Abstract. High time-resolution measurements of *in situ* aerosol and cloud properties provide the ability to study regional atmospheric processes that occur on timescales of minutes to hours. However, one limitation to this approach is that continuous measurements often include periods when the data collected are not representative of the regional aerosol. Even at remote
20 locations, submicron aerosols are pervasive in the ambient atmosphere with many sources. Therefore, periods dominated by local aerosol should be identified before conducting subsequent analyses to understand aerosol regional processes and aerosol-cloud interactions. Here, we present a novel method to validate the identification of regional baseline aerosol data by applying a mathematical algorithm to the data collected at the U.S. Department of Energy's (DOE) Atmospheric Radiation Measurement (ARM) User Facility in the Eastern North Atlantic (ENA). The ENA Central facility (C1) includes an Aerosol Observing
25 System (AOS) for the measurement of aerosol physical, optical, and chemical properties at time resolutions from seconds to minutes. A second temporary Supplementary facility (S1), located ~0.75 km from C1, was deployed for ~1 year during the Aerosol and Cloud Experiments (ACE-ENA) campaign in 2017.

First, we investigate the local aerosol at both locations. We associate periods of high submicron number concentration (N_{tot})
30 in the fine mode Condensation Particle Counter (CPC) and size distributions from the Ultra-High Sensitivity Aerosol Spectrometer (UHSAS) as a function of wind direction using a meteorology sensor with local sources. Elevated concentrations of Aitken mode (< 100 nm diameter) particles were observed in correspondence with the wind directions associated with airport operations. At ENA, the Graciosa airport and its associated activities were found to be the main sources of high concentration aerosol events at ENA, causing peaks in one-minute N_{tot} that exceeded 8,000 cm⁻³ and 10,000 cm⁻³ at C1, in
35 summer and winter, respectively, and 5,000 cm⁻³ at S1 in summer. Periods with high N_{tot} not associated with these wind directions were also observed. As a result, the diverse local sources at ENA yielded a poor relationship between N_{tot} measurements collected at C1 and S1 ($R^2 = 0.03$ with a slope = 0.05 ± 0.001). As a first approach to mask these events, the time periods when the wind direction was associated with the airport operations (west to northwest and southeast to south at C1 and east to south at S1) were applied. The meteorological masks removed 38.9% of the data at C1 and 43.4% at S1, and
40 they did not significantly improve the relationship between the two sites ($R^2 = 0.18$ with a slope = 0.06 ± 0.001).

Due to the complexity of high N_{tot} events observed at ENA, we develop and validate a mathematical ENA Aerosol Mask (ENA-AM) to identify high N_{tot} events using one-minute resolution data from the AOS CPC at C1 and S1. After its

parametrization and application, ENA-AM generated a high correlation between N_{tot} in the summer at C1 and S1 ($R^2 = 0.87$ with a slope = 0.84 ± 0.001). We identified the regional baseline at ENA to be $428 \pm 228 \text{ cm}^{-3}$ in the summer and $346 \pm 223 \text{ cm}^{-3}$ in the winter. Lastly, we compared masked measurements from the AOS with the ARM Aerial Facility (AAF) during flights over C1 in the summer to understand submicron aerosol vertical mixing over C1. The high correlation ($R^2 = 0.71$ with a slope of 1.04 ± 0.01) observed between C1 and the AAF N_{tot} collected within an area of 10 km surrounding ENA and at altitudes < 500 m indicated that the submicron aerosol at ENA were well mixed within the first 500 m of the marine boundary layer during the month of July during ACE-ENA. Our novel method for determining a regional aerosol baseline at ENA can be applied to other time periods and at other locations with validation by a secondary site or additional collocated measurements.

10 **1 Introduction**

1.1 Aerosol and cloud interactions in the Eastern North Atlantic

Ambient aerosols interact with clouds by acting as cloud condensation nuclei and affecting cloud radiative properties, with significant implications for global climate change (Anderson et al., 2003; IPCC, 2014). Currently, climate forcing associated with aerosol-cloud interactions represents one of the largest uncertainties in the climate system (Carslaw et al., 2013) and in future climate projections (Simpkins, 2018). Compounding the effect on climate, regions dominated by clean atmospheric conditions, such as those observed in marine environments with low-lying clouds, are the most susceptible to aerosol perturbations (Rosenfeld et al., 2014). Recently, increases in larger longer-lasting cloud cover and cooling have been correlated with enhanced concentrations of aerosols in ultraclean regimes (Goren and Rosenfeld, 2015).

