

Interactive comment on “Elevated levels of OH observed in haze events during wintertime in central Beijing” by Eloise J. Slater et al.

Anonymous Referee #2

Received and published: 8 June 2020

This paper focuses on the investigation of the OH, HO₂ and RO₂ radical chemistry at extremely high NO in Beijing, China. As it was observed by a previous study in the same area (Tan et al., 2018) the current “known” chemistry at high NO cannot reproduce the measured HO₂ and RO₂ radicals resulting in a large underestimation of the ozone production.

I agree with reviewer one on the possibility of shortening the paper which, at the current status, feels more as a description of the observation (with some model run) but does not really try and push for suggesting possible explanations for the finding or even looking in explanations given in the past (segregation for example or Cl₂ chemistry) to check if they would help the situation in this campaign.

General comments

I would suggest trying and making better use of the complex and simple RO₂ concentrations. Measurement of RO₂ or scarce to start with and here several time the measurement of simple and complex RO₂ separately is brought up but then the data is not really used. Even when mentioning that there seems to be a better agreement between the measurement of simple RO₂ and model results at high NO (which, by the way, I do not agree with), the discussion stops there and there is no additional use of the data. Why not checking for example if the RO₂ measurement is consistent with the VOC load? Does the contribution of simple and complex RO₂ changes with time? During the day? From non-haze to haze periods? I think this type of analysis could maybe also help understanding a little bit more where the large discrepancy between measurement and model results arises from. . .

I am missing a small but useful description of all the measurements used within the model and which instrumentation (with accuracy and precision) was used for the different trace gases. It does not have to go too much in details but there is no mentioning of how NO, which is extremely important for the radicals chemistry, was measured. . . or O₃ or anything. In addition to this, there is no description of how the OH reactivity was measured and how much of a deviation from the mono-exponential decay could be expected for values of NO reaching up to 250 ppbv. What is the accuracy of the kOH measured at high NO? Could this represent a lower limit? This should be discuss appropriately and it could add an additional explanation of why the model is largely underestimating the RO₂ and HO₂ concentrations (lack of some primary VOCs).

Specific comments:

Page2 line46: “. . . quality are of serious concern. . .”

Page2 line49: “. . . of the world fastest. . .”

Page2 line51: I would drop the number after the comma and round the percentages

Page2 line 59: NO_x, SO₂ and VOCs have not been defined

Discussion paper

Chapter 2.1 More information on the specific of the campaign site would be beneficial. Was the site on the street? On a platform? On the roof of the building? What was the distance between different instruments? I understand there is a specific paper on the topic but just two lines with a little bit information would suffice.

Chapter 2.2.2 Here as well more details on the sensitivity towards the different RO₂ is needed. The different concentrations of RO₂ are used later on to justify some of the conclusions on the discrepancies between model and measurements so it is important to mention how well known is the separation in two classes of RO₂ and which sensitivity is applied for which classes.

Page 8 line 212: Is there really no difference between the accuracy of OH, HO₂ and RO₂ accounting that HO₂ requires conversion into OH and RO₂ requires a minimum of 2 NO steps?

Page 9 line 239: What is the concentration of H₂ to 500 ppbv included in the model needed for?

Page 9 line 241: What was the time resolution of the GC data?

Page 11 line 290: Is the diel variation shown the mean or the median of the data?

Page 11 line 300: O₃ does not react with high levels of NO but with a high concentration of NO

Page 21 Section 4.1: I assume that here only the results from the model are shown but this is not clear from reading the text.

Page 24 Lines 516-521: Has the possibility of segregation of air been investigated and ruled out or why this is mentioned here but there is no discussion on how this could have had an impact on this specific site? It could be worth discussing if this could help bringing measurements and model results in agreement.

Page 24 line 539: Assuming that figure 10 is actually figure 11 (where in the caption of

the figure the model line is the red one (?), I do not agree with the statement in the paper that the model can reproduce the simple RO₂ measured for NO above 100 ppbv. Actually, there is overlap between the model and the measured RO₂ 95th percentile for the complex RO₂. In all honesty, I am not sure this plot tells us much as the model equally predicts pretty much zero RO₂ expected at NO above 10 ppbv for both type of RO₂. Although I agree that the simple RO₂ have been studied more carefully, what would be the difference in rate with NO to justify the observed concentration of RO₂ or what type of different chemistry for the most complex RO₂ would be needed? There is no discussion in this study about it and some suggestions of what is feasible are needed.

Page 27 line 570-573: What would be the concentration of CL₂ and/or ClNO₂ needed to justify such a production of RO₂? This could tell us if it could be possible at all.

Page 28 line 602-605: I think one needs to be a bit careful here as, as you pointed out, the conditions (NO in particular) are not comparable and this campaign is one extreme case where NO is so large that dominates the losses of HO₂ in any case. It is also worth citing the study by (Tan et al., 2020) which came to a similar conclusion for smaller levels of NO.

Section 4.3: Although I agree with reviewer 1 that this session is not really needed as it is descriptive and should be substitute by a better analysis of what could bring measurement and model results in agreement, I think at page 31 line 650 the statement that the model over predict HO₂ in non-haze events is wrong. From figure 14 the model clearly under predicts HO₂ radical in non-haze events. Same for page 33 line 684 where I do not clearly see a midday peak for NO₃-?
