

Reponses to reviewer 1

This study investigates the effect of the city of Houston on a convective storm by means of regional numerical simulations. The authors use the WRF model coupled to a bin microphysics scheme and a land surface scheme. The city effect is decomposed into the land effect (the urban heat island effect) and the urban aerosol effect. The aerosol effect is further decomposed into the direct effect (aerosol-radiation interactions, ARI) and the indirect effect (aerosol-cloud interactions, ACI). It is shown that both effects (land and aerosol) drive increase in the convective intensity and precipitation, with the aerosol effect dominate. It is also shown that the interaction between the two effects causes a further intensification of the storm. The aerosol effect is shown to be dominated by the ACI rather than by the ARI. The two effects considered here (land and aerosol) affect the clouds at different stages and different levels in the atmosphere.

We thank the reviewer for your time and constructive comments. We have provided detailed responses point-by-point as below.

The mechanisms behind the different effects are explained. The paper address interesting questions and uses appropriate tools for answering them. I do have a few minor comments and suggestions for the authors:

L26: 15 m/s increase compared to what base-line? Maybe better to present it in percentage change.

The sentence was clear that the increase is the joint effect of both urban land and anthropogenic aerosols therefore it is compared with both effects excluded. The ~15m/s increase is in the maximum updraft speed. Now we have changed to the percentage increase (~75%) (Line 26).

L32: is 40 min change significant? Form the abstract the reader can't evaluate it.

40 min is quite significant since for thunderstorms since the total duration of the case is only a few hours. We have added text about it at Line 494, "...accelerates the development of convective storm into deep cloud stage by ~ 40 min, which is significant for thunderstorms since the storm duration is only a few hours".

L67: It will probably be good to explain what you mean here by: "indirect effect"

Rephrased as "...while aerosols had the opposite effect through the serving as cloud condensation nuclei".

L147: what is the sizes of the domains? From Fig. 1 it looks like domain 2 is of the order of 200-250 km. Is it enough for spin-up of the clouds entering the domain from the lateral boundaries? As the boundary conditions are from MERRA-2 (and not from WRF simulations) I assume that the spin-up requires quite a long time after entering the domain. For a typical windspeed of ~25-30 km/h (Fig. 12, for height below 1 km, and probably even higher windspeed above), the air will spend in the domain about 8- 10 h. Is this enough for the spin-up? In other words, how can you eliminate the domain boundaries effect?

Two nested domains with horizontal grid spacings of 2 and 0.5 km and horizontal grid points of 450×350 and 500×400 for Domain 1 and Domain 2. The initialization time of Domain 2 is 12-hr ahead of the analysis period for this case, so it is enough for spin-up. The information has been added to the revised manuscript (Line 151 and 169).

L220: are you only integrating liquid and no ice here? As you are simulating deep convective clouds, wouldn't it make more sense to include ice?

Since the tracking algorithm from Hu et al. (2019) used the quantity of vertically integrated liquid (VIL), which is an estimate a vertically-integrated column of radar-retrieved precipitation. VIL was shown to be an effective indicator of strong precipitation cells (Greene and Clark, 1972, Hu et al., 2019). Thus, for the tracking of model results, we used LWP, which an equivalent quantity to VIL) for a fair comparison. We explained this in the previous paragraph by the sentence "To apply the algorithm to both model simulation and NEXRAD observations consistently in this study, we calculated liquid water path (LWP), a variable of model output accounting for the column integrated liquid to replace VIL in MCIT for model simulation". We have also added a sentence to better describe VIL for strong precipitation cells, that is "VIL was shown to be an effective indicator of strong precipitation cells (Greene and Clark, 1972, Hu et al., 2019a)" (Line 225-226).

L233: you have twice "first".

Deleted now.

L381: missing ")"

Added.

L405: what about the role of the slower fall speed of hydrometeors under polluted conditions? As it was shown before, smaller droplets, with lower effective terminal velocity, would be pushed higher into the atmosphere (even for a given vertical velocity) and hence invigorate the ice processes (in addition to the increased latent heating by condensation). Does that play a role here? In addition, in this section it might be a good opportunity to comment on a very relevant recent paper: <https://journals.ametsoc.org/doi/pdf/10.1175/JAS-D-20-0012.1>

Here we are discussing the enhanced updraft speeds by the anthropogenic aerosol effects. In the updraft cores, updraft speeds are much stronger than the hydrometeor fall speeds so how much droplets are pushed to the high-levels should be determined by updraft speeds. Thus, slower fall speed would not have a large effect. The slower hydrometeor fall speeds do affect stratiform and anvil properties as shown from Fan et al. 2013 (PNAS), Grabowski and Morrison 2016 and 2020 in JAS.

In our case since the increase of latent heating from condensation is much larger than that from the freezing, deposition, and riming (Fig. 15c-d). Therefore, the enhanced vertical velocity is mainly contributed by enhanced condensation. Both Fan et al. (2018) and Lebo (2018) showed that the same amount of latent heating increase at the low-level plays a more significant role in invigorating convection than at the high-levels.

We showed that the higher droplet concentration in the case with anthropogenic aerosols enhances condensation therefore thermal buoyancy since condensation rates depend on droplet number and size based on accurate solution of supersaturation. Grabowski and Morrison (2020) interpreted the convective invigoration at low-levels in a different way. We have added a paragraph to discuss this on Page 20, that is,

“Grabowski and Morrison (2020) interpreted this warm-phase convective invigoration at low-levels by aerosols in a different way. They argued supersaturation (S) in updrafts rapidly, within a few seconds, approaches the quasi-equilibrium supersaturation (S_{eq}). With this quasi-steady assumption ($S \approx S_{eq}$), the condensation rate and buoyancy only depend on updraft velocity, not droplet number and size. Thus they concluded that the lower quasi-equilibrium supersaturation in the polluted case than the pristine case is the reason for enhanced buoyancy and updraft velocity, not the enhanced condensation. The problem is that the quasi-steady approximation is invalidated for updrafts where droplet concentrations are low or droplets are growing and their sizes are changing based on the explicit solution of supersaturation (Korolev and Mazin 2003). The explicit theoretical solution of supersaturation showed that condensation depends on droplet number and size besides updraft speeds (Pinsky et al. 2013). Here in this study the quasi-equilibrium supersaturation in the updrafts is generally 2-3 times higher than the true supersaturation, and the phase relaxation time is generally above 10 s above 3-km altitude in the case without anthropogenic aerosols and about 60 s when droplet number is of 10 cm^{-3} which occurs frequently in the convective cores where autoconversion and rain accretion are strong.”

Reponses to reviewer 2

The authors have performed a matrix of simulations to investigate the relative roles of urban heat island and aerosol forcing on the behavior of an observed storm in Houston. They find that both mechanisms lead to increased precipitation for a single cell on their study day. This is a valuable approach and a necessary investigation of multiple forcing mechanisms.

The authors use a single microphysical scheme in a single model, which leads to the ability to directly compare the results in the simulation matrix. The authors show that the simulations with full aerosol and land cover effects are better in some respects than those without. The aerosol effect contributes the most toward bringing the simulations closer to the observations of surface precipitation in these simulations ... and the effect is quite significant as noted on lines 345-6. The aerosol dramatically accelerates the growth of the cloud through the mixed phase zone, consistent with prior studies investigating the aerosol invigoration hypothesis.

We thank the reviewer for your time and constructive comments. We have provided detailed responses point-by-point as below.

More generally, the single model used in this study is one among many state of the art models, and as with any parameterization must build in a set of claims about microphysical processes. The study demonstrates that the aerosol invigoration mechanism *can* be large *if* these claims are correct. I would like to see this latter point emphasized more fully. The authors should review of what may or may not be correct about the microphysical process claims embodied in the model.

The most relevant portions of the study that could use clarification are the additional aerosol process models described on lines 133-134. These are relatively new and probably are driving much of the aerosol effects in this study. What are the likely errors in process rates in these parameterizations? What are the likely errors in thermodynamic characterization? Are they as large as the run-to-run difference the authors observe?

The point is not to relitigate prior work in full, but to the extent the authors can clarify the precision of their forecasts the more value the study has in advancing our shared understanding of how to properly model mixed phase microphysics and how to accurately partition the relative roles of aerosol and thermodynamic influences on convection.

Those are all great questions. We have added a paragraph in Summary and Discussion section to address these questions, that is,

“For simulating aerosol-deep convective cloud interactions, there are a few key modeling requirements as summarized in Fan et al. (2016), such as (1) the prognostic supersaturation is needed for secondary aerosol activation, condensation, and evaporation calculations, (2) hydrometeor size distributions need to be prognostic to physically simulate the responses of microphysical processes to CCN changes, and (3) aerosols need to be prognostic, and fixed aerosol concentrations gave unrealistic cloud properties and qualitatively changed aerosol impacts on convective intensity (Fan et al., 2012). With thee SBM used in this study, all these criteria are satisfied. Furthermore, for (3), we are not only prognosing aerosol numbers but also aerosol composition and size distribution by coupling the SBM with the chemistry and aerosol components. With this coupling, the spatial heterogeneity of aerosols is considered. Also, aerosol

regeneration and wet removal processes can be more physically accounted for compared with the WRF-Chem with two-moment bulk schemes (Gao et al., 2016). The spatial heterogeneity of aerosols was shown to play an important role in simulating a torrential rain event observed over Seoul, Korea (Lee et al., 2018). However, bin schemes also have uncertainties in representing ice-related processes mainly due to our poor understanding of convective microphysics such as ice nucleation and riming processes. In particular, the conversions between different ice categories are also determined by threshold sizes or masses. However, those uncertainties are not expected to qualitatively change the warm-phase invigoration mechanism which occurs via enhanced condensation. In the companion paper Zhang et al. (2020), we carried out a small number of ensemble simulations for the anthropogenic aerosol effects for the same case and the results are consistent with this study, indicating this mechanism is robust with the initial thermodynamic and dynamic perturbations. More sophisticated uncertainty qualifications can be done in future with a larger number of ensembles when computer power becomes more advanced.”

Below, I also request clarification of the meteorological setting and terminology used by the authors.

****Major concerns****

The authors claim SBM_anth in Zhang et al. (2020, preprint) is the same as LandAero in this study, but Figs. 7 and 5, respectively, do not match. Likewise, the associated CFADs of reflectivity do not match, though this may be due to a different analysis box size.

Yes, the analysis area is different between the two studies. Here we are focusing on the convective cell in Houston. Besides, Zhang et al. (2020, preprint) represents the ensemble mean of the three ensemble runs with three different initialization time. However, due to the expensive computational cost, we didn't do ensemble runs for No_Land and No_LandAero. The analysis in this study showed the result of one member for fair comparison between four simulations.

Compared to the observations, the CFAD shows significantly enhanced probabilities of moderate reflectivity at high altitudes (line 241). It also significantly underestimates the prevalence of 40-50 dBZ values at and above the homogeneous freezing level. What is the origin of this overestimate? One interpretation of this is that the SBM is too aggressive in the production of smaller ice crystals that grow into snow at high altitudes, at the expense of graupel. Given the authors' interest in an aerosol invigoration pathway, it seems that matching the ice population in glaciated clouds is more important than matching higher reflectivity values at low altitudes, which can result from many intermediate microphysical steps.

We agree that underestimating reflectivity at high levels is probably due to the model biases in simulating snow (should not have much graupel above 10 km). We have added a sentence discussing it, i.e., “At the upper levels (> 10 km), the model underestimates the large reflectivities (> 35 dBZ), suggesting the model does not get enough snow” (Line 250-252).

As the authors note on line 250, rain rates > 2 mm/hr last about 25% longer in the simulation. This is in common among all simulations, and so would seem to indicate a general over-

production of precipitation duration by the SBM scheme overall. This would be consistent with an overactive snow/ice crystal microphysics scheme instead of a shorter-lived cell tied to faster-precipitating graupel. Why is the standard for “better” maximum reflectivity and areal coverage, but not duration of precipitation?

We did bring up the longer precipitation duration bias with the model. Since all simulations get longer duration than the observation, this model bias is not caused by the effects of aerosol and land surface. It could be related to many things such as problems in meteorological conditions, the interactions of microphysics and dynamics, microphysics parameterizations, the coupling of microphysics with other part of physics (PBL, radiative, ..).

Line 88: while Chen et al. (2011) also use the term “prevailing wind,” that term is misleading, especially here in a review of how land-atmosphere interactions *generally* work in Houston. The climatological meaning of prevailing wind (c.f. the AMS Glossary) is the expected value of the wind in a given location over a climatological period. For Houston in the summer, the prevailing wind is onshore, from the southeast (https://mesonet.agron.iastate.edu/sites/windrose.phtml?station=IAH&network=TX_ASOS), and that pattern persists for stations further inland. Chen’s study is of an anomalous day that may be representative of bad air quality days in Houston, but it is probably not typical of summer wind patterns or sea breeze interactions in Houston. It seems the authors are concerned in this paragraph with describing the general role of Houston’s urban environment in influencing the sea breeze, and so this paragraph should be revised to more accurately reflect Houston’s environment.

Thank you for the clarification. We have made changes to the sentences of the paragraph that inappropriately used “prevailing” winds. Now it should be accurate to describe the Houston environment. The revised sentences now read as “The strength and inland propagation of sea breeze circulation can be influenced by land/sea surface temperature contrast, land use/land cover, and the synoptic flow (e.g., Angevine et al., 2006; Bao et al., 2005; Chen et al., 2011). Chen et al. (2011) indicated that the existence of the Houston city favored stagnation because the inland penetration of the sea breeze counteracted the synoptic flow in a case study” (Line 86-90).

Line 112: Neither this study nor Zhang et al. (2020) give a synoptic or mesoscale meteorological overview of this case. Where was the trailing front? How did the meteorology, including the sea breeze, develop during the day in comparison to the expected behavior of the land and sea breeze diurnal cycle in Houston? Rosenfeld et al. (2014) is not listed in the references, and the ACPC website is not a suitable reference for long-term archival purposes.

We have added Fig. 1 and the following discussion to give an overview of the synoptic meteorological conditions of the case, i.e., “As shown in Fig. 1a and Fig. 1c, along a trailing front extended zonally across the southeastern United States, the isolated weak convective clouds formed in the late morning. Deep convective cells over Houston and Galveston bay areas developed in the afternoon with the increased solar heating and strengthened sea breeze circulation (Fig. 1b, d). The sea breeze circulation will be shown in a detail in the result section and it was among the typical summer day sea-breeze conditions (Kocen et al., 2013).” (Line 113-118)

Rosenfeld et al. (2014) has been added now. The ACPC website should be permanent. Also, there is no published paper to cite yet for this intercomparison.

Line 227: What is the “sea breeze wind intensity”? How was the sea breeze perturbation wind identified? This is especially important as the authors discuss Fig. 12 (lines 358 and following), where the sea breeze intensity is said to cause the transition to mixed phase cloud.

As we stated in Line 232-235: “the sea breeze wind intensity at a specific time is calculated by averaging the horizontal wind speeds below 1-km altitude along the black line UO in Fig. 4a.”

****Minor concerns****

Line 64: CG lightning enhancements can also be caused by the presence of tall towers (e.g., Kingfield et al., 10.1002/2017gl073449).

We add this to Line65-67 as: “Kingfield et al. (2017) also found that cloud-to-ground lightning enhancements can also be caused by the presence of tall towers”.