The Eastern North Atlantic (ENA) Ocean is a remote region characterized by a clean marine environment and persistent subtropical marine boundary layer (MBL) clouds (Wood et al., 2015). Throughout the year, transported air masses from North and Central America, Europe, the Arctic, and North Africa (O'Dowd and Smith, 1993; Hamilton et al., 2014; Logan et al., 2014) periodically impact ENA, leading to perturbations in aerosol properties and cloud condensation nuclei concentrations. As a result, ENA is one of the regions in the world with the strongest aerosol indirect forcing and, as a result, has one of the highest associated uncertainties in terms of the aerosol impact on cloud formation, albedo, and lifetime (Carslaw et al., 2013). In the past few decades, major efforts have focused on improving the knowledge of atmospheric processes in the ENA region. Since 1991, several campaigns including the Atlantic Stratocumulus Transition Experiment (ASTEX) (Albrecht et al., 1995), the North Atlantic Regional Experiment (NARE) field mission (Penkett et al., 1998), the International Consortium for Atmospheric Research on Transport and Transformation (ICARTT) (Fehsenfeld et al., 2006) and the BORTAS campaign (Parrington et al., 2012) were conducted in North Atlantic studying cloud structure and long-range transport patterns over the region.

1.2 Ground-based aerosol measurements in the Eastern North Atlantic

Starting in 2009, the U.S. Department of Energy's (DOE) Atmospheric Radiation Measurement (ARM) User Facility has deployed campaigns at ENA to improve comprehensive long-term measurements of marine boundary layer aerosol and low clouds in high latitude marine environments. In 2009, the 21-month field campaign (from April 2009 until December 2010), "Clouds, Aerosol and Precipitation in the Marine Boundary Layer" (CAP-MBL) on Graciosa Island (Azores Archipelago), provided the most extensive characterization of MBL clouds in the North Atlantic (Rémillard et al., 2012; Rémillard and Tselioudis, 2015). The observations collected during the 21 months of the deployment also highlighted a strong synoptic meteorological variability associated to seasonal variations of aerosol properties (Logan et al., 2014; Wood et al., 2015; Pennypacker and Wood, 2017; Wood et al., 2017).

Following the outstanding uncertainties identified during CAP-MBL and to continue the research on aerosol–cloud–precipitation interactions on marine stratocumulus clouds, in 2013, ARM established a fixed site, known as the ENA ARM Facility (Mather and Voyles, 2013; Dong et al., 2014; Logan et al., 2014; Feingold and McComiskey, 2016). The ENA fixed site is located on the north side of Graciosa Island, which is the northernmost island within the central group of islands in the Azores. Graciosa is the second smallest in size with an area of ~ 61 km² and is one of the least populated islands within the Azores archipelago, with a population of less than 5,000 people. These features make Graciosa Island well-suited for collecting measurements representative of the open ocean from an inhabited island with power and infrastructure.

The ENA Central Facility (C1) is equipped with an Aerosol Observing System (AOS). The AOS provides a unique dataset of high temporal resolution measurements of *in situ* aerosol optical, physical, and chemical properties and their associated meteorological parameters (Uin et al., 2019). Most recently, motivated by the need of a characterization of the horizontal variability and the vertical structure of aerosol and clouds over ENA, ARM deployed the Aerosol and Cloud Experiments in the Eastern North Atlantic (ACE-ENA) field campaign (Wang et al., 2019a). In July 2017 during ACE-ENA, ARM established a temporary Supplementary facility (S1), approximately 0.75 km from the central ENA site (C1), to understand the regional representativeness of the AOS data at the ground-level. A subset of AOS instruments was deployed for a period of approximately one year to identify the local impacts at C1 and to add additional constraints for the development of algorithms to mask local aerosol influences. During two Intensive Operating Periods (IOPs), in June-July 2017 and January-February 2018, the ARM Aerial Facility (AAF) Gulfstream-159 (G-1) research aircraft flew over ENA providing high quality measurements of the marine boundary layer and lower free troposphere (FT) structure, as well as the vertical distribution and horizontal variability of low clouds and aerosol over ENA (Wang et al., 2016; Wang et al., 2019a). We use the AAF and S1 data to constrain periods of time when the ENA AOS data was regionally representative of aerosol concentrations at the ground level and when they represented aerosol concentrations that were well-mixed within the boundary layer.

