poor HNO<sub>3</sub> retrievals.  
314 Although wavenumber-dependent surface emissivity atlases are used in FORLI (Hurtmans et al., 2012),  
315 this parameter remains critical and causes poorer retrievals that, in some instances, pass through the  
316 series of quality filters and could affect the drop temperature calculation.

318 The averaged isocontour of 195 K encircles well the area of HNO<sub>3</sub> drop temperatures lower than 195 K  
319 (typically from  $\sim 187$  K to  $\sim 195$  K), which means that the bins inside that area characterize airmasses  
320 that experience the NAT threshold temperature during a long time over the 10 May – 15 July period.  
321 That area encompasses the inner vortex core (delimited by the isocontour of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  for  
322 the PV averaged over the 10 May – 15 July period) and show pronounced minima (lower than  $-0.5 \times 10^{14}$   
323 molec.cm<sup>-2</sup>.d<sup>-2</sup>) in the second derivative of the HNO<sub>3</sub> total column with respect to time (not shown here),  
324 which indicate a strong and rapid HNO<sub>3</sub> depletion. The area enclosed between the two isocontours of  
325 195 K for the temperatures, the averaged one and the one for the minimum temperatures, show generally  
326 higher drop temperatures and weakest minima (larger than  $-0.5 \times 10^{14} \text{ molec.cm}^{-2}.\text{d}^{-2}$ ) in the second  
327 derivative of the HNO<sub>3</sub> total column (not shown). That area is also enclosed by the isocontour of  $-10 \times 10^{-5}$   
328  $\text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  for the minimum PV, meaning that the bins inside correspond, at least for one day over  
329 the 10 May – 15 July period, to airmasses located at the inner edge of the vortex and characterized by  
330 temperature lower than the NAT threshold temperature. The weakest minima in the second derivative  
331 of total HNO<sub>3</sub> (not shown) observed in that area indicate a weak and slow HNO<sub>3</sub> depletion and might be  
332 explained by a short period of the NAT threshold temperature experienced at the inner edge of the vortex.  
333 It could also reflect a mixing with strong HNO<sub>3</sub>-depleted and colder airmasses from the inner vortex  
334 core. The mixing with these already depleted airmasses could also explained the higher drop  
335 temperatures detected in those bins. These high drop temperatures are generally detected later (after the  
336 HNO<sub>3</sub> depletion occurs, i.e. after the 10 May – 15 July period considered here – not shown), which  
337 supports the transport, in those bins, of earlier HNO<sub>3</sub>-depleted airmasses and the likely mixing at the  
338 edge of the vortex. Finally, these spatial variations might also partly reflect the range of maximum  
339 sensitivity of IASI to HNO<sub>3</sub>, while biases in ECMWF reanalysis are too small for explaining the spatial  
340 variation in drop temperatures. Thanks to the assimilation of an advanced Tiros Operational Vertical  
341 Sounder (ATOVS) around 1998–2000 in reanalyses, to the better coverage of satellite instruments and

342 to the use of global navigation satellite system (GNSS) radio occultation (RO) (Schreiner et al., 2007;  
343 Wang et al., 2007; Lambert and Santee, 2018; Lawrence et al., 2018), the uncertainties have been vastly  
344 reduced. Comparisons of the ECMWF ERA Interim dataset used in this work with the COSMIC data  
345 (Lambert and Santee, 2018) found a small warm bias, with median differences around 0.5 K, reaching  
346 0–0.25 K in the southernmost regions of the globe at ~68–21 hPa where PSCs form.  
347 Except above some parts of Antarctica which are prone to larger retrieval errors, the overall range in the  
348 drop 50 hPa temperature for total HNO<sub>3</sub> inside the isocontour for the averaged temperature of 195 K,  
349 typically extends from ~187 K to ~195 K, which falls within the range of PSCs nucleation temperature  
350 at 50 hPa: from slightly below  $T_{NAT}$  to around 3–4 K below the ice frost point -  $T_{ice}$  - depending on  
351 atmospheric conditions, on TTE and on the type of formation mechanisms (Pitts et al., 2011; Peter and  
352 Grooß, 2012; Hoyle et al., 2013). This underlines well the benefit of the excellent spatial and temporal  
353 coverage of IASI that allows capturing the rapid and critical depletion phase over a large scale.

## 354 355 **5 Conclusions**

356  
357 In this paper, we have explored the added value of the dense HNO<sub>3</sub> total columns dataset provided by  
358 the IASI/Metop satellite over a full decade (2008–2017) for monitoring the stratospheric depletion phase  
359 that occurs each year in the S.H. and for investigating its relationship to the NAT formation temperature.  
360 To that end, we focused on and delimited the coldest polar region of the S.H. using a specific PV value  
361 at 530 K (~50 hPa, PV of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$ ) and stratospheric temperatures at 50 hPa, taken from  
362 the ECMWF ERA Interim reanalysis. That single representative pressure level has been considered in  
363 this study given the maximum sensitivity of IASI to HNO<sub>3</sub> around that level over a range where the  
364 PSCs formation/denitrification process occur.