Line 157: not using met from domain 1? Not clear to me. Revisit after reading rest of paper. Maybe condense into a chart or truth table. I see the point that all domain 2 sims use same meteorology to control for the fact that different aerosols will affect the meteorology on domain two? But if the meteorology is processing the aerosols, how much is the spatiotemporal distribution of aerosols conditioned by the meteorology?

Since there are two Domain 1 simulations with different aerosol scenarios (anthropogenic emissions on and off), and the simulations accounted for the small-scale urban land and aerosol effects on meteorology already. If Domain 2 uses the meteorological fields from Domain 1, the initial/boundary meteorological conditions for the cases with high aerosol loadings (LandAero and No_Land) would be different from those with the low aerosol loadings (No_Aero and No_LandAero). To use the same meteorological fields to drive all simulations carried out over Domain 2 (including those with and without anthropogenic emissions), also to avoid using the forcing that already accounted for small-scale urban land and aerosol effects, we choose MERRA-2 for the initial and lateral boundary conditions for meteorological fields. We have revised the text in that paragraph to be clearer (Line 163-167). Either way (using Domain 1 or MERRA-2) has pros and cons and we chose the one fitting our purpose the best here.

Line 258: The reduction is not 45% from the larger LandAero value. Perhaps the authors used the wrong denominator? Reading approximate values from the graph to confirm the visual impression,

$$(6.75-4.8)/6.75 = 0.29$$

$$(6.75-4.8)/4.8 = 0.41$$

The claim is repeated on line 449.

Note we are talking about the enhancement of precipitation by urbanization, which should refer to the case without urbanization, i.e., the denominator should be No_LandAero. The calculation is $(6.8-4.7)/4.7=0.45$.

Line 327 and Fig. 10: Does this total water content include the vapor phase?
Water vapor is not included. This has been noted in the Figure caption now.

Line 331 and Fig. 10: The line marking the onset of the mixed phase cloud (first appearance of blue above the 0°C level) is marked too late in panel b, and perhaps a bit in panel d, making the duration of mixed phase growth artificially short.

The 0°C level is just an approximate mark there. If there is no continuous growing to deeper clouds after the water is a little above the 0°C level, it would still be shallow clouds.

Line 393-4: the phrasing here makes for a confusing physical explanation; “the condensate loading effect is small as a result of enhanced condensational heating” but the condensational heating is directly related to the mass condensed, which should result in more condensate loading.

Sorry the order of the phrases in the original sentence was wrong. It has been revised as “...which is mainly because of the increased thermal buoyancy as a result of enhanced condensational heating since the offset effect of condensate loading is small (Fig. 16a) (Fig. 16c, blue lines)”.

18 **Abstract**

19 Changes in land cover and aerosols resulting from urbanization may impact convective clouds
20 and precipitation. Here we investigate how Houston urbanization can modify sea-breeze induced
21 convective cloud and precipitation through urban land effect and anthropogenic aerosol effect.
22 The simulations are carried out with the Chemistry version of the Weather Research and
23 Forecasting model (WRF-Chem), which is coupled with the spectral-bin microphysics (SBM)
24 and the multilayer urban model with a building energy model (BEM-BEP). We find that
25 Houston urbanization (the joint effect of both urban land and anthropogenic aerosols) notably
26 enhances storm intensity (by $\sim 75\%$ in maximum vertical velocity) and precipitation intensity (up
27 to 45%), with the anthropogenic aerosol effect more significant than the urban land effect. Urban
28 land effect modifies convective evolution: speed up the transition from the warm cloud to mixed-
29 phase cloud thus initiating surface rain earlier but slowing down the convective cell dissipation,
30 all of which result from urban heating induced stronger sea breeze circulation. The
31 anthropogenic aerosol effect becomes evident after the cloud evolves into the mixed-phase
32 cloud, accelerating the development of storm from the mixed-phase cloud to deep cloud by ~ 40
33 min. Through aerosol-cloud interaction (ACI), aerosols boost convective intensity and
34 precipitation mainly by activating numerous ultrafine particles at the mixed-phase and deep
35 cloud stages. This work shows the importance of considering both urban land and anthropogenic
36 aerosol effects for understanding urbanization effects on convective clouds and precipitation.

37

38 **1 Introduction**

39 Urbanization has been a significant change in the earth's environment since
40 industrialization and is expected to further expand during the coming decades (Agli et al., 2004).
41 Many modeling and observational studies have shown that urbanization can impact weather and
42 climate (e.g., Shepherd et al., 2010; Ashley et al., 2012).

43 Urbanization could impact storm properties through two major pathways. The first major
44 pathway is through the changes in land cover types. For urban land, the most typical and
45 extensively studied effect is the increase of surface temperature compared to the surrounding
46 rural area, known as the urban heat island (UHI) effect (e.g., Bornstein and Lin, 2000; Shepherd,
47 2005; Hubbart et al., 2014). Convective storms may be initiated at the UHI convergence zone,
48 created through a combination of increased temperature and mechanical turbulence resulting
49 from complex urban surface geometry and roughness (Bornstein and Lin, 2000; Shepherd, 2005,
50 Hubbart et al., 2014). Urban landscapes impact sensible and latent heat flux, soil moisture, etc.,
51 affecting thunderstorm initiation (Haberlie et al., 2015) and changing the location and amount of
52 precipitation compared to the pre-urbanization period (Shepherd et al. 2002; Niyogi et al. 2011).

53 The second major pathway of the urbanization impacts is through pollutant aerosols
54 associated with industrial and population growth in cities. Previous studies have shown that
55 urban aerosols invigorate precipitation in urban downwind regions through aerosol-cloud
56 interaction (ACI; Van den Heever and Cotton 2007; Carrió et al. 2010; Fan et al., 2018). A
57 recent study showed aerosol spatial variability in the Seoul area played an important role in a
58 torrential rain event (Lee et al., 2018). Many compelling pieces of evidence have emerged
59 showing the joint influences of aerosols and urban land on clouds and precipitation, especially in
60 China where both effects are strong and complex (Li et al., 2019 and references therein).

61 The majority of the past studies focused on one of the abovementioned pathways.
62 Recently, a few studies examined the combined effects of both pathways on lightning and
63 precipitation. A new observational study (Kar and Liou, 2019) indicated that both land and
64 aerosol effects should be considered to explain the cloud-to-ground lightning enhancements over
65 the urban areas. Kingfield et al (2017) also found that cloud-to-ground lightning enhancements
66 can also be caused by the presence of tall towers. A modeling study showed urban land-cover
67 changes increased precipitation over the upstream region but decreased precipitation over the
68 downstream region, while aerosols had the opposite effect through serving as cloud condensation
69 nuclei (Zhong et al. 2015). A long-period (5 years) modeling study in the Yangtze River Delta
70 (YRD) region confirmed the opposite effects on precipitation but the aerosol radiative effect was
71 the dominant reason for the reduced convective intensity and precipitation (Zhong et al. 2017).
72 Sarangi et al. (2018) also showed the enhanced precipitation over the urban core by the urban
73 land effect and at the downwind region by the aerosol effect, consistent with Zhong et al (2015).
74 Schmid and Niyogi (2017) showed that urban precipitation rate enhancement is due to a
75 combination of land heterogeneity induced dynamical lifting effect and aerosol indirect effects.
76 For coastal cities, studies indicated that anthropogenic aerosol effect on precipitation may be
77 more important than the urban land effect (Liu and Niyogi et al., 2019, Ganeshan et al., 2013;
78 Ochoa et al., 2015).

79 Houston is the largest city in the southern United States. It is one of the most polluted
80 areas in the nation based on the most recent “State of the Air” report by the American Lung
81 Association (<http://www.stateoftheair.org/about/>). The Houston urbanization causes both land
82 cover change and anthropogenic emission enhancement which has been a fertile region for air
83 quality studies (i.e., high ozone) (e.g., Chen et al., 2011, Fast et al., 2006). The sea breeze

84 circulation over the region plays a key role not only in convection and precipitation but also in
85 local air quality (Fan et al., 2007; Banta et al. 2005, Caicedo et al., 2019). The strength and
86 inland propagation of sea breeze circulation can be influenced by land/sea surface temperature
87 contrast, land use/land cover, and the synoptic flow (e.g., Angevine et al., 2006; Bao et al., 2005;
88 Chen et al., 2011). Chen et al. (2011) indicated that the existence of the Houston city favored
89 stagnation because the inland penetration of the sea breeze counteracted the synoptic flow in a
90 case study. On the other hand, Ryu et al. (2016) showed the urban heating of the Baltimore–
91 Washington metropolitan area strengthened the bay breeze thus promoted intense convection and
92 heavy rainfall. In Shanghai, however, the sea-land breeze has exhibited a weakening trend over
93 the past 21 years, which was hypothesized to result from the joint influences of aerosol, UHI,
94 and greenhouse effects (Shen et al., 2019). While sorting out the various factors is a daunting
95 task especially by means of observation analysis, it is essential to enhance our understanding of
96 both overall effects by human activity and individual ones for which much fewer have been
97 done.

98 In this study, we aim at understanding how the changes in Houston land cover and
99 anthropogenic aerosols as a result of urbanization modify the sea-breeze induced convective
100 storm and precipitation jointly and respectively. To answer the science question, we employ the
101 Chemistry version of Weather Research and Forecast (WRF) model coupled with the spectral-
102 bin microphysics (WRF-Chem-SBM) scheme, a model we previously developed and applied to
103 warm stratocumulus clouds (Gao et al., 2016), to simulate a deep convective storm case that
104 occurred over the Houston region and produced heavy precipitation. Sensitivity tests are
105 performed to look into the joint and respective effects of urban land and anthropogenic aerosol
106 on storm development and precipitation.

107 2 Case Description, Model, and Analysis Method

108 2.1 Case description

109 The deep convective cloud event we simulate in this study occurred on 19-20 June 2013
110 near Houston, Texas. The case was also selected for the ACPC Model Intercomparison Project
111 (Rosenfeld et al., 2014; www.acpcinitiative.org). In another companion study (Zhang et al., 2020),
112 this case was simulated to study the impact of cloud microphysics parameterizations on ACI. As
113 shown in Fig. 1a and Fig. 1c, along a trailing front extended zonally across the southeastern United
114 States, the isolated weak convective clouds formed in the late morning. Deep convective cells over
115 Houston and Galveston bay areas developed in the afternoon with the increased solar heating and
116 strengthened sea breeze circulation (Fig. 1b, d). The sea breeze circulation will be shown in a detail
117 in the result section and it was among the typical summer day sea-breeze conditions (Kocen et al.,
118 2013). A strong convective cell observed in the Houston city that we focused on was initiated at
119 2145 UTC (local time 16:45) and developed to its peak precipitation at 2217 UTC.

120 The simulated case was evaluated extensively in aerosol and cloud properties in the
121 companion paper mentioned above. The observations of radar reflectivity and precipitation are
122 also used in the evaluation. The radar reflectivity is obtained from the Next-Generation Weather
123 Radar (NEXRAD) network for the KHGX site at [https://www.ncdc.noaa.gov/data-access/radar-](https://www.ncdc.noaa.gov/data-access/radar-data/nexrad-products)
124 [data/nexrad-products](https://www.ncdc.noaa.gov/data-access/radar-data/nexrad-products), with a temporal frequency of every ~5 minutes and a spatial resolution of 1
125 km. The high-temporal and spatial precipitation data retrieved based on radar reflectivity is used
126 for simulation evaluation.

127 **2.2 Model description and experiment design**

128 The WRF-Chem-SBM model used in this study is based on Gao et al. (2016), with updates
129 in both WRF-Chem (Grell et al., 2005; Skamarock et al., 2008) and the SBM (Khain et al., 2004;
130 Fan et al., 2012). The SBM version coupled with WRF-Chem is a fast version with only four sets
131 of 33 bins for representing size distribution of CCN, drop, ice/snow, and graupel/hail, respectively.
132 It is currently coupled with the four-sector version of the Model for Simulating Aerosol
133 Interactions and Chemistry (MOSAIC) (Fast et al., 2006; Zaveri et al., 2008). Compared with the
134 original WRF-Chem model which uses two-moment bulk microphysics schemes, besides the
135 advancements in cloud microphysical process calculations in SBM, the aerosol-cloud interaction
136 processes which impact both cloud and aerosol properties are physically improved. These
137 processes are aerosol activation, resuspension, and in-cloud wet-removal (Gao et al., 2016).
138 Theoretically, both aerosol and cloud processes can be more realistically simulated compared with
139 the original WRF-Chem, particularly under the conditions of complicated aerosol compositions
140 and aerosol spatial heterogeneity. This would result in improved simulations of both ACI and
141 aerosol-radiation interactions (ARI). Following on Gao et al. (2016) where the model was applied
142 to a warm stratocumulus cloud case, we apply the model to the deep convective storm case in this
143 study.

144 The dynamic core of WRF-Chem-SBM is the Advanced Research WRF model that is fully
145 compressible and non-hydrostatic with a terrain-following hydrostatic pressure vertical coordinate
146 (Skamarock et al., 2008). The grid staggering is the Arakawa C-grid. The model uses the Runge-
147 Kutta 3rd order time integration schemes, and the 3rd and 5th order advection schemes are selected
148 for the vertical and horizontal directions, respectively. The positive-definite option is employed
149 for the advection of moist and scalar variables.

150 The model domains are shown in Fig. 2. Two nested domains have horizontal grid
151 spacings of 2 and 0.5 km and horizontal grid points of 450×350 and 500×400 , respectively,
152 with 51 vertical levels up to 50 hPa. Domain 1 simulations are run with WRF-Chem using
153 Morrison double-moment scheme (Morrison et al., 2005) to produce realistic aerosol fields for
154 Domain 2 simulations. Two simulations were run over Domain 1 with anthropogenic emissions
155 turned on and off, respectively, starting from 0000 UTC 14 Jun and ending at 1200 UTC 20 June
156 with about 5 days for chemical spin up. The chemical lateral boundary and initial conditions for
157 Domain 1 simulations were from a quasi-global WRF-Chem simulation at 1-degree grid spacing,
158 and meteorological lateral boundary and initial conditions were created from MERRA-2 (Gelaro
159 et al., 2017). Domain 2 simulations use WRF-Chem-SBM, driven with the initial and lateral
160 boundary aerosol and chemical fields from Domain 1 outputs, but the initial and lateral boundary
161 conditions for meteorological fields are from MERRA-2. The reason for not using the
162 meteorological fields from Domain 1 simulations is that the meteorological fields are different
163 between the two Domain 1 simulations with and without anthropogenic emissions. To use the
164 same meteorological fields to drive all simulations carried out over Domain 2 (including those
165 with and without anthropogenic emissions), also to avoid using the forcing that already
166 accounted for small-scale urban land and aerosol effects, we choose MERRA-2 for the initial and
167 lateral boundary conditions for meteorological fields. Domain 2 simulations are initiated at 0600
168 UTC 19 June (~ 5 days later from the initial time of Domain 1 simulations) and run for 30 hours.
169 The analysis period is ~ 12 hours after the initiation time of Domain 2. The modeled dynamic
170 time step was 6 s for Domain 1 simulations and 3 s for Domain 2 simulations.

171 For all simulations over both domains, the anthropogenic emission was from NEI-2011
172 emissions. The biogenic emission came from the Model of Emissions of Gases and Aerosols

173 from Nature (MEGAN) product (Guenther et al., 2006). The biomass burning emission was from
174 the Fire Inventory from NCAR (FINN) model (Wiedinmyer et al., 2011).