1.3 Masking local aerosol sources

The impact of local sources on aerosol and trace gas measurements is a common issue for continuous ambient datasets (Drewnick et al., 2012). Even at remote sites such as ENA, local sources can be pervasive and unavoidable. At ENA, the location for C1 was selected by ARM to minimize local aerosol and trace gas sources since they can interfere with regional and large-scale atmospheric aerosol processes. However, competing needs of instruments, logistics, and operations (e.g. requirement of large flat surface areas for the radars, power and infrastructure to operate the facility, etc.) constrained the site selection. As a consequence, episodes of local aerosols are sampled by the AOS and can be observed in the high time-resolution data. Thus, we identify all known local sources and develop a mask to isolate the regionally representative data (Aiken and Gallo, 2020; Gallo and Aiken, 2020a; Gallo and Aiken, 2020b).

One method to estimate the regionally representative concentrations at sites affected by local aerosol is with meteorological filters (Giostra et al., 2011; Gao et al., 2019; Wang et al., 2019b). This approach masks all data related to air masses coming from wind directions associated with sources. However, meteorological filters rely upon accurate knowledge of the local sources and the availability of high quality meteorological data (Giostra et al., 2011). This method has limited use at locations where local sources originate from a wide range of wind directions, vary with time, such as seasonal sources, and at locations with complex meteorology, terrain, and high wind speeds.

With high time-resolution continuous data, it is possible to implement post data processing methods using statistics to identify and mask high concentration aerosol events without removing a large fraction of the data or relying on observational data to

identify nearby sources. Smoothing methods based on robust nonlinear data smoothing algorithms have been used historically to improve the signal-to-noise for data that includes occasional high signals due to random noise and other events that can bias the measurements (Beaton and Tukey, 1974; Velleman, 1977; Goring and Nikora, 2002). Smoothing algorithms separate data into a smoothed sequence that can be used to represent the baseline and a residual sequence composed of the “noise”. Recently, Liu et al. (2018) used a smoothing algorithm based on a 24-hour running median to mask short-term local events with an average duration of 0.5 ± 6 minutes due to nearby road traffic using Condensation Particle Counter (CPC) number concentration data at Ross Island, in Antarctica during the ARM West Antarctic Radiation Experiment (Lubin et al., 2020). Mathematical algorithms (Giostra et al., 2011; McNabola et al., 2011; Drewnick et al., 2012; Hagler et al., 2012; Ruckstuhl et al., 2012; Brantley et al., 2014; Wang et al., 2015) that evaluate the statistically different behaviour of adjacent data points have also been shown to be effective for masking real-time atmospheric data affected by local events in clean environments. The challenge, however, is to identify and mask the time periods impacted by local aerosol sources without masking the regionally representative data that may include periods of long-range transport or other sources with high aerosol number concentrations. Hence, for the successful application of mathematical algorithms, it is important to know how local sources impact the measurements, especially in terms of the signal change and duration of the events, to appropriately configure the algorithm (El Yazidi et al., 2018; Wang et al., 2019b). In this context, collocated and/or additional nearby aerosol and trace gas data are useful to understand the origins and pervasiveness of local aerosol and to validate the application of different masking algorithms.

The first aerosol filter applied to ENA AOS data by Zheng et al. (2018) was used to study seasonal aerosol–cloud interactions. The authors used AOS CPC data to mask time periods when the first derivative of the submicron aerosol number concentration exceeded $60 \text{ particles cm}^{-3} \text{ s}^{-1}$. With this method, $< 20\%$ of data was masked within each one-hour averaging interval. Other potential methods, that require further development and validation, include the application of machine learning. The External Data Center (XDC) identified periods in ENA AOS data that were impacted by local combustion sources due to planes and runway operations at the Graciosa airport over a five day time period during the winter (Mitchell et al., 2017). Future efforts to develop and apply this code at ENA should be investigated but were beyond the scope of the work presented here.

