Abstract. In this paper, we exploit the first 10-year data-record (2008-2017) of nitric acid (HNO_3) total columns measured by the IASI-A/Metop infrared sounder, characterized by an exceptional daily sampling and a good vertical sensitivity in the mid-stratosphere (around 50 hPa), to monitor the causal relationship between the temperature decrease and the observed HNO_3 loss that occurs each year in the Antarctic stratosphere during the polar night. Since the HNO_3 depletion results from the formation

5 of polar stratospheric clouds (PSCs) which trigger the development of the ozone (O_3) hole, its continuous monitoring is of high importance. We verify here, from the 10-year time evolution of the pair HNO_3-temperature (taken from reanalysis at 50 hPa), the recurrence of specific regimes in the cycle of IASI HNO_3 and identify, for each year, the day and the 50 hPa-temperature ("drop temperature") corresponding to the onset of denitrification in Antarctic winter. Although the measured HNO_3 total column does not allow differentiating the uptake of HNO_3 by different types of PSC particles along the vertical profile, an

10 average drop temperature of $\sim$191 $\pm$ 3 K, consistent with the nitric acid trihydrate (NAT) formation temperature (close to 195 K at 50 hPa), is found. The spatial distribution and inter-annual variability of the drop temperature are briefly investigated and discussed in the context of previous PSCs studies. This paper highlights the capability of the IASI sounder to monitor the long-term evolution of the polar stratospheric composition and processes involved in the depletion of stratospheric O_3.

15 # 1 Introduction

The cold and isolated air masses found within the polar vortex during winter are associated with a strong denitrification of the stratosphere due to the formation of PSCs (composed of HNO_3, sulphuric acid (H_2SO_4) and water ice (H_2O)) (Peter, 1997; Voigt et al., 2000; von König, 2002; Schreiner et al., 2003). These clouds strongly affect the polar chemistry by (1) acting as surfaces for the heterogeneous activation of chlorine and bromine compounds, in turn leading to enhanced O_3 destruction

20　(Solomon, 1999; Wang and Michelangeli, 2006; Harris et al., 2010; Wegner et al., 2012) and by (2) removing gas-phase HNO$_3$ temporarily or permanently through uptake by PSCs and sedimentation of large PSC particles to lower altitudes. The denitrification of the polar stratosphere during winter delays the reformation of chlorine reservoirs and, hence, intensifies the O$_3$ hole (Solomon, 1999; Harris et al., 2010). The heterogeneous reaction rates on PSCs surface and the uptake of HNO$_3$ strongly depend on the temperature and on the PSCs particle type. The PSCs are classified into three different types based on

25　their composition and optical properties: type Ia solid nitric acid trihydrate - NAT (HNO$_3 \cdot (H_2O)_3$), type Ib liquid supercooled ternary solution - STS (HNO$_3$/H$_2$SO$_4$/H$_2$O with variable composition) and type II, crystalline water-ice particles (likely composed of a combination of different chemical phases) (e.g. (Toon et al., 1986; Koop et al., 2000; Voigt et al., 2000; Lowe and MacKenzie, 2008)). In the stratosphere, they mostly consist of mixtures of liquid/solid STS/NAT particles in varying number densities, with HNO$_3$ being the major constituent of these particles. The large-size NAT particles of low number

30　density are the principal cause of sedimentation(Lambert et al., 2012; Pitts et al., 2013; Molleker et al., 2014; Lambert et al., 2016). The formation temperature of STS (T$_{STS}$) and the thermodynamic equilibrium temperatures of NAT (T$_{NAT}$) and ice (T$_{ice}$), have been determined, respectively, as: $\sim$ 192 K (Carslaw et al., 1995), $\sim$ 195.7 K (Hanson and Mauersberger, 1988) and $\sim$ 188 K (Murphy and Koop, 2005) for typical 50 hPa atmospheric conditions (5 ppmv H$_2$O and 10 ppbv HNO$_3$). While the NAT nucleation was thought to require temperature below T$_{ice}$ and pre-existing ice particles, recent observational and