365  
366 The annual cycle of total HNO<sub>3</sub>, as observed from IASI, has first been characterized according to the  
367 temperature evolution. Three various regimes (R1 to R3) in the total HNO<sub>3</sub> - 50 hPa temperature  
368 relationship were highlighted from the time series over the S.H. polar region and described along the  
369 cycle: R1 is defined at play during April and May and characterized by a rapid decrease in 50 hPa  
370 temperatures while HNO<sub>3</sub> accumulates in the poles; R2, from June to September, shows the onset of the  
371 depletion when the 50 hPa temperatures fall below 195 K (considered here as the onset of PSCs  
372 nucleation phase at that level), with a strong consistency between each year; R3, defined from November  
373 until March when total HNO<sub>3</sub> remains at low R2 plateau levels, despite the return of sunlight and heat,  
374 characterizes the strong denitrification of the stratosphere, likely due to PSCs sedimentation at lower  
375 levels where the IASI sensitivity is low. For each year over the IASI period, the use of the second  
376 derivative of the HNO<sub>3</sub> column versus time was then found particularly valuable to detect the onset of  
377 the HNO<sub>3</sub> condensation to PSCs. It is captured, on average from IASI, a few days before June with a  
378 delay of 4–23 days after the maximum in total HNO<sub>3</sub>. Except for the year 2014, the corresponding  
379 temperatures ('drop temperatures') were detected between 189.2 K and 198.6 K ( $194.1 \pm 2.8$  on average  
380 over the 10 years, excluding the year 2014 that shows a drop temperature of 202.8 K), which tends to  
381 demonstrated the good consistency between the 50 hPa drop temperature and the PSCs formation  
382 temperatures in that altitude region. Finally, the annual and spatial variability (within  $1^\circ \times 1^\circ$ ) in the drop  
383 temperature was further explored from IASI total HNO<sub>3</sub>. Inside the isocontours of 195 K for the average  
384 temperatures and of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  for the averaged PV at 50 hPa, the drop temperatures are  
385 detected between ~mid-May and mid-July, typically range between ~187 K to ~195 K and are associated  
386 with the highest minima (lower than  $-0.5 \times 10^{14} \text{ molec.cm}^{-2}.\text{d}^{-2}$ ) in the second derivative of the HNO<sub>3</sub> total  
387 column with respect to time, indicating a strong and rapid HNO<sub>3</sub> depletion. Except for extreme drop  
388 temperatures (~210 K) that were found from year to year above eastern Antarctica and suspected to  
389 result from unfiltered poor quality retrievals in case of emissivity issues above ice, the range of drop  
390 temperatures is interestingly found in line with the PSCs nucleation temperature that is known, from

391 previous studies, to strongly depend on a series a factors (e.g. meteorological conditions, HNO<sub>3</sub> vapour  
392 pressure, temperature threshold exposure, presence of meteoritic dust). At the edge of the vortex,  
393 considering the isocontours of 195 K for the minimum temperatures or of  $-10 \times 10^{-5} \text{ K.m}^2.\text{kg}^{-1}.\text{s}^{-1}$  for the  
394 minimum PV, higher and later drop temperatures along with weakest minima in the second derivative  
395 of the HNO<sub>3</sub> total column with respect to time, indicating a slow HNO<sub>3</sub> depletion, are found. It likely  
396 results from a short temperature threshold exposure or a mixing with already depleted airmasses from  
397 the inner vortex core. The results of this study highlight the ability of IASI to measure the variations in  
398 total HNO<sub>3</sub> and, in particular, to capture and monitor the rapid depletion phase over the whole polar  
399 regions.

400

401 We show in this study that the IASI dataset allows capturing the variability of stratospheric HNO<sub>3</sub>  
402 throughout the year (including the polar night) in the Antarctic. In that respect, it offers a new  
403 observational means to monitor the relation of HNO<sub>3</sub> to temperature and the related formation of PSCs.  
404 Despite the limited vertical resolution of IASI which does not allow to investigate the HNO<sub>3</sub> uptake by  
405 the different types of PSCs during their formation and growth along the vertical profile, the HNO<sub>3</sub> total  
406 column measurements from IASI constitute an important new dataset for exploring the strong polar  
407 depletion over the whole stratosphere. This is particularly relevant considering the mission continuity,  
408 which will span several decades with the planned follow-on missions. Indeed, thanks to the three  
409 successive instruments (IASI-A launched in 2006 and still operating, IASI-B in 2012, and IASI-C in  
410 2018) that demonstrate an excellent stability of the Level-1 radiances, the measurements will soon  
411 provide an unprecedented long-term dataset of HNO<sub>3</sub> total columns. Further work could also make use  
412 of this unique data set to investigate the relation between HNO<sub>3</sub>, O<sub>3</sub>, and meteorology in the changing  
413 climate.

414

#### 415 **Data availability**

416 The IASI HNO<sub>3</sub> data processed with FORLI-HNO<sub>3</sub> v0151001 are available upon request to the  
417 corresponding author.

418

#### 419 **Author contributions**

420 G.R. performed the analysis, wrote the manuscript and prepared the figures. C.W. and L.C. contributed  
421 to the analysis. C.W., S.S., P.-F. C. and L.C. contributed to the interpretation of the results. D.H. was  
422 responsible for the retrieval algorithm development and the processing of the IASI HNO<sub>3</sub> dataset. All  
423 authors contributed to the writing of the text and reviewed the manuscript.