We present data from two facilities at ENA, C1 and S1, during ACE–ENA to identify the local aerosol sources at ENA and to determine their influence on the AOS data. Submicron aerosol concentrations, size distributions, and meteorological data are presented. We develop a new aerosol mask at ENA using AOS data to identify periods of short-duration high concentration submicron particle events. Our mathematical algorithm and the determination of a regional baseline for submicron aerosol is validated using the data from C1 and S1. After determining the regional baseline, we compare AOS masked data with the AAF data collected during ACE-ENA flights over C1 to understand the vertical distribution of aerosol at ENA.

2 Measurements

2.1 ENA Central Facility (C1) and aerosol Supplementary site (S1)

The ENA Central facility (C1) is located on Graciosa Island within the Azores Archipelago at $39^{\circ} 5' 28'' \text{ N}$, $28^{\circ} 1' 36'' \text{ W}$. C1 is located on the northern part of the Island as the area is flat, has access to local power, and is mostly unpopulated (Fig. 1). High temporal-resolution measurements (seconds to minutes) of aerosol properties at C1 are made with the ENA AOS (McComiskey and Ferrare, 2016; Uin et al., 2019). The AOS at ENA C1 includes instruments for measuring aerosol optical, physical, and chemical properties, trace gases, and meteorological parameters. The AOS is comprised of one container that

samples aerosols using instrumentations connected to a central inlet located approximately 10 m above ground level (Bullard et al., 2017; Uin et al., 2019).

The Aerosol Supplementary site (S1) was deployed at 39° 5' 43" N, 28° 02' 02" W, ~ 0.75 km from C1 (Fig. 1), in July of 2017. S1 was sited within 1 km of C1 to maintain the relevance of S1 data to the AMF measurements at C1. S1 was located at ~0.2 km from the shore (closer than C1) at ~50 m a.s.l. Data was collected at S1 until the site was decommissioned in April of 2018 after the conclusion of ACE-ENA.

10 **Figure 1.** Satellite image of ENA C1 and S1 on Graciosa Island, Azores, Portugal (© Google Earth).

Three instruments, duplicate models of those used within the AOS at C1, were deployed at S1. Two aerosol instruments were selected for their ability to measure submicron aerosol concentrations in high time resolution. The third instrument was included to associate the measurements with meteorological parameters as is done in the AOS. The aerosol instruments were powered and located inside a converted garage in an unoccupied house, with the computer for data acquisition. The meteorology sensor was mounted above the inlet at ~3 m above the roofline. Measurements were designed to duplicate those made within the AOS as best possible without the use of an AOS inlet at S1. Prior to the deployment at S1, the instruments were calibrated at C1 alongside the AOS instruments. Ambient data from the three instruments were compared over a period of one week at S1. The S1 inlet flow rate was optimized to minimize submicron particle loss (Bullard et al., 2017).

20 Briefly, the fine mode Condensation Particle Counter (CPC) (TSI, Inc., Shoreview, MN, USA; Model 3772) measures the submicron number concentration (N_{tot}) of aerosols from ~ 7 nm to 1 μm in particle diameter (D_p). Particles are grown by condensing butanol vapour onto the particles before they are optically counted by illuminating them with a laser beam to count the number of light pulses that are scattered (Kuang, 2016). The Ultra-High Sensitivity Aerosol Spectrometer (UHSAS) (Droplet Measurement Technologies, Inc., Longmont, CO, USA) is an optically scattering, laser-based aerosol spectrometer for sizing particles from ~ 60 to 1,000 nm D_p . Aerosols scatter the laser light as a function of their optical D_p . The UHSAS detection efficiency is ~100% for particles > 100 nm and for concentrations < 3,000 cm^{-3} (Cai et al., 2008). Concentration measurement errors occur for smaller particles that have low scattered light intensities and during periods of higher N_{tot} due to particle coincidence. Sizing of spherical and irregular particles by the UHSAS are within 10% of the mobility diameters measured by the Scanning Mobility Particle Sizer (SMPS) for particles with $D_p > 70$ nm (Cai et al., 2008). Therefore, in this study, we use the UHSAS submicron data for particles > 70 nm (Uin, 2016). CPC and UHSAS sample flows are dried using

a shared Nafion dryer that reduces the relative humidity of the samples to $\leq 30\%$ (Uin et al., 2019). Since submicron data was collected at S1 and compared with the submicron data collected at C1, we make no inferences on supermicron particles. The meteorology sensor (Met) (Vaisala, Finland; WXT520), provides ambient air temperature, relative humidity, atmospheric pressure, wind speed and direction relative to true North, and precipitation data (rain amount, duration and intensity) (Kyrouac, 5 2016).