35　modelling studies have shown that HNO$_3$ starts to condense in early PSC season in liquid NAT mixtures well above T$_{ice}$ ($\sim$ 4 K below T$_{NAT}$, close to T$_{STS}$) even after a very short temperature threshold exposure (TTE) to these temperatures but also slightly below T$_{NAT}$ after a long TTE, whereas the NAT existence persists up to T$_{NAT}$ (Pitts et al., 2013; Hoyle et al., 2013; Lambert et al., 2016; Pitts et al., 2018). It has been recently proposed that the higher temperature condensation results from heterogeneous nucleation of NAT on meteoritic dust in liquid aerosol (Hoyle et al., 2013; Grooß et al., 2014; James et al.,

40　2018). Further cooling below T$_{STS}$ and T$_{ice}$ leads to nucleation of liquid STS, of solid NAT onto ice and of ice particles mainly from STS (type II PSCs) (Lowe and MacKenzie, 2008). The formation of NAT and ice has also been shown to be triggered by stratospheric mountain-waves (Carslaw et al., 1998; Hoffmann et al., 2017). Altough the formation mechanisms and composition of STS droplets in stratospheric conditions are well described (Toon et al., 1986; Carslaw et al., 1995; Lowe and MacKenzie, 2008), the NAT and ice nucleation processes still require further investigation. This could be important as the

45　chemistry-climate models (CCMs) generally oversimplify the heterogeneous nucleation schemes for the PSCs formation (Zhu et al., 2015; Spang et al., 2018; Snels et al., 2019) preventing an accurate estimation of O$_3$ levels. The influence of HNO$_3$ in modulating O$_3$ abundances in the stratosphere is furthermore underrepresented in CCMs (Kvissel et al., 2012).

　　Several satellite instruments measure stratospheric HNO$_3$ (MLS/Aura (Santee et al., 2007), MIPAS/ENVISAT (Piccolo and Dudhia, 2007), ACE-FTS/SCISAT (Sheese et al., 2017) and SMR/Odin (Urban et al., 2009)). The spaceborne lidars

50　CALIOP/CALIPSO and the infrared instrument MIPAS/Envisat) are capable to detect and classify the PSC types, and to follow their formation mechanisms (e.g. (Lambert et al., 2016; Pitts et al., 2018; Spang et al., 2018) and references therein), which complements in situ measurements (Voigt et al., 2005) and ground-based lidar (Snels et al., 2019). From these available observational datasets, the HNO$_3$ depletion has been linked to the PSCs formation and detected below the T$_{NAT}$ threshold (Santee et al., 1999; Urban et al., 2009; Lambert et al., 2016; Ronsmans et al., 2018), but its relationship to PSCs still needs fur-

55   ther investigation given the complexity of the nucleation mechanisms that depends on a series of parameters (e.g. atmospheric temperature, water and HNO_3 vapour pressure, time exposure to temperatures, temperature history).

In contrast to the limb satellite instruments mentioned above, the infrared nadir sounder IASI offers a dense spatial sampling of the entire globe, twice a day (Section 2). While it cannot provide a vertical profile of HNO_3 similar to the limb sounders, IASI provides reliable total column measurements of HNO_3 with a maximum sensitivity in the mid-stratosphere around 50

60   hPa (Ronsmans et al., 2016, 2018) where the PSCs cloud form (Voigt et al., 2005; Lambert et al., 2012; Spang et al., 2016, 2018). This study aims to explore the 10-years continuous HNO_3 measurements from IASI for providing a long-term global picture of denitrification and of its dependence to temperatures during polar winter (Section 3). The temperature corresponding to the onset of the strong depletion in HNO_3 records (here referred to as 'drop temperature') is identified in Section 4 for each observed year and discussed in the context of previous studies.

2 Data

65

The HNO_3 data used in the present study are obtained from measurements of the Infrared Atmospheric Sounding Interferometer (IASI) embarked on the Metop-A satellite. IASI measures the Earth's and atmosphere's radiation in the thermal infrared spectral range ($645 - 2760$ cm^{-1}), with a 0.5 cm^{-1} apodized resolution and a low radiometric noise (Clerbaux et al., 2009; Hilton et al., 2012). Thanks to its polar sun-synchronous orbit with more than 14 orbits a day and a field of view of four si-

70   multaneous footprints of 12 km at nadir, IASI provides global coverage twice a day (9.30 AM and PM mean local solar time). That extensive spatial and temporal sampling in the polar regions is key to this study.