175 The baseline simulation over Domain 2 uses the initial and boundary chemical and
176 aerosol conditions from the Domain 1 simulation with anthropogenic emissions turned on. This
177 simulation uses all available emissions as abovementioned including anthropogenic emissions. It
178 is the same simulation as “SBM_anth” in Zhang et al. (2020). Here we renamed it “LandAero”,
179 in which the effects of urban land and anthropogenic aerosols are considered (Fig. 3a, c). Based
180 on LandAero, sensitivity tests are conducted to investigate the combined and individual effects
181 of urban land and anthropogenic aerosols. No_Aero is the simulation based on LandAero, except
182 that anthropogenic emissions are turned off and the initial and boundary chemical and aerosol
183 conditions are from the Domain 1 simulation without anthropogenic aerosols considered (Fig.
184 3b). No_Land is also based on LandAero, except the Houston urban land is replaced by the
185 surrounding cropland and pasture (Fig. 3d). The aerosols used in No_Land include the
186 anthropogenic sources (Fig. 3a), which is analogous to the scenario of downwind a big city (i.e.,
187 rural area with pollution particles transported from the city). We also run a simulation with both
188 the urban land cover replaced by the surrounding cropland and the anthropogenic aerosols
189 excluded (Fig. 3b, d), which is referred to as “No_LandAero”. That is, both effects of urban land
190 and anthropogenic aerosol are not considered in this simulation. By comparing LandAero with
191 No_LandAero, the joint effect of urban land and anthropogenic aerosols can be obtained. The
192 individual urban land and anthropogenic aerosol effect can be obtained by comparing LandAero
193 with No_Land and LandAero with No_Aero, respectively.

194 The simulated aerosol and CCN properties are evaluated with observations in Zhang et al.
195 (2020), which shows that the model captures aerosol mass and CCN number concentrations

196 reasonably well. Aerosol number concentration is not evaluated because the measurements are
197 not available at the Texas Commission for Environmental Quality (TCEQ) sites. A snapshot of
198 simulated aerosol number concentrations in LandAero and No_Aero at the time of 6 hours before
199 the initiation of the Houston cell is shown in Fig. 3a-b. Houston anthropogenic emissions
200 produce about 10 times more aerosol concentrations over the Houston area than those in the Gulf
201 of Mexico and ~ 5 times than those in the rural area shown in Fig. 3a. The background aerosol
202 concentrations are relatively low (around 250 cm^{-3}) in this region. Aerosols over the Houston
203 urban area are mainly contributed by organic aerosols, which are highly related to the oil refinery
204 industry and ship channel emissions. The aerosol compositions are mainly sulfate in the rural
205 area and sea salt over the Gulf of Mexico in our simulations. Therefore, aerosol properties are
206 extremely heterogenous in this region. Fig. 4 shows the mean aerosol size distributions from the
207 three **areas** as marked up in Fig. 3a in LandAero. In the Houston area, the majority of aerosols
208 (75%) have a size (diameter) smaller than 100 nm, and 51% of the aerosols are ultrafine aerosol
209 particles (smaller than 60 nm). Those small particles are substantially reduced in the rural area
210 and the Gulf of Mexico (Fig. 4).

211 To see how the land cover type change affects temperature, Fig. 5 shows the differences
212 in 2-m temperature and surface sensible heat fluxes between LandAero and No_Land at 1600
213 UTC when the sea breeze begins to show differences. The urban land increases near-surface
214 temperature over Houston and its downwind area by about 1-2 °C (Fig. 5a), corresponding to the
215 increase of surface sensible heat fluxes (Fig. 5b). More information about the temporal evolution
216 and vertical distribution of the urban heating will be discussed in the result section.

217 2.3 Analysis Method

218 To quantify the convective cell properties occurring over Houston, we employ the Multi-
219 Cell Identification and Tracking (MCIT) Algorithm from Hu et al. (2019a) to track the
220 convective storms. The MCIT is a watershed-based algorithm and shows better tracking
221 capabilities compared with traditional centroid based tracking algorithms. The MCIT identifies
222 cells by local maxima of vertically integrated liquid (VIL) based on watershed principles and
223 performs tracking of multiple cells based on maximum common VIL between the consecutive
224 scans. In this way, convective storm life cycle from initiation to dissipation can be better tracked
225 than the traditional methods as detailed in Hu et al. (2019a). **VIL was shown to be an effective**
226 **indicator of strong precipitation cells (Greene and Clark, 1972, Hu et al., 2019a).**

227 To apply the algorithm to both model simulation and NEXRAD observations
228 consistently in this study, we calculated liquid water path (LWP), a variable of model output
229 accounting for the column integrated liquid to replace VIL in MCIT for model simulation. We
230 track local maxima of LWP by identifying the two cells in consecutive radar scans that have
231 maximum common LWP. A cell is identified and tracked when the local maxima LWP exceeds
232 50 g m^{-2} . This value is selected because it allows us to start recognizing the deep convective cell
233 by filtering a lot of shallow clouds surrounded it. The storm area of the tracked cell is defined as
234 the grid area with $\text{LWP} > 50 \text{ g m}^{-2}$.

235 To examine sea breeze circulation over the Houston region, the sea breeze wind intensity
236 at a specific time is calculated by averaging the horizontal wind speeds below 1-km altitude
237 along the black line UO in Fig. 5a. The cross section of the winds along this line is also analyzed
238 in the result section.

239 3 Results

240 3.1 Radar reflectivity, precipitation, and convective intensity

241 We first discuss the evaluation of the baseline simulation LandAero. The simulation is
242 comprehensively evaluated in Zhang et al. (2020). Here the comparisons with observed radar
243 reflectivity and precipitation are included. The composite radar reflectivity at the time of the
244 peak reflectivity of the storm in Houston shows that LandAero captures the convective cell in
245 Houston, with the maximal radar reflectivity of 58 dBZ, very close to the observed 57 dBZ (Fig.
246 6a, b). The modeled convective cell in LandAero has a larger size compared with the radar
247 observations. The contoured frequency by altitude diagram (CFAD) over the major storm period
248 (1800 UTC 19 Jun to 0000 UTC 20 Jun) shows that the model overestimates the frequencies of
249 moderate reflectivity (i.e., 15-35 dBZ) over the entire vertical profile (Fig. 7a-b), but captures the
250 occurrence frequencies of high reflectivity (larger than 45 dBZ) reasonably well. **At the upper**
251 **levels (> 10 km), the model underestimates the large reflectivities (> 35 dBZ), suggesting the**
252 **model does not get enough snow.** The magnitude of the surface rain rate averaged over the study
253 area defined by the red box in Fig. 6 from LandAero agrees with the retrieved value from the
254 NEXRAD reflectivity, with a peak time about 40 min earlier than the observation (Fig. 8a). The
255 probability density function (PDF) of rain rates shows that LandAero reproduces the occurrence
256 frequencies of low and mediate rain rates well (left two columns in Fig. 8b) and overestimates
257 the occurrence frequencies of high rain rates (> 10 mm h⁻¹; right two columns in Fig. 8b). The
258 accumulated precipitation over the time period shown in Fig. 8a is about 7.2 mm from LandAero
259 and 5.5 mm from observations, with a model overestimated of ~ 30% because of the
260 overestimation of occurrences of high rain rates and a longer precipitation period.

261 Without Houston urbanization (i.e., both effects of urban land and anthropogenic aerosol
262 are removed), the Houston convective cell is a lot smaller in the area and has reflectivity values
263 of ~ 7 dBZ lower in general compared with LandAero and the NEXRAD observation (Fig. 6c vs.
264 5a-b). There is almost no radar reflectivity larger than 50 dBZ in No_LandAero (Fig. 7c), in
265 contrast with the significant occurrences of reflectivity larger than 50 dBZ in LandAero and the
266 NEXRAD observation. Those differences are more clearly shown in Fig. 7f. The peak surface
267 rain rate in No_LandAero is reduced by $\sim 45\%$ compared with LandAero and observations (Fig.
268 8a; black vs. red line), with the occurrences of large rain rates ($> 15 \text{ mm h}^{-1}$) reduced by nearly
269 an order of magnitude (Fig. 8b). In terms of updraft intensity, the CFAD plots in Fig. 9a-b show
270 that there is extremely low or no occurrence for updraft velocity larger than 15 m s^{-1} in
271 No_LandAero, while the occurrences of 30 m s^{-1} still exist in LandAero. There are fewer
272 occurrences of weak updraft velocities and more occurrences of relatively strong updraft
273 velocities over the vertical profile (Fig. 9e). These results indicate the urbanization (i.e., the joint
274 urban land and aerosol effects) drastically enhances the convective intensity and precipitation.

275 Now let's look at the individual effect from the Houston urban land and anthropogenic
276 aerosols. Fig. 6 shows that the urban land effect enlarges the storm area (Fig. 6d vs. 5b) but the
277 aerosol effect is more significant (Fig. 6e vs. 5b). The CFAD of radar reflectivity in Fig. 7 also
278 shows that changes in the PDF by the urban land effect is notably smaller than the anthropogenic
279 aerosol effect. For the occurrence frequencies of high reflectivity larger than 48 dBZ, the change
280 is mainly from the anthropogenic aerosol effect (Fig. 7f-h).

281 For precipitation, we do not see an important effect of urban land on the magnitudes of
282 precipitation rate and the PDF of rain rate (Fig. 8a-b; No_Land vs LandAero). The accumulated
283 rain is about 6.9 mm, which is also not much different from 7.2 mm in LandAero. On the

284 contrary, the anthropogenic aerosol effect increases the peak rate by $\sim 30\%$. The frequency of
285 large rain rates ($> 15 \text{ mm h}^{-1}$) is increased by about 5 times (Fig. 8b; No_Aero vs LandAero).
286 The joint effect of both urban land and aerosol increases the accumulated rain by $\sim 26\%$, the
287 peak rain rates by 45%, and the frequency of large rain rates by an order of magnitudes (from
288 No_LandAero to LandAero), suggesting the interactions between the two factors amplify the
289 effect on precipitation, particularly on the large rain rates. Although the Houston urban land
290 alone does not much affect the magnitude of precipitation, the initial time of the rain is advanced
291 by ~ 30 min from No_Land to LandAero (Fig. 8a), indicating that the urban land effect speeds
292 up the rain formation. Aerosol effect delays the initial and peaks rain by ~ 10 min (from
293 No_Aero to LandAero). This will be further discussed in Section 3.2 on convective evolution.

294 On convective intensity, the large increases in occurrence frequencies of the updraft
295 speed greater than 10 m s^{-1} in the upper-levels by the joint effect are mainly contributed by the
296 anthropogenic aerosol effect (Fig. 9e, g). Below 6 km, both the urban land and aerosol effects
297 play evident roles in increasing the occurrences of relatively large updraft speeds (Fig. 9e-g). The
298 larger anthropogenic aerosol effect is also clearly seen from the occurrences of maximal vertical
299 velocity: $\sim 30 \text{ m s}^{-1}$ in LandAero, while only $\sim 19 \text{ m s}^{-1}$ in No_Aero when the anthropogenic
300 aerosol effect is removed, whereas the value is 27 m s^{-1} in No_Land when the urban land effect
301 is turned off (Fig. 9a, c-d). The large effect of anthropogenic aerosols on convective intensity
302 supports the significant aerosol effects on large precipitation rates as shown in Fig. 8. With both
303 effects removed (No_LandAero), there is almost a 100% reduction for the vertical velocity
304 greater than $\sim 15 \text{ m s}^{-1}$, showing a quite strong enhancement of convective intensity as a result of
305 urbanization, mainly through the anthropogenic aerosol effects.

306 3.2 Convective evolution

307 The urban land effect initiates surface rain about 30 minutes earlier as discussed above,
308 suggesting that convective cloud development is affected when the urban land effect is
309 considered. We examine the convective evolution for the cell over Houston using the cell-
310 tracking method described in Section 2. The time evolution of the tracked cell properties is
311 shown in Fig. 10a-b. Clearly, the urban land effect enhances the reflectivity and area for the
312 tracked cell over the lifetime (from the black dashed line to black solid line), and it also
313 accelerates the development to the peak reflectivity but slows down the dissipation after the peak
314 radar reflectivity is reached (Fig. 10a-b). The anthropogenic aerosols also enhance the convective
315 cell reflectivity and area throughout the cell lifecycle (from the black dotted line to black solid
316 line), with a much larger effect compared with the urban land effect. The anthropogenic aerosol
317 effect does not affect the timing of peak reflectivity (dotted vs. solid black in Fig. 10a-b). The
318 overall reflectivity and cell area properties are shown in Fig. 10c-d, which presents a consistent
319 story as Fig. 10a-b. The baseline simulation LandAero tends to overestimate the frequency of big
320 cell sizes (200-300 km²) and underpredict the frequency of small cell size (Fig. 10d). Since
321 LandAero predicts a similar rain intensity and rain rate PDF as observations as discussed above,
322 this means that a larger storm cell than observations is needed to predict a similar precipitation
323 intensity as observations. For this reason, No_LandAero which predicts much smaller cell size
324 agrees better with the observations compared with the other simulations purely based on cell size
325 (Fig. 10b, d). However, as discussed above, other metrics such as peak precipitation rate and
326 PDF do not support it. It also should be noted that radar reflectivity in model calculation has a
327 large uncertainty and the model's overestimation can be partly the result of crude Rayleigh
328 scattering assumptions applied to the model fields. The model overestimation of radar

329 reflectivity has been commonly found in previous studies at cloud-resolving scales (Varble et al.
330 2011; 2014, Fan et al., 2015; 2017).

331 Since the small and numerous shallow cumulus clouds are difficult to be tracked with cell
332 tracking algorithm and they are excluded from the above tracking, to examine how the
333 convective storm evolves from the initial shallow cumulus period, we chose the red box shown
334 in Fig. 6 which contains the Houston cell as the study area. Since the convective storm does not
335 spatially move much with time in this study, this is a valid way to look at the temporal evolution.
336 Fig. 11 shows the temporal evolution of the maximal total water content (TWC; color contours)
337 at each level and the maximal vertical velocity in the study area (black line). The convective
338 storm has three distinct periods: warm cloud, mixed-phase cloud, and deep cloud. The mixed-
339 phase and deep cloud are defined with a cloud top temperature (cloud top is defined with $TWC >$
340 0.01 g kg^{-1} at the topmost level) between 0 and $-40 \text{ }^\circ\text{C}$ and below $-40 \text{ }^\circ\text{C}$, respectively. The purple
341 and black dashed lines in Fig. 11 mark the initiation of mixed-phase and deep clouds,
342 respectively.

343 As we can see, there is a relatively long warm cloud period for this case (Fig. 11a). With
344 both urban land and anthropogenic aerosol effects removed, the cloud development from the
345 warm cloud to mixed-phase cloud is delayed by $\sim 30 \text{ min}$ (Fig. 11d vs. 10a), so is the
346 development from the mixed-phase cloud to deep cloud. Compared Fig. 11a with 10b and 10c,
347 we see that it is mainly the urban land effect that enhances the development of warm cloud to the
348 mixed-phase cloud by nearly 30 min, while aerosol effect does not affect it (Fig. 11a vs. 10c).
349 However, it is mainly the aerosol effect that accelerates the development from the mixed-phase
350 cloud to deep cloud by about 35 min. In the case of the urban land effect removed (i.e.,
351 No_Land; Fig. 11b), the anthropogenic aerosol effect makes the duration of the mixed-phase

352 cloud very short - about 35 mins shorter relative to LandAero in which both effects are
353 considered and 75 min shorter relative to No_Aero in which aerosol effect is removed but the
354 urban land effect is considered. This is due to the aerosol invigoration effect in the mixed-phase
355 cloud stage which will be elaborated later.