2.2 ARM Aerial Facility (AAF)

The ARM Aerial Facility (AAF) Gulfstream-159 (G-1) research aircraft flew from Terceira Island (~90 km from the ENA C1 site) during two IOPs in early summer 2017 (June to July) and winter 2018 (January to February). Flight patterns included spirals to obtain vertical profiles of aerosol and clouds and ascendant and descendent legs at multiple altitudes to provide 10 characterization of the boundary layer and lower free troposphere structure. Data were collected up to an altitude of ~4,970 meters.

N_{tot} collected by the AAF with the CPC (TSI, Inc., Shoreview, MN, USA; Model 3772) during the summer were compared to CPC data collected at C1 and S1. The CPC was installed behind an isokinetic inlet to minimize particle loss in aircraft sampling 15 and was operated on the AAF G-1 (Schmid et al., 2014). During the first ACE-ENA IOP there were 20 Research Flights (RF). We analyzed data from the seven flights that collected data over C1 at low altitudes between 54 and 500 meters.

3 Data analysis

3.1 C1 and S1 intercomparison

We present and evaluate different strategies to identify periods when the AOS data are impacted by high submicron aerosol 20 concentrations and associate them with nearby potential aerosol sources. The impact of local aerosol sources at ENA C1 are evaluated by comparing data collected at C1 and S1. We analyzed two one-month time periods that represent two seasons: summer (7/22/17 – 8/20/17) and winter (12/01/17 – 12/30/17).

Measurements from the UHSAS and CPC are combined to describe the submicron aerosol size distribution by dividing the 25 data into three optical size modes. Zheng et al. (2018) used lognormal fitting of the submicron aerosol size distributions from the UHSAS to define three modes to study aerosol–cloud interactions at ENA. The lognormal fittings gave three parameters: mode diameter, mode number concentration, mode σ (standard deviation), (Table 2 in Zheng et al. (2018)). Number concentrations (N) of the fitted modes were classified by the mode diameter into three bins: (1) N_{At} , number concentration of Aitken (At) mode aerosol ($D_p \leq 100$ nm), (2) N_{Ac} , number concentration of Accumulation (Ac) mode aerosol ($D_p = 100 - 300$ 30 nm), and (3) N_{LA} , number concentration of Large Accumulation (LA) mode aerosol ($D_p = 300 - 1,000$ nm). The N_{Ac} and N_{LA} mode number concentrations reported here are directly measured by the UHSAS. Since there is not a direct measurement of the full range of At mode particles, N_{At} is determined by combining the measurements from the CPC and the UHSAS. N_{At} is calculated as the difference between the N_{tot} , as measured by the CPC, and the sum of the UHSAS number concentrations from the two larger modes: $N_{At} = N_{tot} - (N_{Ac} + N_{LA})$. All D_p referenced in the text refer to aerosol optical diameter unless they are 35 stated as otherwise.

One way to determine statistical outliers in the data is by comparing the difference between the median and the mean. Time periods when the median and mean N_{tot} differ significantly are used to indicate periods when the data is affected by outlying 40 events, such as high number concentration aerosol events. Median values represent the midpoints in the data, which are minimally affected by outlying events. Mean values describe the central tendency of the data and are affected by outlying

events. As such, comparison between the two values provides information about the variability within the overall dataset. Erroneous data and their ARM quality assurance/quality control (QA/QC) flags (e.g. negative values and -9999) have been removed prior to the analysis presented here. Significant deviations between the mean and median concentrations, where the mean is biased high, are used to indicate when aerosol N_{tot} have a statistically relevant higher variability due to the presence of high concentration aerosol events.