The HNO_3 vertical profiles are retrieved on a uniform vertical 1 km grid of 41 layers (from the surface to 40 km with an extra layer above to 60 km) in near-real-time by the Fast Optimal Retrieval on Layers for IASI (FORLI) software, using the optimal estimation method (Rodgers, 2000). Detailed information on the FORLI algorithm and retrieval parameters specific to

75   HNO_3 can be found in previous papers (Hurtmans et al., 2012; Ronsmans et al., 2016). For this study, only the total columns (v20151001) are used, considering (1) the low vertical sensitivity of IASI with only one independent piece of information, (2) the limited sensitivity of IASI to tropospheric HNO_3, (3) the dominant contribution of the stratosphere to the HNO_3 total column and (4) the largest sensitivity of IASI is the region of interest, i.e. in the mid-stratosphere (from ∼10 to ∼30 km), where the HNO_3 abundance is the highest (Ronsmans et al., 2016). The total columns yield a total retrieval error of 10% and a low

80   bias (10.5 %) compared to ground-based FTIR measurements (Hurtmans et al., 2012; Ronsmans et al., 2016). Quality flags similar to those developed for O_3 in previous IASI studies (Wespes et al., 2017) were applied a posteriori to exclude data (i) with a corresponding poor spectral fit, (ii) with less reliability or (iii) with cloud contamination (defined by a fractional cloud cover ≥ 25 %). Note that the HNO_3 total column distributions illustrated in sections below use the median as a statistical average since it is more robust against the outliers than the normal mean.

85   Temperature and potential vorticity (PV) fields are taken from the ECMWF ERA Interim Reanalysis dataset, respectively at 50 hPa and at the potential temperature of 530 K (corresponding to ∼ 20 km altitude where the IASI sensitivity to HNO_3 is high during the Southern Hemisphere (S.H.) winter). Because the HNO_3 uptake by PSCs starts a few degrees or slightly

below T_{NAT} ($\sim$ 195.7 K at 50 hPa (Hanson and Mauersberger, 1988)) depending on the meteorological conditions (Pitts et al.,
2013; Hoyle et al., 2013; Lambert et al., 2016; Pitts et al., 2018), a threshold temperature of 195 K is considered in the sections
90   below to identify the PSCs-containing regions. The potential vorticity is used to delimit dynamically consistent areas in the
polar regions. In what follows, we use either the equivalent latitudes ("eqlat", calculated from PV fields at 530 K) or the PV
values to characterize the relationship between HNO_3 and temperatures in the cold polar regions. Uncertainties in ERA-Interim
temperatures will also be discussed below.

3   Annual cycle of HNO_3 vs temperatures

95   Figure 1a shows the yearly HNO_3 cycle (solid lines, left axis) in the southernmost equivalent latitudes ($70° − 90°$ S), as
measured by IASI over the whole period of measurements (2008–2017). The total HNO_3 variability in such equivalent latitudes
has already been discussed in a previous IASI study (Ronsmans et al., 2018) where the contribution of the PSCs into the HNO_3
variations was highlighted. The temperature time series, taken at 50 hPa, is here represented as well (dashed lines, right axis).
From this figure, different regimes of HNO_3 total columns vs temperature can be observed throughout the year and from one
100 year to another. In particular, we define here three main regimes (R1, R2 and R3) along the HNO_3 cycle. The full cycle and
the main regimes in the $70° − 90°$ S eqlat region are further represented in Fig. 1b that shows a histogram of the HNO_3 total
columns as a function of temperature for the year 2011. The red vertical line in Fig. 1a and Fig. 1b represent the 195 K threshold
temperature used to identify the onset of HNO_3 uptake by PSCs (see Section 2). The three identified regimes correspond to:

- R1 is defined by the maxima in the total HNO_3 abundances covering the months of April and May ($\sim 3 \times 10^{16}$ molec.cm^{-2},
105   R1 in Figure 1a and b), when the 50 hPa temperature strongly decreases (from $\sim$220 to $\sim$195 K). These high HNO_3
         levels result from low sunlight, preventing photodissociation, along with the heterogeneous hydrolysis of N_2O_5Santee
         et al. (1999); Urban et al. (2009); de Zafra and Smyshlyaev (2001).