356 Accompanying with the faster development of warm cloud to mixed-phase cloud by the
357 urban land effect is the stronger updraft speeds in the warm cloud stage (shown from the
358 maximal updraft velocity in Fig. 11 and the mean of the top 25th percentile updraft speeds in Fig.
359 12a). Similarly, for the simulations with the aerosol effect considered (i.e., LandAero and
360 No_Land), the convection is stronger in the mixed-phase cloud stage (Fig. 12b), which
361 accelerates the development into the deep cloud.

362 Now the questions are: (1) how does the urban land effect enhance convective intensity at
363 the warm cloud stage and speeds up the cloud development from the warm to mixed-phase
364 cloud, but slows down the storm dissipation? (2) how do the anthropogenic aerosols increase
365 convective intensity at the mixed-phase cloud stage and accelerate the development of mixed-
366 phase into the deep cloud?

367 For Question (1), Fig. 11a and Fig. 13a show that the development of the warm cloud to
368 mixed-phase cloud occurs when the sea breeze circulation reaches its strongest. Also, the
369 development corresponds to the fastest and largest increase of sea breeze intensity by the urban
370 land effect (Fig. 13a). Anthropogenic aerosol does not seem to affect sea breeze circulation. The
371 enhanced sea breeze circulation in the simulations with the urban land effect considered (i.e.,
372 LandAero and No_Aero) compared with No_Land and No_LandAero corresponds to the
373 increases of surface sensible heat flux and air temperature at low levels (Fig. 13b, d), which is
374 so-called “urban heat island”. The urban heating effect on temperature is significant up to 0.8-km

375 altitude at its strongest time that also corresponds to the strongest sea breeze time (Fig. 14b). The
376 urban heating enhances convergence in Houston and at the same time increases the temperature
377 differences between Houston and the Gulf of Mexico, both of which would contribute to a
378 stronger sea breeze circulation. Past studies showed that urban roughness could also enhance
379 low-level convergence (e.g., Niyogi et al., 2006). However, the majority of the studies indicated
380 that increased surface sensible heat flux is the main reason for the enhanced convergence (Liu
381 and Niyogi, 2019; Shimadera et al., 2015).

382 The stronger sea breeze circulation transports more water vapor to Houston (Fig. 15). At
383 the time 1930 UTC when the sea breeze is strongest and the enhancement is the largest (Fig.
384 13a), as well as the temperature contrast between the Houston urban area and the Gulf of Mexico
385 is the largest (Fig. 14b), the low-level moisture in the urban area is clearly higher in LandAero
386 compared with No_Land (Fig. 15b, color contour), which would help enhance convection. As a
387 result, the updraft speed of the Houston convective cell is much larger in LandAero compared
388 with No_Land (Fig. 15b, contoured line). The stronger convection continues even when sea
389 breeze dissipates (Fig. 15c) because the heating effect in the urban area extends to the nighttime
390 until 2300 UTC (local time 18:00; Fig. 13c-d and 13c). This explains the slower dissipation of
391 the tracked Houston cell by the urban land effect as shown in Fig. 10a-b. In a word, the urban
392 heating along with the strengthened sea breeze circulation induced by the urban heating enhances
393 convection at the warm cloud stage and speeds up the development from the warm to mixed-
394 phase cloud, and the temporally-extended urban heating effect leads to a slower dissipation of
395 the convective cell.

396 For Question (2), which is about how anthropogenic aerosols increase convective intensity
397 at the mixed-phase cloud stage and accelerate the development of mixed-phase into deep cloud,

398 Fig. 12b shows the anthropogenic aerosol effect on updraft speeds becomes notable at the mixed-
399 phase cloud stage, the effect is doubled compared with the urban land effect at the mixed-phase
400 regime (6-9 km altitudes). This corresponds to the increased net buoyancy (Fig. 16a, black lines)
401 at those levels from No_Aero to LandAero, which is mainly because of the increased thermal
402 buoyancy as a result of enhanced condensational heating since the offset effect of condensate
403 loading is small (Fig. 16a) (Fig. 16c, blue lines). The condensational heating increase is most
404 significant at 3-5 km and 6-9 km altitudes, corresponding to notably increased secondary droplet
405 nucleation of small aerosol particles which are not able to be activated at the cloud base (Fig. 16e).
406 In this case, aerosols with a diameter smaller than 80 nm but larger than 39 nm (the smallest size
407 in the 4-sectional MOSAIC), which account for about two-thirds of the total simulated aerosols,
408 are not activated around cloud bases. All of them can be activated in the strong updrafts (Fan et
409 al., 2018). This strong secondary nucleation leads to increased droplet number and mass by the
410 anthropogenic aerosol effects (from No_Aero to LandAero; Fig. 17a, c). To recap, the
411 anthropogenic aerosols enhance updraft velocity at the mixed-phase cloud stage mainly through
412 enhanced condensation heating (i.e., “warm-phase invigoration”), as a result of nucleating small
413 aerosol particles below 60 nm which are transported to higher-levels. Enhanced secondary
414 nucleation promotes condensation because of larger integrated droplet surface area associated with
415 a higher number of small droplets (Fan et al., 2007, 2013, 2018; Khain et al., 2012; Sheffield et
416 al., 2015; Lebo, 2018). Thus, the stronger convection speeds up the development of mixed-phase
417 into deep cloud from No_Aero to LandAero. For the same reason, a similar acceleration is seen in
418 No_Land compared with No_Aero and No_LandAero because the anthropogenic aerosol effect is
419 considered in No_Land.

420 Grabowski and Morrison (2020) interpreted this warm-phase convective invigoration at
421 low-levels by aerosols in a different way. They argued supersaturation (S) in updrafts rapidly,
422 within a few seconds, approaches the quasi-equilibrium supersaturation (S_{eq}). With this quasi-
423 steady assumption ($S \approx S_{eq}$), the condensation rate and buoyancy only depend on updraft velocity,
424 not droplet number and size. Thus they concluded that the lower quasi-equilibrium supersaturation
425 in the polluted case than the pristine case is the reason for enhanced buoyancy and updraft velocity,
426 not the enhanced condensation. The problem is that the quasi-steady approximation is invalidated
427 for updrafts where droplet concentrations are low or droplets are growing and their sizes are
428 changing based on the explicit solution of supersaturation (Korolev and Mazin 2003). The explicit
429 theoretical solution of supersaturation showed that condensation depends on droplet number and
430 size besides updraft speeds (Pinsky et al. 2013). Here in this study the quasi-equilibrium
431 supersaturation in the updrafts is generally 2-3 times higher than the true supersaturation, and the
432 phase relaxation time is generally above 10 s above 3-km altitude in the case without
433 anthropogenic aerosols and about 60 s when droplet number is of 10 cm^{-3} which occurs frequently
434 in the convective cores where autoconversion and rain accretion are strong.

435 At the deep cloud stage, the anthropogenic aerosol effect becomes more significant
436 compared with that in the mixed-phase cloud stage (Fig. 12c vs. 11b), particularly at the low-
437 levels. We can still see the enhancement of convective intensity by the urban land effect
438 although the sea breeze difference is relatively smaller at this stage as explained above. The
439 larger aerosol effect at the deep cloud stage compared with the mixed-phase cloud stage is
440 because the secondary droplet nucleation above the cloud base becomes larger (Fig. 16f). More
441 aerosols get activated is the result of higher supersaturation since (a) updrafts are stronger than
442 the mixed-phase cloud stage and (b) more rain forms and removes droplet surface area for

443 condensation (Fan et. al., 2018). As a result, the latent heating from condensation and then the
444 thermal buoyancy is increased in a larger magnitude (Fig. 16b, d), thus a larger aerosol impact is
445 seen at the deep cloud stage. The invigorated deep convection has up to 2 times more ice particle
446 number concentration and 30% larger ice particle mass mixing ratio (Fig. 17b, d), with the
447 maximal cloud top height increased by ~ 1 km. The enhanced ice number and mass
448 concentrations also partially result from the freezing of more droplets that are being transported
449 from low levels (Rosenfeld et al., 2008), as suggested by the increased latent heating associated
450 with the ice phase processes (Fig. 16d). But this is not the major mechanism for the large aerosol
451 effects on convective intensity in this case.

452 Note that both ACI and ARI are considered in the aerosol effects we discussed above,
453 and the results above suggest ACI plays a key role in invigorating convection. To confirm that,
454 we conducted two additional sensitivity tests by turning off ARI based on LandAero and
455 No_Aero, referred to as LandAero_ACI and No_Aero_ACI, respectively. The differences in
456 precipitation and convective intensity between LandAero_ACI and No_Aero_ACI (i.e., ACI
457 effect) are only slightly smaller than the differences between LandAero and No_Aero (i.e., the
458 total aerosol effect). This confirms that ACI is the major factor responsible for the convective
459 invigoration and precipitation enhancement by aerosols.

460 **4 Conclusions and discussion**

461 We have investigated the Houston urbanization effects on convective evolution,
462 convective intensity, and precipitation of a sea-breeze induced convective storm using the WRF-
463 Chem coupled with SBM and the BEM-BEP urban canopy model. The baseline simulation with
464 the urbanization effects considered was extensively evaluated in Zhang et al. (2020) in aerosol
465 and CCN, surface meteorological measurements, reflectivity and precipitation, and in this study

466 in Houston cell reflectivity and precipitation. The simulated convective storm in Houston was
467 shown to be consistent with the observed maximal radar reflectivity and peak precipitation
468 intensity and PDF, despite the peak precipitation time was about ~40 min earlier. The
469 accumulated rain is overestimated by the baseline simulation due to the longer rain period.

470 Model sensitivity tests were carried out to examine the joint and respective effects of
471 urban land and anthropogenic aerosols as a result of Houston urbanization on convective
472 evolution and precipitation. We find that the joint effect of Houston urban land and
473 anthropogenic aerosols enhances the storm intensity (by ~60% in the mean of top 25 percentiles
474 in deep cloud stage), radar reflectivity (by up to 10 dBZ), peak precipitation rate (by ~ 45%), and
475 the accumulated rain (by ~ 26%), with the anthropogenic aerosol effect more significant than the
476 urban land effect overall. The anthropogenic aerosol effect increases the peak precipitation rate
477 by ~ 30% and the frequency of large rain rates ($> 15 \text{ mm h}^{-1}$ by about 5 times). Although urban
478 land effect alone (under the condition of existence of anthropogenic aerosols) does not impact
479 the peak precipitation rate and the frequency of large rain rates much, its interaction with aerosol
480 effects leads to an increase in the peak rain rates by 45% and the frequency of large rain rates by
481 an order of magnitudes. Therefore, the interactions between the two factors amplify the effect on
482 precipitation, particularly on the large rain rates, emphasizing the importance of considering both
483 effects in studying urbanization effects on convective clouds and precipitation.

484 The Houston urban land effect affects the convective evolution, making the initiation of
485 mixed-phase cloud and surface rain ~30 min earlier because of the strengthened sea breeze
486 circulation as a result of urban heating. It also slows down the dissipation of convective storm
487 because the urban heating extends to late afternoon and evening. The aerosol effect from
488 Houston anthropogenic emissions overall invigorates convection and precipitation, with ACI

489 dominant. The ACI effect is mainly through enhanced condensation (so-called “warm-phase
490 invigoration”) by activating numerous small aerosol particles at higher levels above the cloud
491 base. This invigoration is notable starting from the mixed-phase cloud stage and becomes more
492 significant at the deep cloud stage. The enhanced convective intensity in the mixed-phase cloud
493 stage by aerosols accelerates the development of convective storm into the deep cloud stage by ~
494 40 min, which is significant for thunderstorms since the storm duration is only a few hours.

495 This study improves our understanding of how Houston urban land and anthropogenic
496 aerosols jointly shape thunderstorms in the region. Our findings of the relative importance of
497 urban land effect versus anthropogenic aerosol effects are consistent with some of the previous
498 studies, which showed that for coastal cities, the anthropogenic aerosol effect on precipitation
499 was relatively more important than the urban land effect (Liu and Niyogi et al., 2019; Ganeshan
500 et al., 2013; Ochoa et al., 2015, Hu et al. 2019b). The low background aerosol concentration in
501 coastal cities is one of the factors responsible for the significant aerosol effect. In Houston,
502 another factor would be the warm and humid meteorological conditions, in which aerosols were
503 shown to invigorate convective clouds in many previous studies as reviewed in Tao et al. (2012)
504 and Fan et al. (2016).

505 For simulating aerosol-deep convective cloud interactions, there are a few key modeling
506 requirements as summarized in Fan et al. (2016), such as (1) the prognostic supersaturation is
507 needed for secondary aerosol activation, condensation, and evaporation calculations, (2)
508 hydrometeor size distributions need to be prognostic to physically simulate the responses of
509 microphysical processes to CCN changes, and (3) aerosols need to be prognostic, and fixed
510 aerosol concentrations gave unrealistic cloud properties and qualitatively changed aerosol
511 impacts on convective intensity (Fan et al., 2012). With the SBM used in this study, all these

512 criteria are satisfied. Furthermore, for (3), we are not only prognosing aerosol numbers but also
513 aerosol composition and size distribution by coupling the SBM with the chemistry and aerosol
514 components. With this coupling, the spatial heterogeneity of aerosols is considered. Also, aerosol
515 regeneration and wet removal processes can be more physically accounted for compared with the
516 WRF-Chem with two-moment bulk schemes (Gao et al., 2016). The spatial heterogeneity of
517 aerosols was shown to play an important role in simulating a torrential rain event observed over
518 Seoul, Korea (Lee et al., 2018). However, bin schemes also have uncertainties in representing
519 ice-related processes mainly due to our poor understanding of convective microphysics such as
520 ice nucleation and riming processes. In particular, the conversions between different ice
521 categories are also determined by threshold sizes or masses. However, those uncertainties are not
522 expected to qualitatively change the warm-phase invigoration mechanism which occurs via
523 enhanced condensation. In the companion paper Zhang et al. (2020), we carried out a small
524 number of ensemble simulations for the anthropogenic aerosol effects for the same case and the
525 results are consistent with this study, indicating this mechanism is robust with the initial
526 thermodynamic and dynamic perturbations. More sophisticated uncertainty qualifications can be
527 done in future with a larger number of ensembles when computer power becomes more
528 advanced.

529 The finding that urban land effect enhances sea breeze circulation, which transports more
530 moisture into the urban area and enhances convection and precipitation, is consistent with
531 previous studies, such as Ryu et al. (2016) for the Baltimore–Washington metropolitan area, and
532 You et al. (2019) for the Pearl River Delta (PRD) region.

760

761

762 **Figure 1** (a-b) 2-m Temperature (shaded) and 10-m wind (arrows) from the North American
 763 Regional Reanalysis (NARR) reanalysis data (32 km grid spacing), and the stationary front; (c-d)
 764 composite reflectivity observed at KHGX (Houston NEXRAD) at 1500 UTC (left) and 1800 UTC
 765 (right), 19 Jun 2013.