3.2 ENA Aerosol Mask (ENA-AM)

ENA Aerosol Mask (ENA-AM) is a standard deviation algorithm that was parameterized for the ENA N_{tot} data collected by the CPC. Application of the algorithm requires the statistical differences between adjacent data points to distinguish periods of short-duration high aerosol number concentrations from the baseline measurements. The time resolution of the data has to be shorter than the typical time period of the high concentration events. The variation within the clean baseline periods also has to be smaller than the variation of N_{tot} during the high concentration events. Therefore, the algorithm works best with high time-resolution data, as is collected by the AOS at time intervals on the order of seconds to minutes, and for identifying local sources that have high temporal variability. An additional requirement is that at least half of the total data points have to be representative of the baseline conditions otherwise the algorithm is not able to identify the high N_{tot} events properly. The flow chart in Figure 2 describes the requirements and recommended procedures to apply the algorithm to data affected by local aerosol events. A perfect algorithm would identify only the noise and retain all of the natural variability. Since data may include periods when the local sources are less variable than the natural baseline no separation will be perfect. Here, we test and develop an algorithm optimized to balance the separation of the noise from the baseline. The one-minute N_{tot} data collected at C1 and S1 fulfil these requirements, and we, therefore, developed ENA-AM as described below using two one-month periods of data collected at ENA (Aiken and Gallo, 2020; Gallo and Aiken, 2020a; Gallo and Aiken, 2020b).

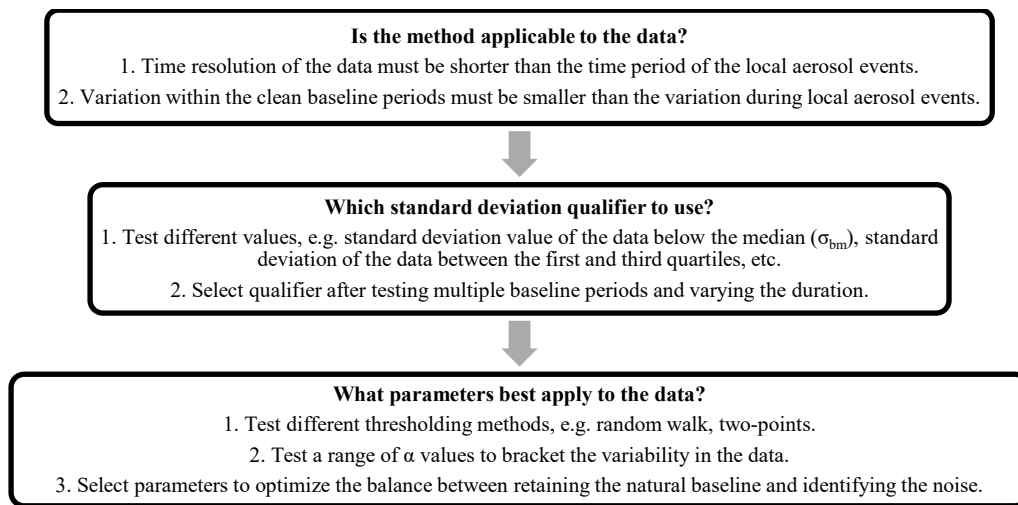

Figure 2. Flow chart to apply the standard deviation algorithm to high time-resolution aerosol data.

We determined the standard deviation of the data below the median (σ_b) of N_{tot} for each of the two one-month periods. Any data point that differs by more than α times the σ_b from the preceding data points is identified and masked as a high concentration aerosol event. The retained data points are defined as the baseline. The variable α is used to set the threshold, and its value is defined as a function of the specific dataset and time series variability. The utilization of one-month time periods was chosen to limit biases in the characterization of the regional baseline after testing a range of periods from two weeks to two months. At ENA, we observed that when using longer periods of time (> 6 weeks), σ_b removed the long-term variability associated with seasonal changes. Simultaneously, considering shorter time periods (< 2 weeks), σ_b was unable to retain periods when ENA was affected by episodes of long-range transported continental aerosols. An alternative

parameterization would be to use the standard deviation between the first and the third quartiles. This approach has been shown to be effective for masking continuous time series of greenhouse gas measurements that present daily and monthly natural fluctuations and positive short-term spikes (seconds to minutes) due to local emissions (El Yazidi et al., 2018). We tested this alternative at ENA and observed similar results for both methods. The data filtered using σ_b agreed with the data filtered between the first and third quartiles 98.6% of the time.