- R2 which extents from June to September is characterized by the onset of the strong decrease in HNO_3 total columns at the
         beginning of June, when the temperatures fall below 195 K, followed by a plateau of total HNO_3 minima. In this regime,
110   the HNO_3 total columns average below 2×10^{16} molec.cm^{-2} and the 50 hPa temperatures range mostly between 180
         and 190 K.

- R3 starts in October when sunlight returns and the 50 hPa temperatures rise above 195 K. Despite the stratospheric warming
         with 50 hPa temperatures up to 240 K in summer, the HNO_3 total columns stagnate at the R2 plateau levels (around $1.5 \times$
         10^{16} molec.cm^{-2}). This regime likely reflects the photolysis of NO_3 and HNO_3 itself (Ronsmans et al., 2018) as well as
115   the permanent denitrification of the mid-stratosphere, caused by the PSCs sedimentation, despite the renitrification of the
         lowermost stratosphere (Braun et al., 2019) where the IASI sensitivity to HNO_3 is lower (Ronsmans et al., 2016). The
         plateau lasts until approximately February, where HNO_3 total column slowly starts increasing, reaching the April-May
         maximum in R1.
Figure 1. (a) Time series of daily averaged HNO_3 total columns (solid lines) and temperatures taken at 50 hPa (dashed lines) at the $70° - 90°$ S equivalent latitudes, for the years 2008–2017. The green dotted line represents the temperatures at 20 hPa for the year 2010. (b) HNO_3 total columns versus temperatures (at 50 hPa) histogram for the whole year (top) and for the 3 defined regimes (R1 - R3) separated in (a) for the year 2011. The colors refer to the number of measurements in each cell. (c) Evolution of daily averaged HNO_3 total columns with the highest occurrence (in the range of 0.1×10^{16} molec.cm^{-2}) as a function of the 50 hpa temperature for the years 2008–2017.

As illustrated in Fig. 1a, the three regimes are observed each year with, however, some interannual variations. For instance,

120   the sudden stratospheric warming (SSW) that occurs in 2010 (see the temperature time series at 20 hPa for the year 2010; green dotted line) yielded higher HNO_3 total columns (see green solid line in July and August) (de Laat and van Weele, 2011; Klekociuk et al., 2011; WMO, 2014; Ronsmans et al., 2018).

Figure 1c shows the evolution of the relationship between the daily averaged HNO_3 (calculated from a 7-days moving average) with the highest occurrence (in the range of 0.1×10^{16} molec.cm^{-2}) and the 50 hPa temperature, over the 10 years of

125   IASI. It clearly illustrates the slow increase in HNO_3 columns as the temperatures decrease (February to May, i.e. R3 to R1), the strong and rapid HNO_3 depletion in June (R1 to R2), the plateau of low HNO_3 abundances in winter and spring (from August to November; R2 to R3). Figure 1c also highlights the interannual variability in total HNO_3, which is found to be the largest in R3, and shows a strong consistency in the onset of the depletion between each year (beginning of June when the temperatures fall below 195 K as indicated by the red vertical line). Fig. 1c is accompanied by an animation, provided in the

130   Supplementary material, showing the daily evolution of the histogram of the HNO_3 total columns as a function of the 50 hPa temperature, averaged in a 7-days windows over all the years. Given the span of PSCs formation over a large range of altitudes (typically between 10 and 30 km) (Höpfner et al., 2006, 2009; Spang et al., 2018; Pitts et al., 2018) and that of maximum IASI sensitivity to HNO_3 around 50 hPa (Hurtmans et al., 2012; Ronsmans et al., 2016), the temperatures at two other pressure levels, namely 70 and 30 hPa (i.e. $\sim$15 and $\sim$25 km), have also been tested to investigate the relationship between HNO_3

135   and temperature in the mid-stratosphere. The results (not shown here) exhibit a similar HNO_3-temperature behavior at the different levels with, as expected, lower and larger temperatures in R2, respectively, at 30 hPa (180 and 185 K) and at 70 hPa ($\sim$190 K), but still below the NAT formation threshold at these pressure levels (T_{NAT} $\sim$193 K at 30 hPa and $\sim$197 K at 70 hPa) (Lambert et al., 2016). Therefore, the altitude range of maximum IASI sensitivity to HNO_3 (see Section 2) is characterized by the PSCs formation and the denitrification process. Furthermore, the consistency between the 195 K threshold temperature