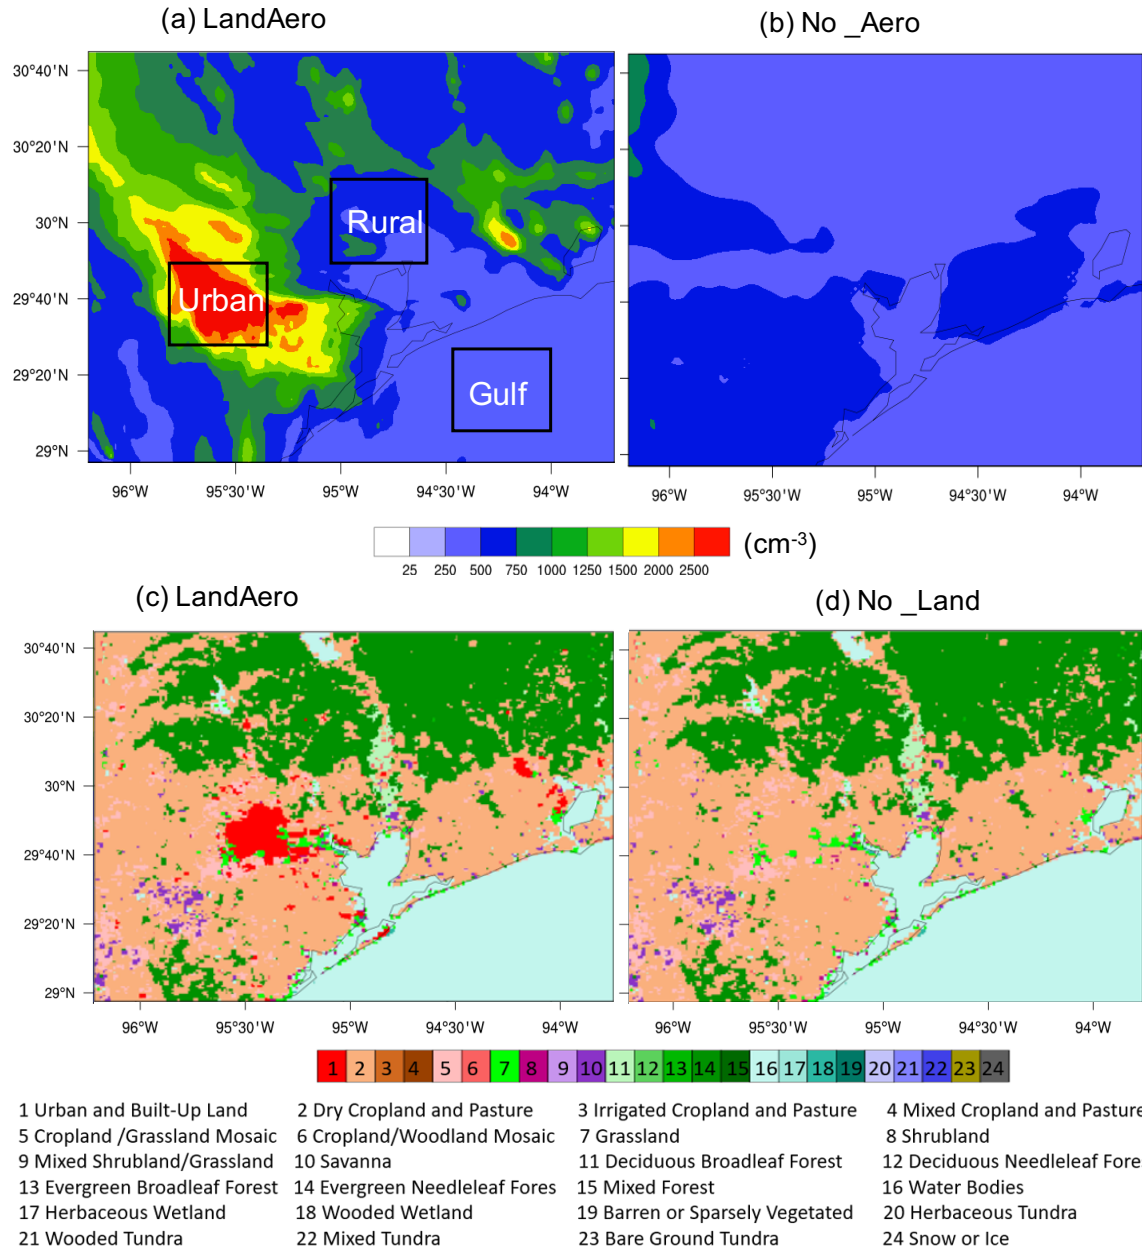

767

768

769 **Figure 2** The model domain setup. Domain 1 (d01) and Domain 2 (d02) are marked with black
 770 boxes. Terrain heights (m) are in color contours. Houston urban area is denoted by a pink
 771 contoured line.

772

773

774

775

776

777

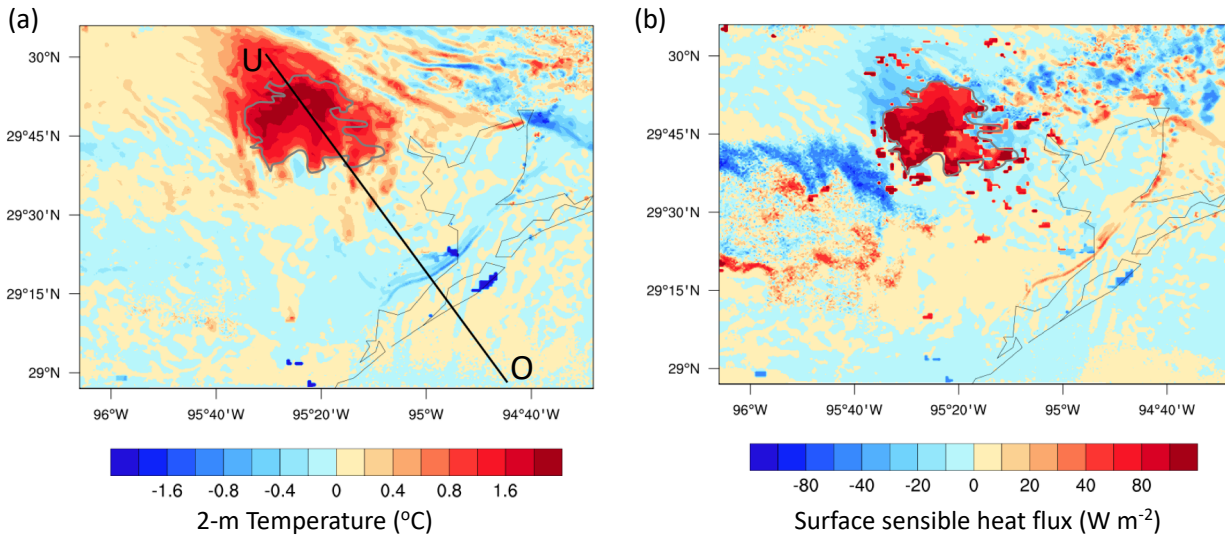

Figure 3 Aerosol number concentration (cm⁻³) from (a) LandAero (with anthropogenic emission) and (b) No_Aero (with anthropogenic emission turned off) at 1200 UTC, 19 Jun 2013 (6-hr before the convection initiation), and land cover types in (c) LandAero and (d) No_Land.

778

779 **Figure 4** Aerosol size distribution over the Urban, Rural, and Gulf of Mexico as marked by three
 780 black boxes in Figure 3a from LandAero at 1200 UTC, 19 Jun 2016.

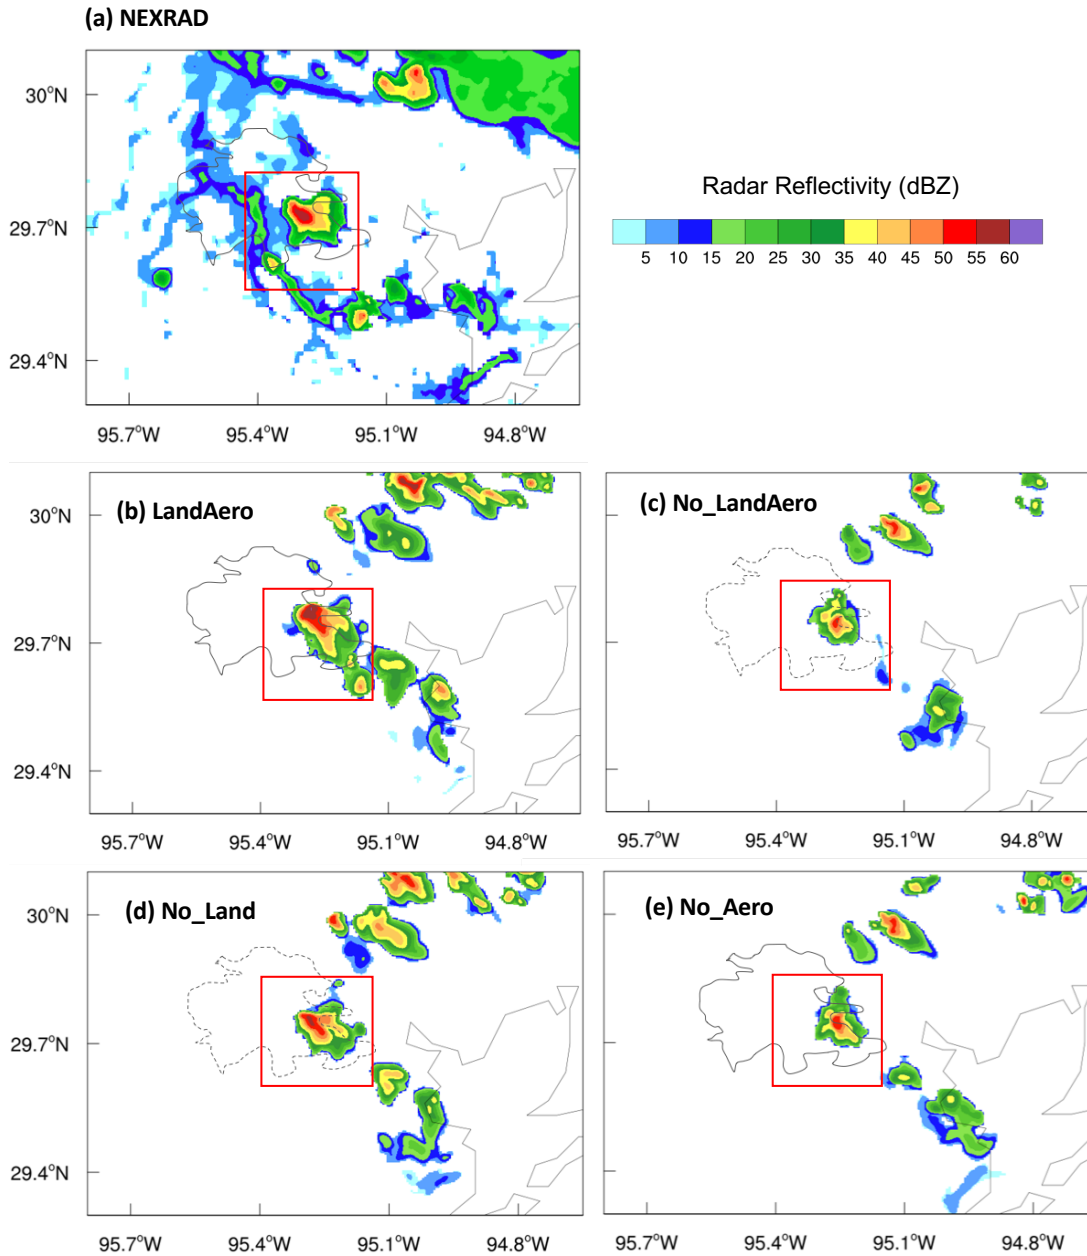

781

782

783 **Figure 5** Differences of (a) 2-m temperature ($^{\circ}\text{C}$) and (b) surface sensible heat flux (W m^{-2})
 784 between LandAero and No_Land at 1600 UTC 19 Jun 2013. Line UO is where the cross section
 785 of sea breeze circulation is examined.

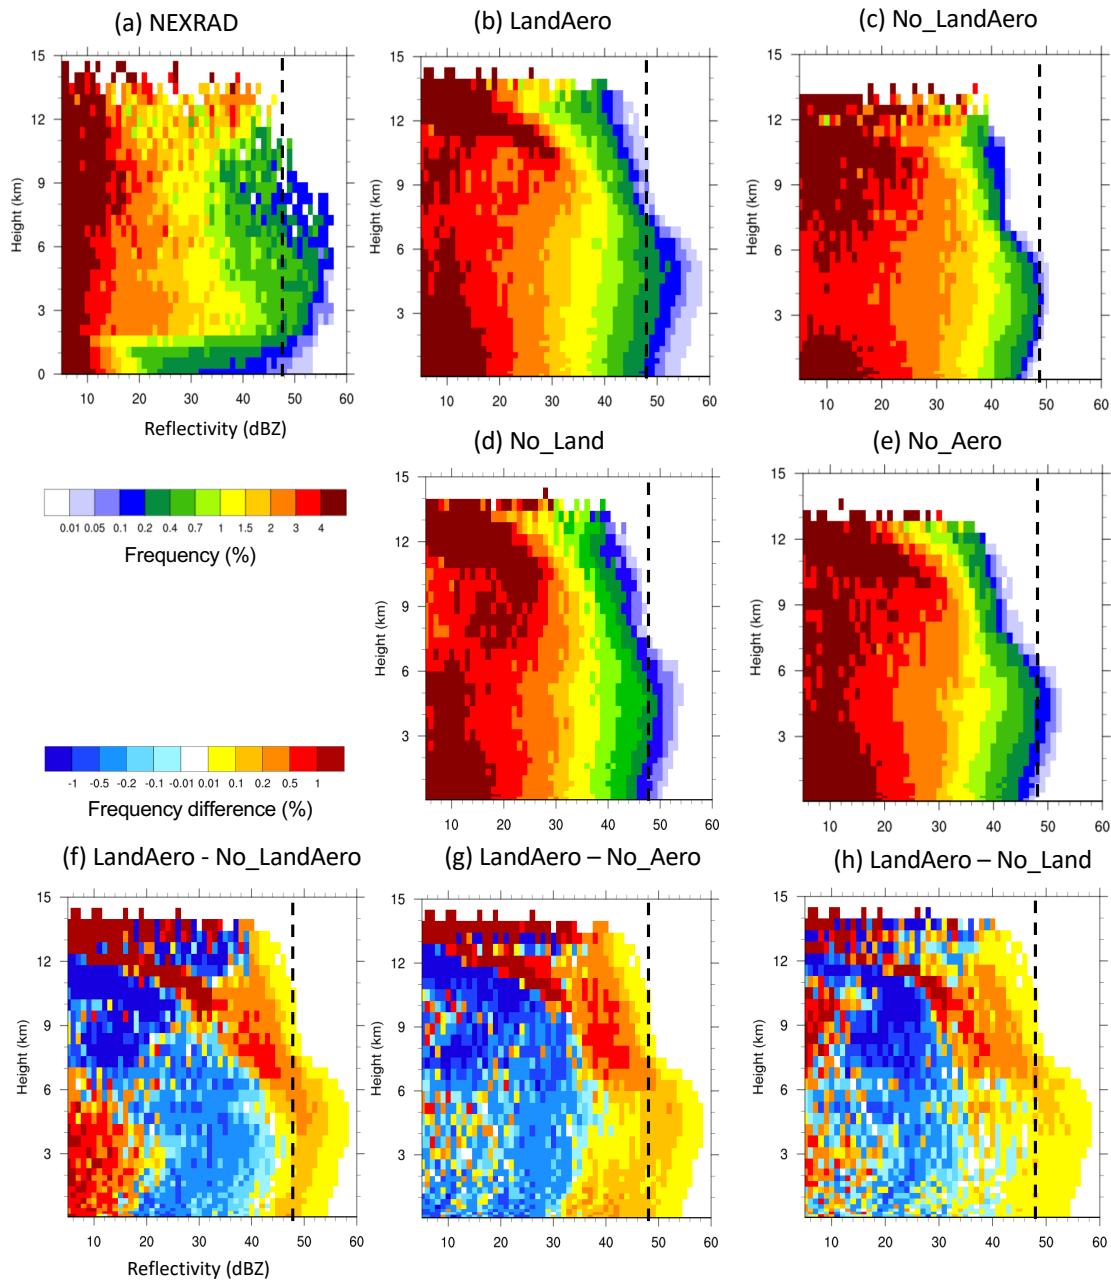

786

787

788 **Figure 6** Composite reflectivity (dBZ) from (a) NEXRAD (2217 UTC), (b) LandAero (2140
 789 UTC), (c) No_LandAero (2120 UTC), (d) No_Land (2135 UTC), and (e) No_Aero (2125 UTC)
 790 at the time when the maximal reflectivity of the storm in Houston is reached. Houston city is
 791 marked as dark grey solid contour based on the land cover data shown in Figure 3c. The red box
 792 is the study area for the Houston convective cell.

