Review of “Determination of the absorption cross-sections of higher order iodine oxides at 355 nm and 532 nm” by Lewis et al.

This paper presents photochemical data for iodine oxides (I_xO_y), a hitherto elusive family of atmospheric transients thought to play an important role in the coastal marine boundary layer. Results were determined via laser photolysis / photodepletion experiments using mass-spectrometry detection of I_xO_y, supplemented by ab-initio calculations. This first extensive dataset can provide valuable information needed to construct models of atmospheric chemistry. However, there were a few points that require further clarification and discussion within the manuscript prior to publication in ACP.

C1

Firstly, experiments appear to have been conducted under very different conditions of gas pressure and identity to those found in the boundary layer. At the top of page 6 it was stated that experimental pressures of 4 to 7 Torr were used (though whether of He or N₂ was not clear). This is clearly a very different matrix of gases to 760 Torr of N₂, O₂ and H₂O found in coastal boundary layer air. There is surely some doubt therefore, whether some qualitative observations from this work are valid for atmospheric models. The chemical mechanisms for I_xO_y formation will surely differ to some extent due to changes in stabilization rates for association products at the different gas-pressure, or perhaps reactions of transients with O₂ (or even H₂O) that would proceed faster in the boundary layer. Specifically, much is made of the absence of I₄O_y species, but we simply do not know if these compounds would be formed in realistic atmospheric conditions. If there is clear evidence for why such pressure or O₂ effects are unimportant then this needs to be detailed in the manuscript.

Second, regarding more quantitative results, could photolysis quantum yields and therefore photolysis cross-sections differ as the pressure and identity of the surrounding gas matrix changes? Certainly these effects can be important for many atmospheric transients, not least for the actinometer NO₂ though at a longer wavelength than used in this work. I suspect that such pressure effects will have a negligible impact on the quantitative results from this work, given, as stated on page 16, the featureless nature of the spectra. However, given the large divergence from atmospheric conditions noted above, a strong statement to the effect that these cross-sections / quantum yields are applicable to realistic atmospheric conditions would be advisable.

Third regards the use of OIO as the actinometer for 532 nm experiments. I can understand why this molecule was used, given a limited set of alternatives. However, the manuscript needs to properly represent the problems that this introduces into the interpretation of results. The cross-section for OIO may be “relatively well known” as stated on page 8 (line 176), but I was not able to find a recent review justifying this statement. On the contrary, of the two references quoted in this work for OIO cross-

C2

sections, only one (from Bloss et al.) quotes a value at 532 nm. A very quick look in the literature yielded cross-section data from five additional papers (Spietz 2005, Joseph 2005, Himmelmann 1996, Tucceri 2006 and from Ingham 2000) that differ by up to a factor of two at some wavelengths. Further, the quantum yield (QY) for atomic iodine production from OIO is certainly not established. Ingham et al. reported $QY < 0.15$ for this channel, in direct contrast to the value of unity taken from Gomez Martin et al. and used for the purposes of this work. Happily, a careful re-wording of the manuscript here can rectify these problems. First, the section on page 8 needs to take full account of the published literature on OIO. Second, the results obtained in this work need to be clearly denoted as being determined relative to the rather uncertain cross-sections and quantum yields for OIO at 532 nm.

Lastly, on Figure 4 “an empirical fit” was used to obtain depletion parameters. What was the function? More interestingly, which processes were responsible for the delay in signal depletion following (presumably rapid) photolysis. Is this delay instrumental, and therefore present in other experiments? It is not possible for the reader to assess for themselves, as a very different timescale is presented on Figs 6 and 7.

More minor comments: Page 2 it was stated that the main atmospheric fate of iodine atoms is reaction with O₃ to form IO. This is likely true across much of the globe, but a significant alternative exists in polluted air (as encountered in many important areas of the coastal MBL) where reaction with NO₂ to form INO₂ would be competitive. The text on page 3 reports flows diluted in He whilst Figure 1 appears to indicate N₂ as the principal diluent. Which is correct? If a mixture of the two then please use the text and / or the caption to Figure 1 to offer more detail. Similarly in the experimental details a laser energy of 120 mJ pulse⁻¹ was reported. A more useful quantity for the reader would be the energy per pulse per square centimetre, as this more directly relates to absorption cross-sections (quoted in cm² molecule) and consequent radical densities. Please supply this information / clarify. The same applies to the YAG laser energy (page 5 line 116). Technical: Page 3 line 63 – 65 was confusing. I think the authors

C3

mean to say “Since all reaction paths for I, IO or OIO with H₂O are endothermic” Page 3 line 86 “introduced in the reactor” should be something like “introduced to the reactor” The use of low-contrast colours on e.g. Fig 8 without other visual markers will make it very difficult for some readers to distinguish e.g. I₂O₂ from I₂O₃ from I₂O₄. Could dots or dashes be introduced to help with this issue of accessibility? Fig. 9 uses the same symbol type (circles) to represent I₃O₆, I₃O₇ and I₅O₁₂ – please make use of triangles / squares. Additionally, information was missing from the legend where only I₅O₁₂ is mentioned.