140   taken at 50 hPa and the onset of the strong total HNO_3 depletion seen in IASI data (see Fig. 1a and Fig. 1c) is in agreement with the largest NAT area that starts to develop in June around 20 km (Spang et al., 2018), which justifies the use of the 195 K temperature at that single representative level in this study. Despite the limited vertical resolution of IASI which does not allow to investigate the HNO_3 uptake by the different types of PSCs during their formation and growth along the vertical profile, the HNO_3 total column measurements from IASI constitute an important new dataset for exploring the polar denitrification over

145   the whole stratosphere. This is particularly relevant considering the mission continuity, which will span several decades with the planned follow-on missions.

4   Onset of HNO_3 depletion and drop temperature detection

To go beyond the vertically integrated view of denitrification and to identify its spatial and temporal variability, the daily time evolution of HNO_3 during the first 10 years of IASI measurements and the temperatures at 50 hPa are explored. In particular,

150   the second derivative of HNO_3 total column with respect to time is calculated to detect the strongest rate of decrease seen in the HNO_3 time series and to identify its associated day and 50 hPa temperature.
Figure 2. Time series of total HNO_3 second derivative (blue, left y-axis) and of the temperature (red, right y-axis), in the region of potential vorticity lower than -10×10^{-5} $K.m^2.kg^{-1}.s^{-1}$. The red horizontal line corresponds to the 195 K temperature. The vertical dashed lines indicate the second derivative minimum in HNO_3 for each year. The corresponding dates (in bold, on the x-axis) and temperatures also are indicated. The time series of total HNO_3 second derivative (dashed blue) and of temperature (grey) in the 70–90°S Eqlat band are also represented.

4.1 HNO₃ vs temperature time series

Figure 2 shows the time series of the second derivative of HNO_3 total column with respect to time (blue) and of the temperature (red) averaged in the areas of potential vorticity smaller than -10×10^{-5} $K.m^2.kg^{-1}.s^{-1}$ to encompass the regions inside the inner

155   polar vortex where the temperatures and the total HNO_3 depletion are the coldest (Ronsmans et al., 2018). The use of that PV threshold value explains the gaps in the time series during the summer when the PV does not reach such low levels, while the time series averaged in the 70° - 90° S Eqlat band (dashed blue for the second derivative of HNO_3 and grey for the temperature) covers the full year.

Note that the HNO_3 time series has been smoothed with a simple spline data interpolation function to avoid gaps before

160   calculating the second derivative of HNO_3 total column with respect to time as the daily second-difference HNO_3 total column. The horizontal red line shows the 195 K threshold. As already illustrated in Fig. 1a and Fig. 1c, the strongest rate of HNO_3 depletion (i.e. the second derivative minimum) is found around the 195 K threshold temperature, within a few days (4 to 23 days) after total HNO_3 reaches its maximum, i.e. typically between the 17th of May (2010, 2013 and 2017) and the 10th of June (2009). The 50 hPa drop temperature are detected between 188.2 K and 196.6 K, with an average of 191.1±3.2 K (1σ standard

165   deviation) over the ten years. Knowing that T_{NAT} can be higher or lower depending on the atmospheric conditions and that NAT starts to nucleate from ∼2–4 K below T_{NAT} (Pitts et al., 2011; Hoyle et al., 2013; Lambert et al., 2016), the results here demonstrate the consistency between the 50 hPa drop temperature, i.e. the temperature associated with the strongest HNO_3 depletion detected from IASI, and the PSCs occurrence in the mid-stratosphere at polar latitudes. It further justifies the use of the single 50 hPa level for characterizing and investigating the onset of HNO_3 denitrification from IASI.
Figure 3. Zonal distributions of (a) HNO_3 total columns (in molec.cm^{-2}) from IASI and (b) temperatures at 50 hPa from ERA Interim (in K) between 55° to 90° south and averaged over the years 2008–2017. Three isocontours for PV of -5 (black), -8 (cyan) and -10 (blue) (in $\times 10^{-5}$ K.m^2.kg^{-1}.s^{-1}) and one isocontour for the 195 K temperature at 50 hPa (pink) are sumperimposed. The vertical red dashed line indicates, at 90°S, the 10-year average of the drop temperatures calculated from the HNO_3 time series second derivative in the area delimited by a -10×10^{-6} K.m^2.kg^{-1}.s^{-1} PV contour.