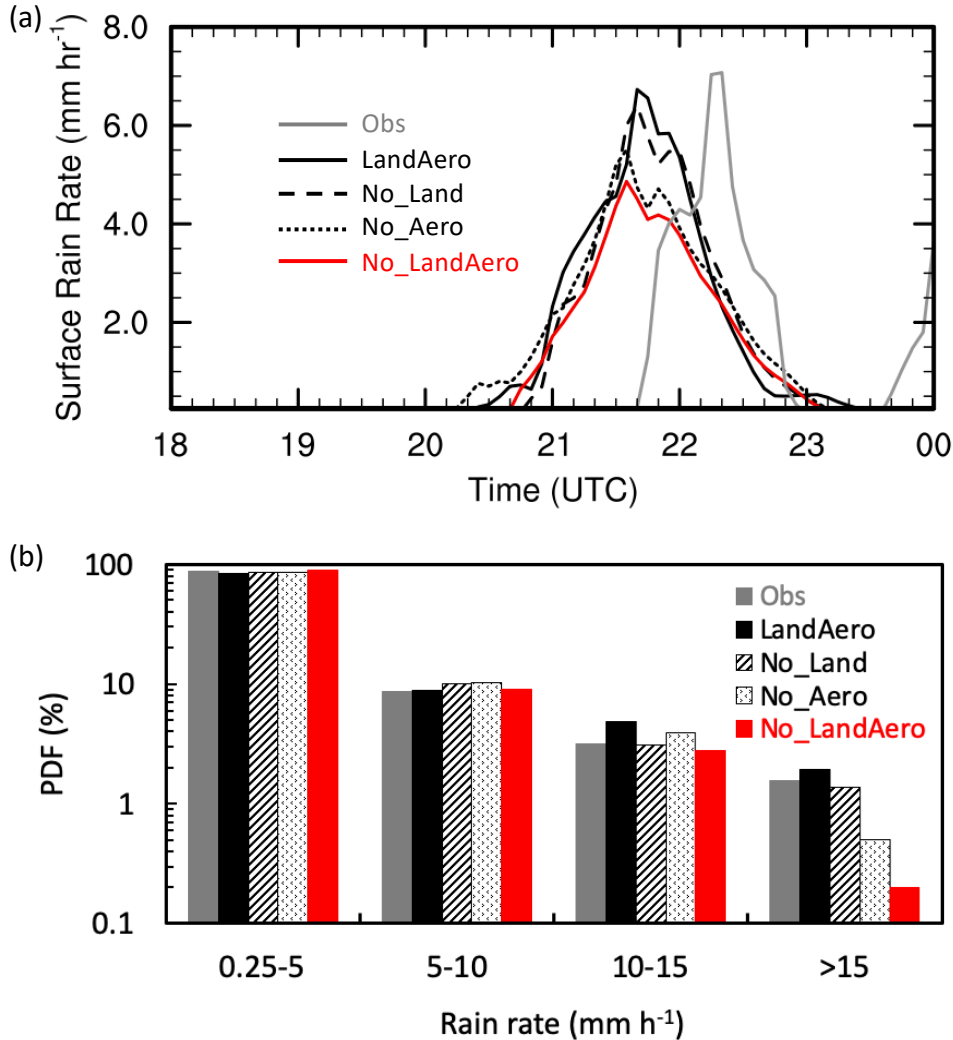

793

795

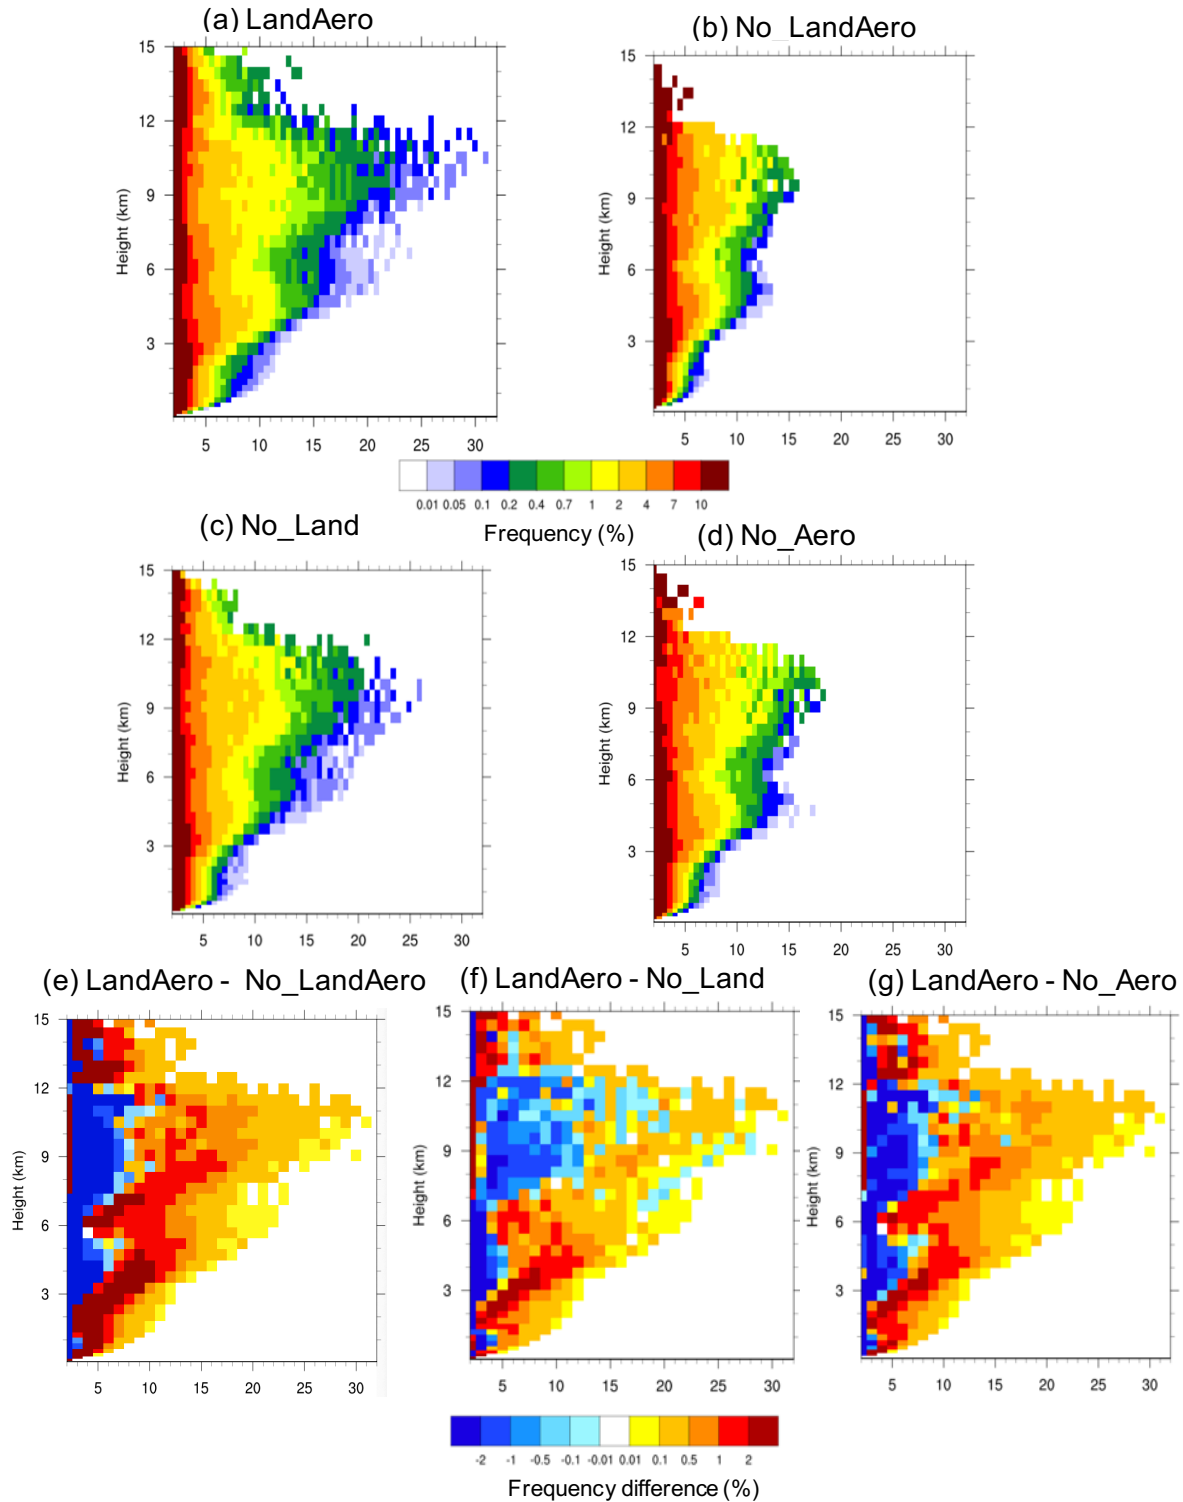

796 **Figure 7** Contoured frequency by altitude diagram (CFAD; %) of reflectivity for the values
 797 larger than 0 dBZ from (a) NEXRAD, (b) LandAero, (c) No_LandAero, (d) No_Land, and (e)
 798 No_Aero. (f-h) present the differences of CFAD (%) of reflectivity for (f) LandAero -
 799 No_LandAero, (g) LandAero - No_Aero, and (h) LandAero - No_Land. Data are from the study
 800 area (red box in Figure 6) over 1800 UTC 19 Jun to 0000 UTC 20 Jun. The vertical dashed line
 801 marks the value for the reflectivity of 48 dBZ.

802

803

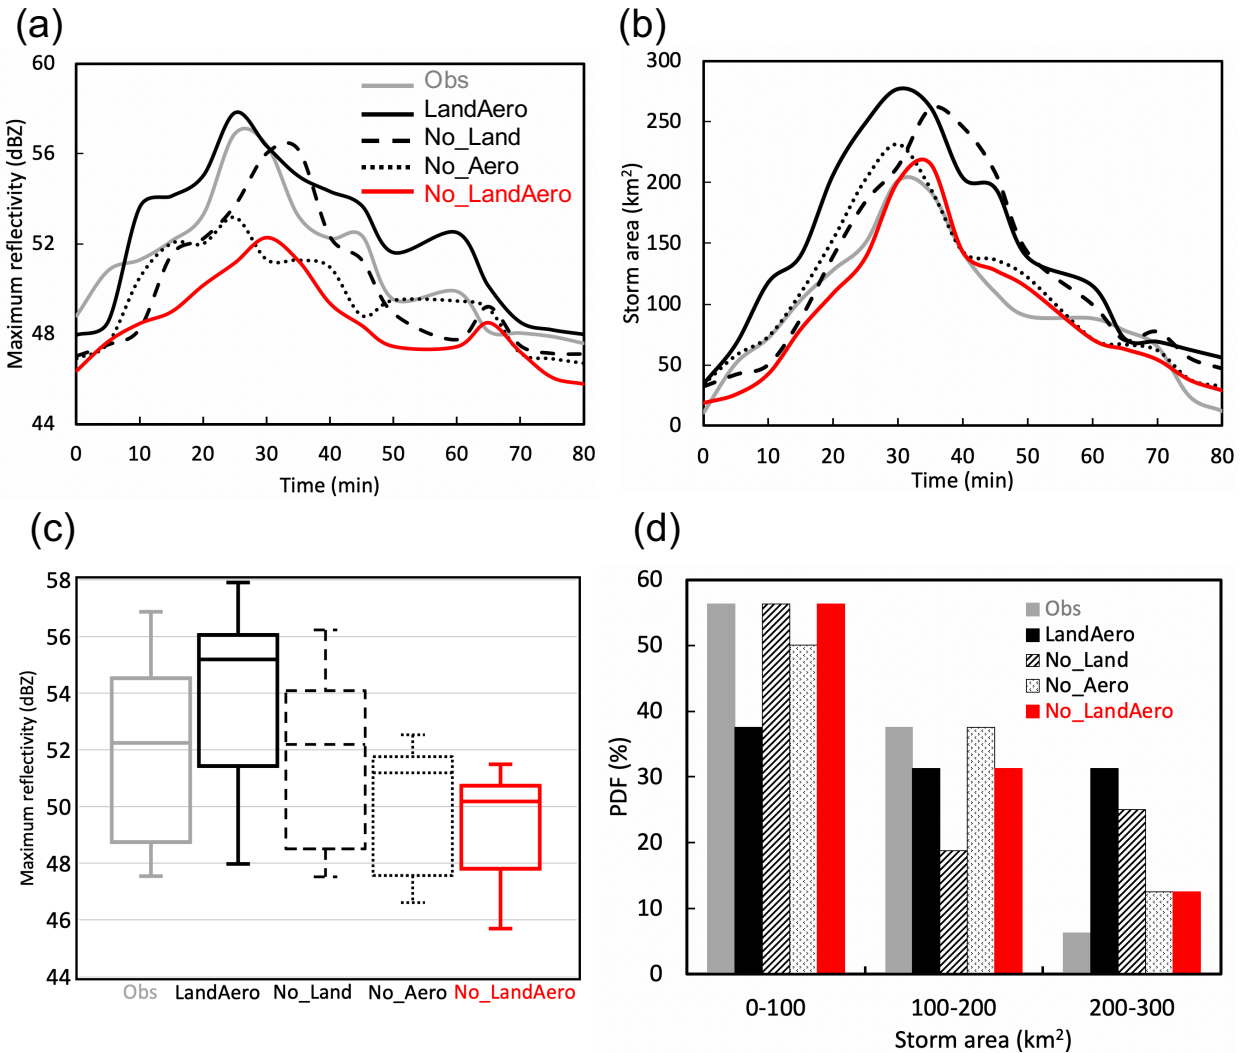

804 **Figure 8** (a) Time series of surface rain rate (mm h⁻¹) averaged over the values larger than 0.25
805 mm h⁻¹ for the Houston convective cell (red box in Figure 6) and (b) PDFs (%) of rain rates (>
806 0.25 mm h⁻¹) from 1800UTC 19 Jun to 0000 UTC 20 Jun 2013, from Observations, LandAero,
807 No_LandAero, No_Land, and No_Aero. The observation is the NEXRAD retrieved rain rate.
808 Both observation and model data are in every 5-min frequency.