Whenever a data point is identified above the threshold, the next point in the time series is evaluated using a random walk method (threshold = $(\sigma_b + \text{sqrt}(n)) * \alpha$), where n is the number of data points since the last data point that was within the standard variability. In this way, the threshold is slightly increased to account for normal temporal development of the baseline. If the density of the high concentration particle events is high, the algorithm is not able to identify the baseline variability properly. In such cases, α should be set to a lower value, and the random walk method threshold might be better substituted with a two-point thresholding method. With two-point thresholding, the two data points after each masked point are considered to be part of the event. Thus, the value of α and the thresholding method are dependent on the time series variability as is the selection of the time period over which to apply the algorithm. Selection of both must be optimized for the specific dataset.

We tested six different parametrizations of the algorithm, which included two α values and the two thresholding methods as well as different time lengths. Table 1 presents the combination of α values and thresholding methods used. A sensitivity analysis was conducted to determine the best parametrization of the algorithm for N_{tot} measurements at ENA. After the parameters for ENA-AM were determined, we compare masked C1 with AAF N_{tot} measurements.

Table 1. Standard deviation algorithm input parameters tested at C1 and S1 in the summer.

	Random Walk (RW) Threshold	Two-Point (TP) Threshold
$\alpha = 0.5$	$\alpha 05\text{-RW}$	$\alpha 05\text{-TP}$
$\alpha = 1$	$\alpha 1\text{-RW}$	$\alpha 1\text{-TP}$
$\alpha = 3$	$\alpha 3\text{-RW}$	$\alpha 3\text{-TP}$

4 Results and discussion

4.1 High concentration aerosol events

Wind directions can be used with aerosol measurements to determine aerosol sources (Zhou et al., 2016; Cirino et al., 2018). To understand the frequency and direction from which local aerosols originate at ENA, we present mean aerosol N_{tot} and N_{UHSAS} as a function of wind direction. N_{tot} and N_{UHSAS} are used to understand the directional and temporal influence of observed high aerosol concentrations at C1 and S1 and to evaluate the use of wind direction data to create an aerosol mask at ENA.

In Fig. 3, one-minute N_{tot} , N_{UHSAS} and wind measurements were averaged as a function of wind degree direction in the summer and winter. A detailed analyses of wind speeds and wind directions at ENA during summer and winter is presented in the Supplemental Information (SI) (Section S1). When plotted by wind degree direction, we observed $N_{tot} > 1,000 \text{ cm}^{-3}$ at C1 and S1. Mean N_{tot} for all directions in the summer were 710 cm^{-3} (C1) and 490 cm^{-3} (S1). N_{UHSAS} mean concentrations were less than half of N_{tot} during the same time periods: 342 cm^{-3} (C1) and 210 cm^{-3} (S1). The higher N_{tot} is due to a significant fraction of aerosol below the UHSAS lower detection size limit of 70 nm since the instruments have similar upper limits for counting particles. Without the N_{tot} that counts particles $< 70 \text{ nm } D_p$, the high concentration aerosol would be harder to identify by wind

direction alone due to the lower variability in N_{UHSAS} . For this reason, we continue our analysis by wind direction focusing on N_{tot} .

The largest mean N_{tot} plotted by wind degree direction that was observed at C1 was $\geq 3,000 \text{ cm}^{-3}$ (Fig. 3a, c) during summer and winter when the winds were from the west to northwest, wind directions that are associated with the airport (see Fig. 1; Supplemental Information (SI) and Table S1). These directions were attributed to the utilization of the runway and the airplane parking lot with AOS camera visual validations of aircraft. The next highest N_{tot} were observed from the south to southeast at C1. $N_{tot} \geq 1,000 \text{ cm}^{-3}$ were observed in the summer and $N_{tot} \geq 1,600 \text{ cm}^{-3}$ in the winter. These directions are associated with the direction of the road that leads from the airport to the town of Santa Cruz (Figs. 1 and SI.1).