Figure 3a and b show the zonal distribution of HNO_3 total columns and of the temperature at 50 hPa, respectively, spanning 55°-90°S over the whole IASI period, with, superimposed, three isocontours levels of potential vorticity (-10, -8 and -5×10^{-5} K.m^2.kg^{-1}.s^{-1} in blue, cyan and black, respectively) and one isocontour for the 50 hPa temperature. The PV isocontour of -10×10^{-5} K.m^2.kg^{-1}.s^{-1} is clearly shown to separate well the region of strong depletion in total HNO_3 according to the latitude and the time. The red vertical dashed lines indicates, at 90°S, the average of the drop temperatures calculated in the area of PV -10×10^{-5} K.m^2.kg^{-1}.s^{-1} (191.1 $\pm$ 3.2 K; see Fig. 2) over the IASI period. It shows that the strongest rate in HNO_3 depletion occurs on average a few days before June. The delay of 4–23 days between the maximum in total HNO_3 and the start of the depletion (see Fig. 2) is also visible in Fig. 3a. The yearly zonally averaged time series over the ten years of IASI can be found in Fig. 4; it shows the reproducibility in the HNO_3 depletion measured from IASI from year to year.
Figure 4. Zonally averaged distributions of (top) HNO_3 total columns (in molec.cm^{-2}) from IASI and (bottom) temperatures at 50 hPa from ERA Interim (in K). The latitude range is from $55°$ to $90°$ south, and the isocontours are PVs of -5 (black), -8 (cyan) and -10 (blue) (in $\times 10^{-5}$ K.m^2.kg^{-1}.s^{-1}). The vertical red dashed lines correspond to the second derivative minima each year in the area delimited by a -10×10^{-5} K.m^2.kg^{-1}.s^{-1} PV contour.

4.2 Distribution of drop temperatures

180   To explore the capability of IASI to monitor the onset of denitrification at a large scale from year to year, Figure 5 shows the spatial variability of the drop 50 hPa temperatures (based on the second derivative minima of total HNO_3 averaged in $1° \times 1°$ grid cells) inside a PV region of $\leq -8 \times 10^{-5}$ K.m^2.kg^{-1}.s^{-1}, for each year of the IASI period. The red contour represents the PV isocontour of $\leq -10 \times 10^{-5}$ K.m^2.kg^{-1}.s^{-1} that delimits our region of interest. The dates corresponding to the onset of HNO_3 depletion inside that region are found to range between mid-May and early-July (not shown here). The calculated drop

185   temperatures vary significantly between ~ 180 and ~ 210 K. These high extremes are only found in very few cases and should be considered with caution as they correspond to specific regions above ice shelves with emissivity features that are known to yield errors in the IASI retrievals (Hurtmans et al., 2012; Ronsmans et al., 2016). Note also that these spatial variations might partly reflect the range of maximum sensitivity of IASI to HNO_3 (hence, the use of temperature at a single pressure level might be restrictive to some extent) and biases in ECMWF reanalysis. Reanalysis data sets are, indeed, known to feature large