809

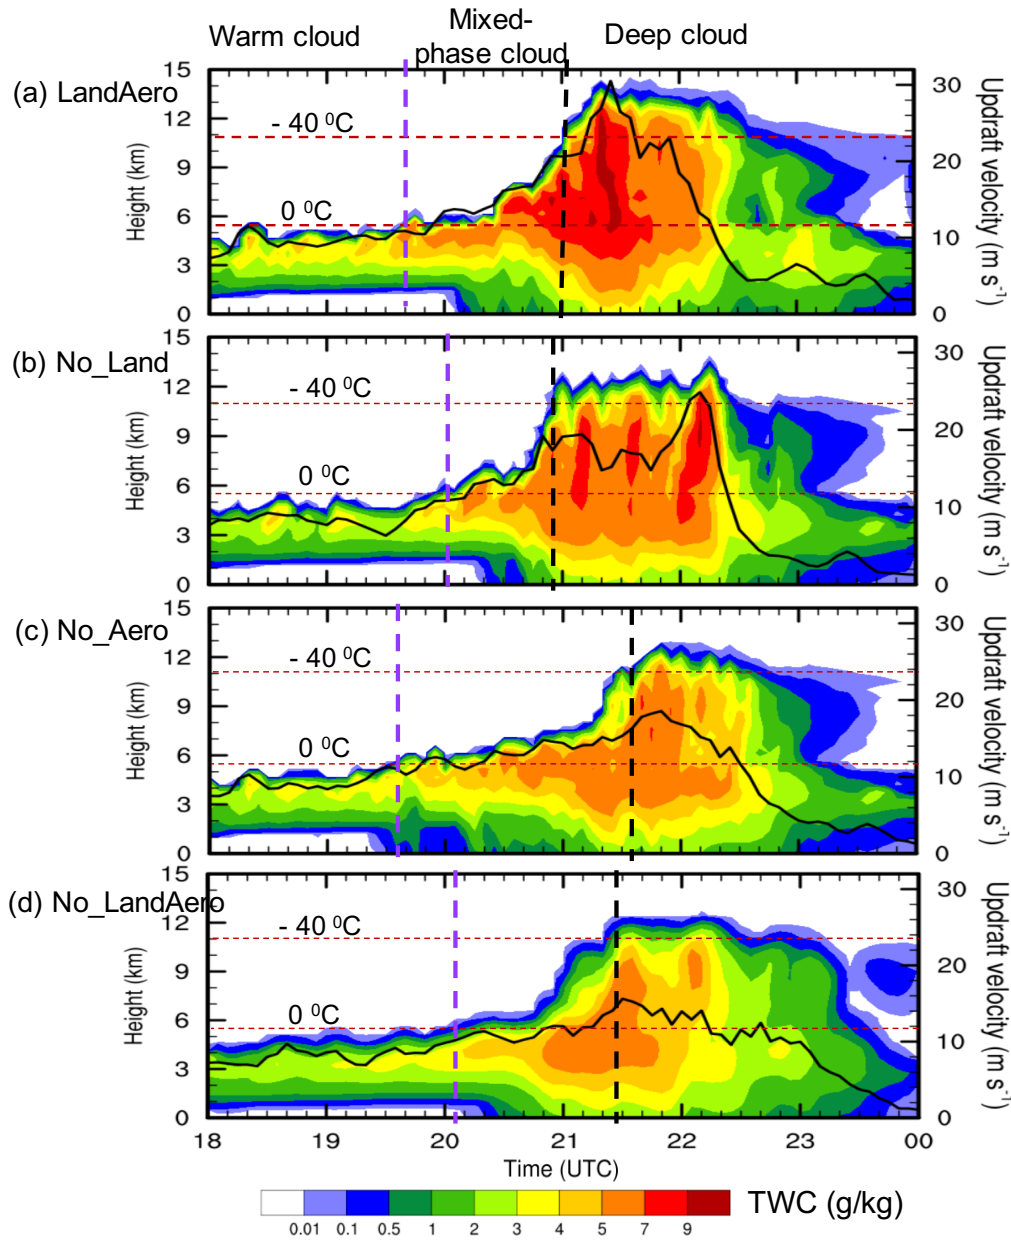

810 **Figure 9** CFAD (%) of updraft velocity for values larger than 2 m s^{-1} from (a) LandAero, (b)
 811 LandAero - No_LandAero, (c) LandAero - No_Land, and (d) LandAero - No_Aero over the
 812 study area as shown in the red box in Figure 6 during the strong convection periods (60-min

813 duration with 30 min before and after the strongest convection). (e-g) present the differences of
 814 CFAD (%) of reflectivity for (e) LandAero - No_LandAero, (f) LandAero -No_Land, and (g)
 815 LandAero – No_Aero.
 816

817
 818 **Figure 10** Time series of (a) maximum reflectivity (dBZ) and (b) storm area (km²) for the
 819 tracked convective cell from NEXRAD, LandAero, No_LandAero, No_Land, and No_Aero. The
 820 time window is from 2140 UTC to 2300 UTC for observations and from 2100 UTC to 2220
 821 UTC for model simulations. (c) Box-whisker plots of maximum reflectivity and (d) PDFs of
 822 averaged storm areas for the Houston cell from NEXRAD, LandAero, No_LandAero, No_Land,
 823 and No_Aero over the respective 80 min time windows as described above. The center line of
 824 the box indicates the median value, and the lower (upper) edge of the box indicates the 25th (75th)

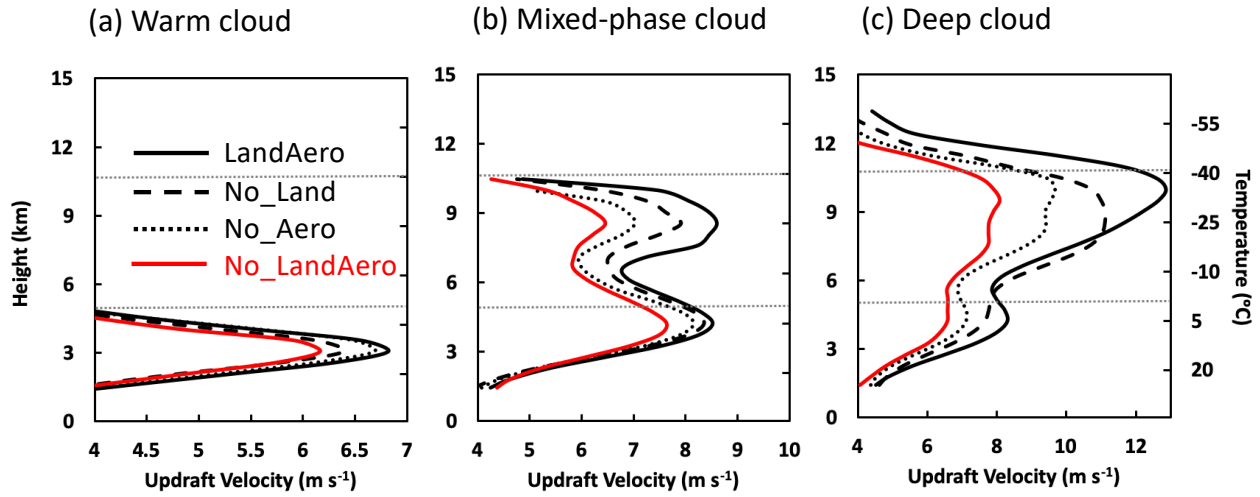

825 percentiles. The whiskers indicate the minimum and maximum values. The storm area of the
 826 tracked cell is defined as the number of grid points with LWP > 50 g m⁻² multiplied by the grid
 827 box area (0.5 km * 0.5 km).
 828

829
 830
 831 **Figure 11** Time series of maximal total water content (shaded; water vapor is not included) and
 832 maximal updraft velocity (black line, second y-axis) over the study area as shown in the red box
 833 in Figure 6 from LandAero, No_LandAero, No_Land, and No_Aero. Brown horizontal dashed

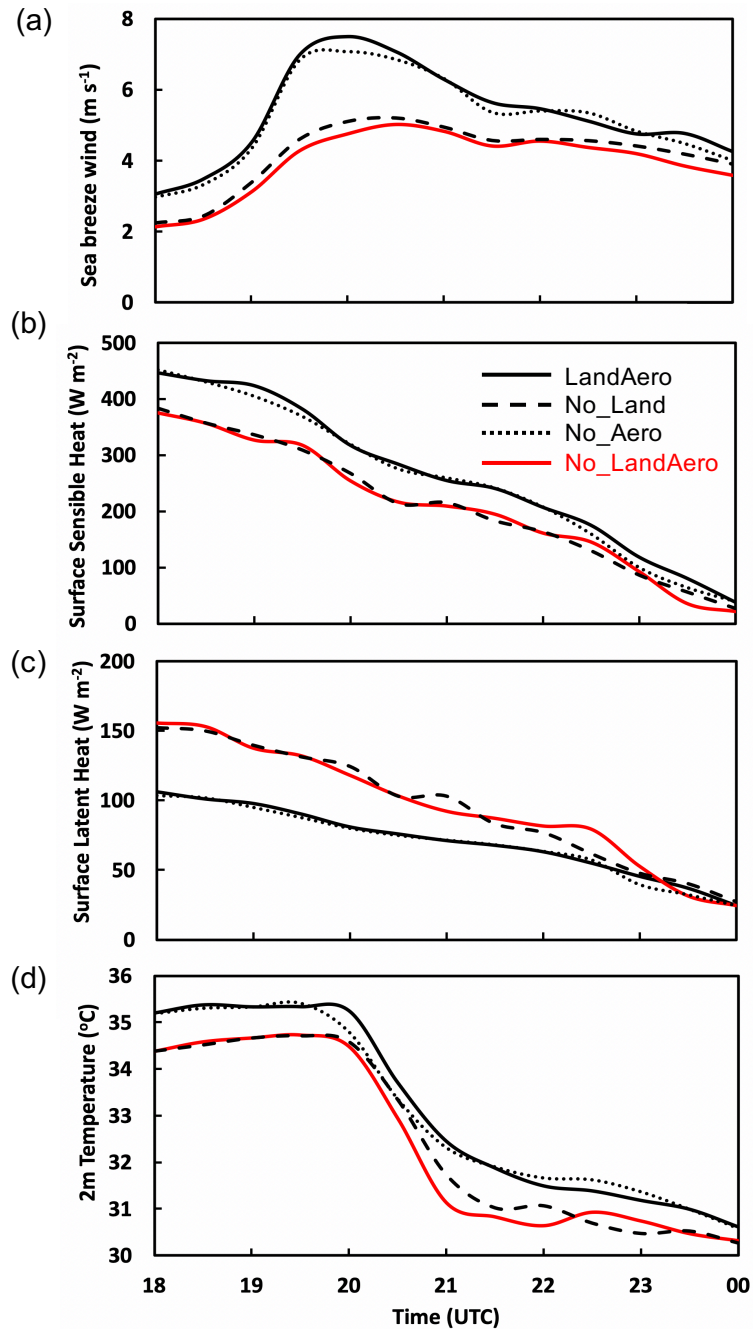

834 lines denote the freezing level (0 °C) and homogeneous freezing level (-40 °C). The initiation of
835 the mix-phase cloud and deep cloud is denoted by the purple and black vertical dashed lines,
836 respectively.

837

839

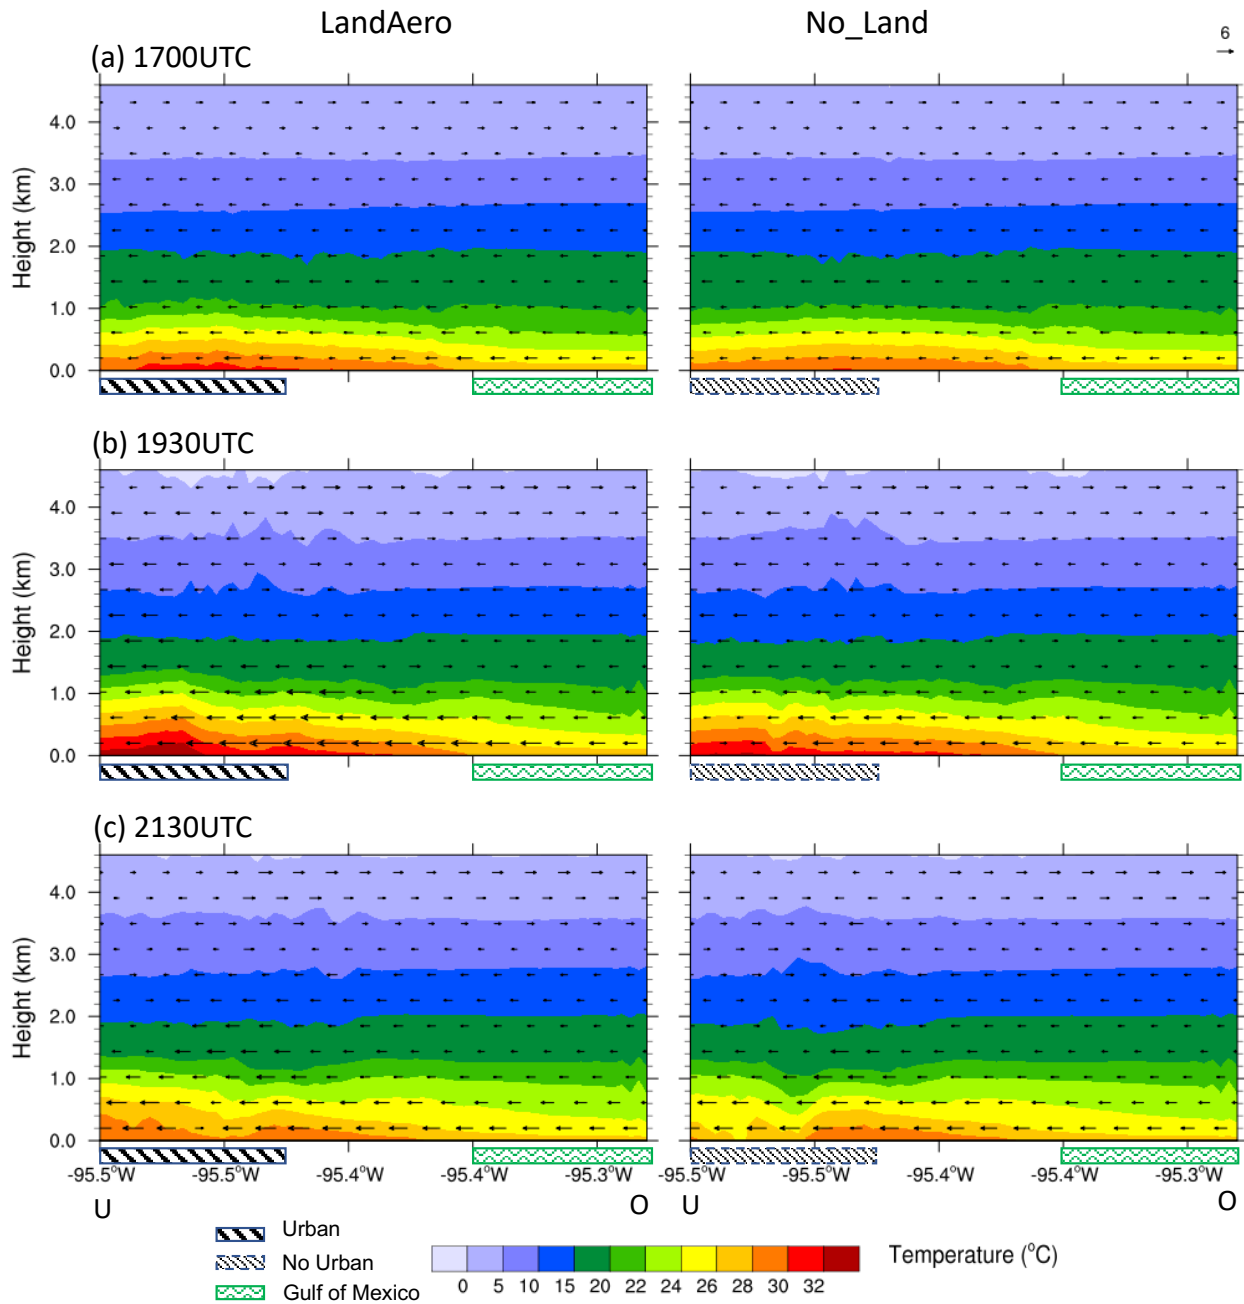

840 **Figure 12** Vertical profiles of updraft velocity averaged over the top 25 percentiles (i.e., 75th to
 841 100th) of the updrafts with a value greater than 2 m s^{-1} from the simulations LandAero,
 842 No_LandAero, No_Land, and No_Aero over the study area at the (a) warm cloud, (b) mixed-
 843 phase cloud, and (c) deep cloud stages. The dotted line denotes the freezing level ($0 \text{ }^\circ\text{C}$).

844

845 **Figure 13** Time series of (a) sea breeze wind speed (m s^{-1}), (b) surface sensible heat flux (W m^{-2}), (c) surface latent heat flux (W m^{-2}), (d) 2-m temperature ($^{\circ}\text{C}$) from LandAero, No_Land, No_Aero, and No_LandAero. Sea breeze winds are averaged over the horizontal winds along line UO (Figure 5a) from O to U below 1km. Heat fluxes and temperature are averaged over the study area.

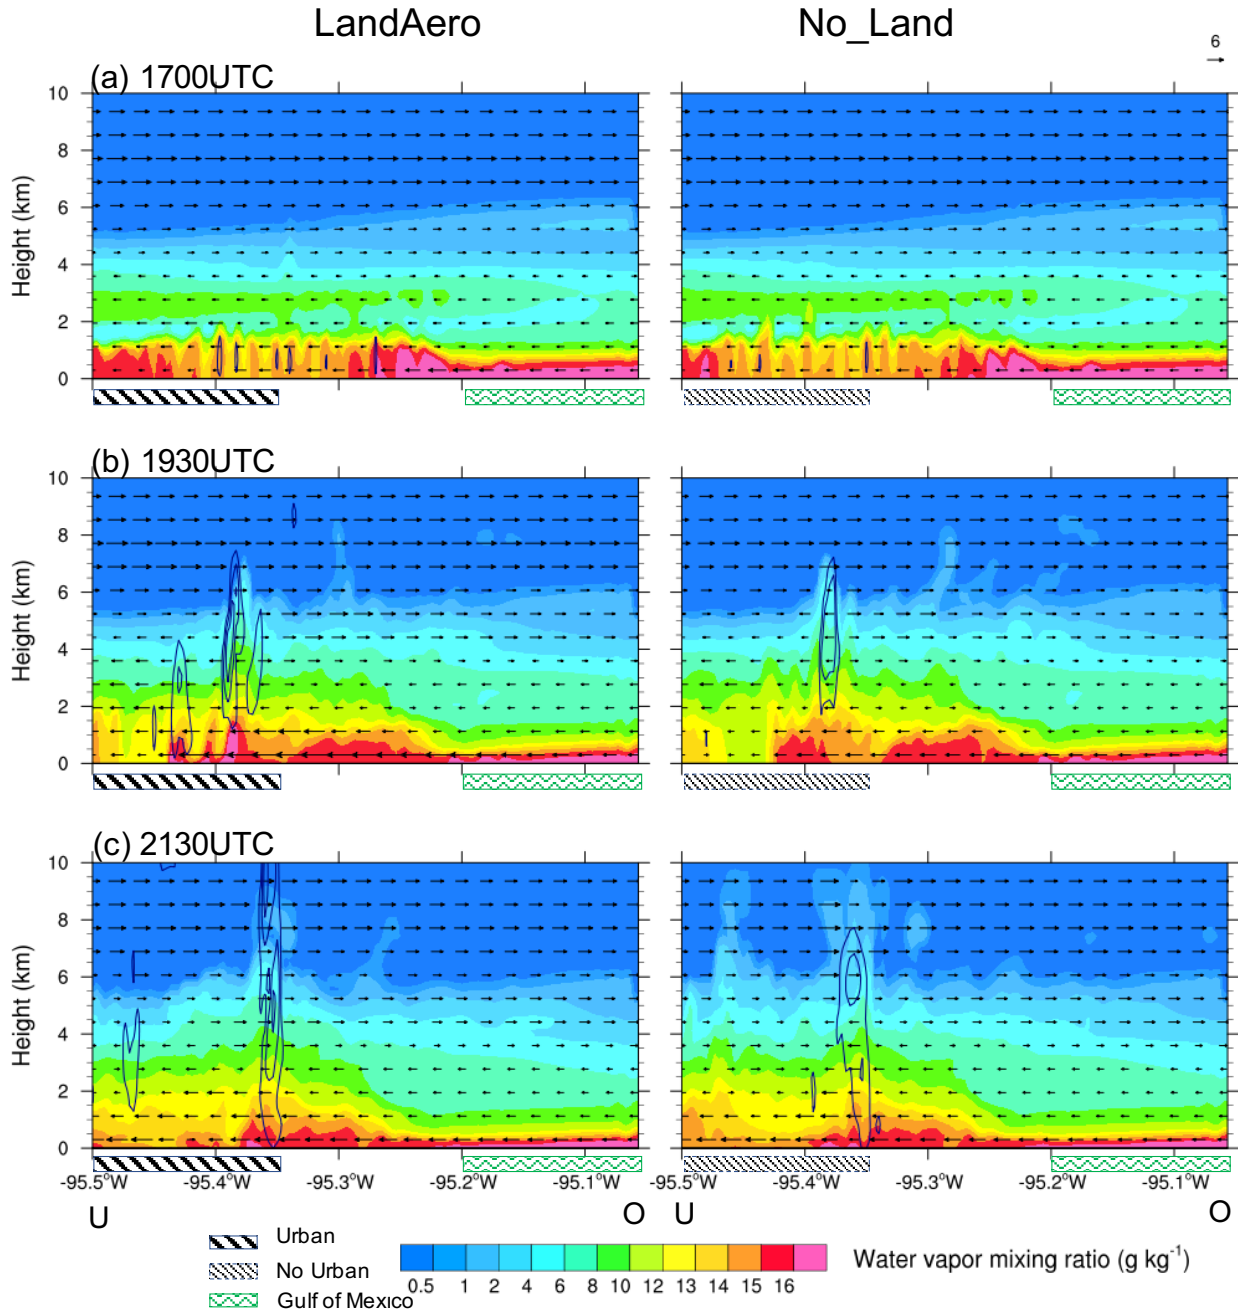

850

851

852 **Figure 14** Vertical cross sections of temperature ($^{\circ}\text{C}$; shaded) and wind vectors (m s^{-1}) along the
 853 line UO in Figure 5a for LandAero (left) and No_Land (right) at (a) 1700, (b) 1930, and (c) 2130
 854 UTC. The bars with stripes and waves on the x-axis represent the urban land and water body in
 855 the Gulf of Mexico, respectively.

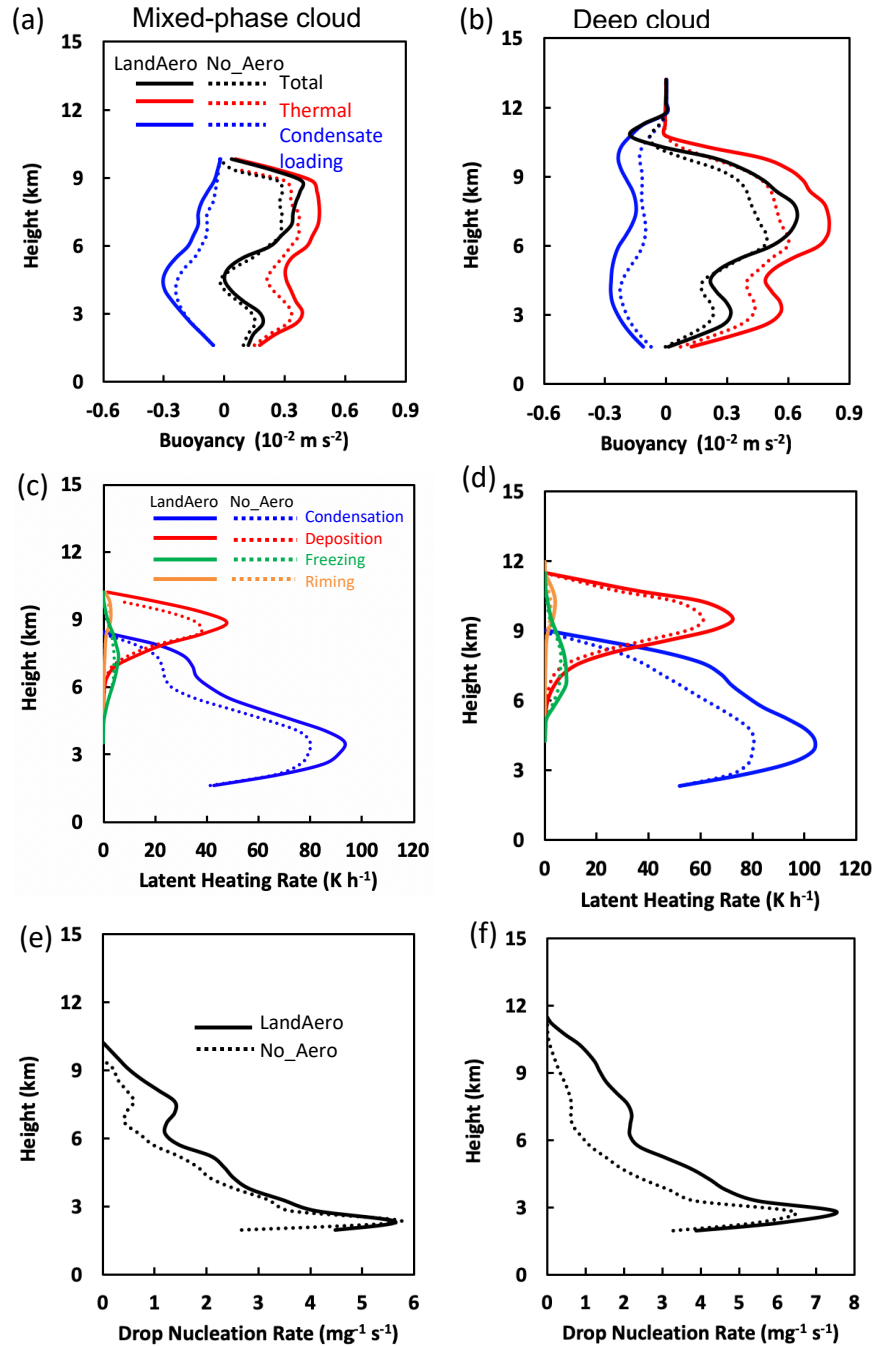

856

857

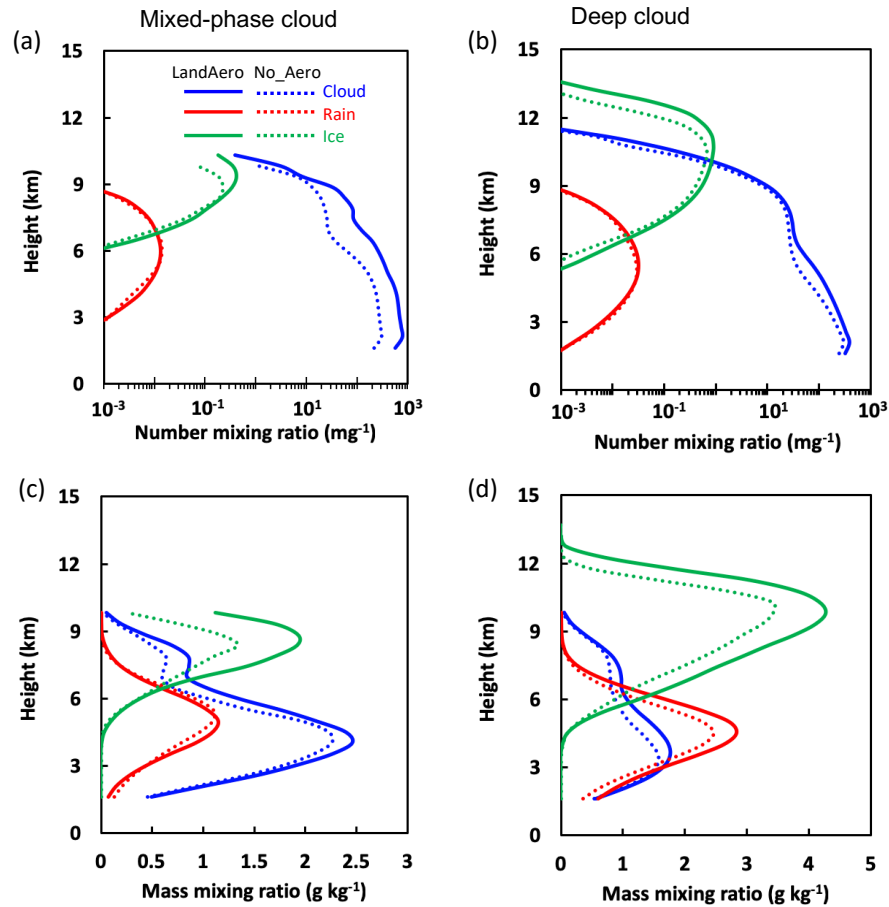

858 **Figure 15** Vertical cross sections of water vapor mixing ratio (g kg^{-1} ; shaded), updraft velocity
 859 (contour lines are 2, 6, and 11 m s^{-1}), and wind vectors along the line UO in Figure 5a for
 860 LandAero and No_Land at (a) 1700, (b) 1930, and (c) 2130 UTC.

861

862

863 **Figure 16** Vertical profiles of (a-b) buoyancy terms (m s^{-2} ; red for Thermal buoyancy, blue for
 864 condensate loading and black for total buoyancy), (c-d) latent heating (K h^{-1}) from condensation
 865 (blue), deposition (red), drop freezing (orange), and riming (green), and (e-f) droplet nucleation
 866 rate ($\text{mg}^{-1} \text{ s}^{-1}$) averaged over the top 25 percentiles (i.e., 75th to 100th) of the updrafts with a
 867 value greater than 2 m s^{-1} from the simulations LandAero and No_Aero in the study area during
 868 the mixed-phase cloud (left) and deep cloud (right) stages.

869

870 **Figure 17** Vertical profiles of (a-b) number mixing ratio (mg^{-1}) and (c-d) mass mixing ratio (g
 871 kg^{-1}) of cloud droplets (blue), raindrops (red) and ice particles (green) averaged over the top 25
 872 percentiles (i.e., 75th to 100th) of the updrafts with a value greater than 2 m s^{-1} from the
 873 simulations LandAero and No_Aero in the study area during the mixed-phase cloud (left) and
 874 deep cloud (right) stages.