190   uncertainties. In particular, they do not always capture small-scale fluctuations due to the limited spatial resolution, especially in the south polar regions. Nevertheless, the uncertainties are reduced for several years, thanks to the assimilation of an advanced Tiros Operational Vertical Sounder (ATOVS) around 1998–2000 in reanalyses, to the better coverage of satellite instruments
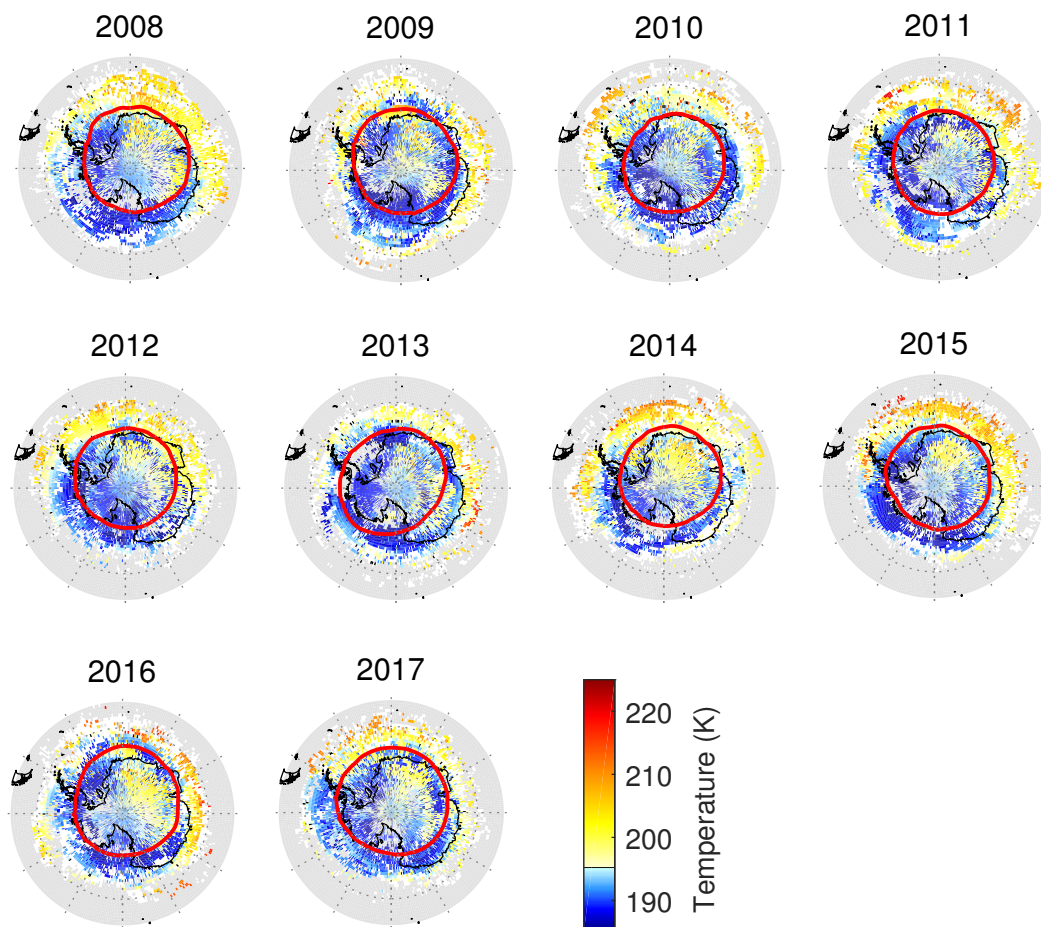

Figure 5. Spatial distribution ($1° \times 1°$) of the drop temperature at 50 hPa (K) (calculated from the total HNO_3 second derivative minima) for each year of IASI (2008–2017), in a region defined by a PV of $\leq -8 \times 10^{-5}$ K.m^2.kg^{-1}.s^{-1}. The red lines represented the isocontour PV of -10×10^{-5} K.m^2.kg^{-1}.s^{-1} averaged over the period 15.05–15.10 for each year.

and to the use of global navigation satellite system (GNSS) radio occultation (RO) (Schreiner et al., 2007; Wang et al., 2007; Lambert and Santee, 2018; Lawrence et al., 2018). Comparisons of the ECMWF ERA Interim dataset used in this work with the COSMIC data (Lambert and Santee, 2018) found a small warm bias, with median differences around 0.5 K, reaching 0–0.25 K in the southernmost regions of the globe at $\sim$ 68–21 hPa where PSCs form. Overall, despite these limitations, the spatial variability in the drop 50 hPa temperatures for IASI total HNO_3 is well in agreement with the natural variation in PSCs nucleation temperatures (from around 3-4 K below the ice frost point - T_{ice} - to slightly below T_{NAT} depending on atmospheric conditions, on TTE, on the type of formation mechanisms (Pitts et al., 2011; Peter and Grooss, 2012; Hoyle et al., 2013)). It underlines well the benefit of the excellent spatial and temporal coverage of IASI that allows to capture the rapid and critic denitrification phase over a large scale.

5 Conclusions

In this paper, we have explored the added value of the dense HNO_3 total columns dataset provided by the IASI/Metop satellite over a full decade (2008–2017) for monitoring the stratospheric denitrification phase that occurs each year in the S.H. and for in-
205 vestigating its relationship to stratospheric temperature, hence, to PSCs occurrence of PSCs. To that end, we focused on and delimited the coldest polar region of the S.H. using a specific PV value at 530 K ($\sim$50 hPa, PV of $\leq -10\times 10^{-5}$ K.m^2.kg^{-1}.s^{-1}) and stratospheric temperatures at 50 hPa, taken from the ECMWF ERA Interim reanalysis. That single representative pressure level has been considered in this study given the maximum sensitivity of IASI to HNO_3 around that level over a range where the PSCs formation/denitrification process occur.

210 The annual cycle of total HNO_3, as observed from IASI, has first been characterized according to the temperature evolution. Three various regimes (R1 to R3) in the total HNO_3 - 50 hPa temperature relationship were highlighted from the time series over the S.H. polar region and described along the cycle: R1 is defined at play during April and May and characterized by a rapid decrease in 50 hPa temperatures while HNO_3 accumulates in the poles; R2, from June to September, shows the onset of the depletion when the 50 hPa temperatures fall below 195 K (considered here as the onset of PSCs nucleation phase at
215 that level), with a strong consistency between each year; R3, defined from November until March when total HNO_3 remains at low R2 plateau levels, despite the return of sunlight and heat, characterizes the strong denitrification of the stratosphere, likely due to PSCs sedimentation at lower levels where the IASI sensitivity is low. For each year over the IASI period, the use of the second derivative of the HNO_3 column versus time was then found particularly valuable to detect the onset of the HNO_3 condensation to PSCs. It is captured, on average from IASI, a few days before June with a delay of 4–23 days after the
220 maximum in total HNO_3. The corresponding temperatures ('drop temperatures') were detected between 188.2 K and 196.6 K (191$\pm$3 K on average over the 10 years), which demonstrated the good consistency between the 50 hPa drop temperature and the PSCs formation temperatures in that altitude region. Finally, the annual and spatial variability (within $1° \times 1°$) in the drop temperature was further explored from IASI total HNO_3 and shown to range between $\sim$180 and $\sim$210 K. While recurrent patterns of extreme high drop temperatures were found from year to year and suspected to result from unfiltered poor quality
225 retrievals in case of emissivity issues above ice, the range of drop temperatures is interestingly found in line with the PSCs nucleation temperature that is known, from previous studies, to strongly depend on a series a factors (e.g. meteorological conditions, HNO_3 vapour pressure, temperature threshold exposure, presence of meteoritic dust). The results of this study highlighted the ability of IASI to measure the variations in total HNO_3 and, in particular, to capture and monitor the rapid denitrification phase over the whole polar regions.

230 To the best of our knowledge, it is the first time that such a large satellite observational data set of stratospheric HNO_3 concentrations is exploited to monitor the evolution HNO_3 versus temperatures. Thanks to the three successive instruments (IASI-A launched in 2006 and still operating, IASI-B in 2012, and IASI-C in 2018) that demonstrate an excellent stability of the Level-1 radiances, the measurements will soon provide an unprecedented long-term dataset of HNO_3 total columns. It could constitute a new accurate climatological parameter that could be inserted in the PSCs classification schemes. Further work

235   could also make use of this unique data set to investigate the relation between HNO_3, O_3, and meteorology in the changing climate.

Data availability. The IASI HNO_3 data processed with FORLI-HNO_3 v0151001 are available upon request to the corresponding author.

Author contributions. G.R. performed the analysis, wrote the manuscript and prepared the figures. C.W. and L.C. contributed to the analysis. C.W., S.S., P.-F. C. and L.C. contributed to the interpretation of the results. D.H. was responsible for the retrieval algorithm development and
240   the processing of the IASI HNO_3 dataset. All authors contributed to the writting of the text and reviewed the manuscript.

Competing interests. The authors declare no competing interests.