10

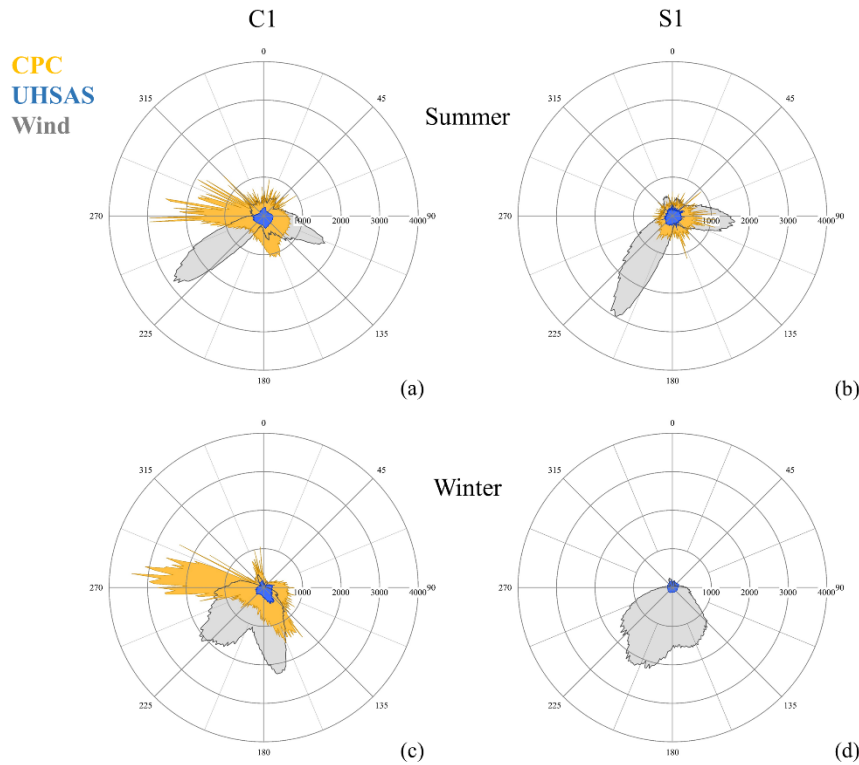

Figure 3. Polar graphs of the mean N_{tot} and N_{UHSAS} as a function of wind direction during summer (a, b) and winter (c, d) at C1 and S1. One-minute N_{tot} from the CPC, in orange (data not available at S1 in the winter), and N_{UHSAS} from the UHSAS, in blue, were averaged as a function of wind degree direction. The frequency of wind direction is in grey.

15

While mean N_{tot} were lower at S1 than C1, S1 also had $N_{tot} > 1,000 \text{ cm}^{-3}$ (Fig. 3b). The three highest N_{tot} at S1 that exceeded $1,000 \text{ cm}^{-3}$ were observed from the south-southeast, east-southeast and east. The wind directions of the maxima N_{tot} were associated with the airport runway, rural road, and pasture at S1. Wind directions with $N_{tot} \sim 1,000 \text{ cm}^{-3}$, observed from the northeast, were likely due to the rural road along the shore. $N_{tot} \sim 500 \text{ cm}^{-3}$ from the southwest were from the direction of the decommissioned landfill that still has active vents as well as the airport runway. N_{tot} was not available during the winter at S1 to make a comparison with summer.

20

The results of the wind direction analysis indicates that the main sources of $N_{tot} \geq 1,000 \text{ cm}^{-3}$ at C1 and S1 are most likely associated with airport activities and road traffic due to the proximity and direction of the sources. However, at ENA, other unattributed local sources, not related to airport operations could also be present that are not identified here. One example of an aerosol source that we could not verify was a potential brick production facility $\sim 1 \text{ km}$ to the south-southeast of C1.

25

Complex meteorological conditions known to exist in the region might also be responsible for high N_{tot} at C1 and S1 that we were not able to attribute to local sources based on wind direction.

4.2 Submicron aerosol modes

5 Number concentrations from three aerosol modes that we defined in Section 3.1 are presented in Fig. 4 from C1 and S1 in the summer and winter. The smallest mode number concentration, N_{At} , represents the size range most likely impacted by nearby combustion sources (aircrafts and gasoline and diesel vehicles) as discussed in the Section SI.3 of the Supplemental Information. N_{Ac} is expected to include some of these particles as well, especially for the less efficient combustion sources and operational modes, such as those produced by diesel engines and wood burning sources that may or may not be significant at
10 ENA, and are not discussed here due to their unconfirmed use on the island. The third and largest mode number concentration, N_{LA} , is not expected to be significantly impacted by nearby combustion aerosol sources. However, N_{LA} is presented since it includes natural aerosol sources such as sea spray (Burrows et al., 2014; Quinn et al., 2015) and secondary organic aerosol (Jimenez et al., 2009; Shrivastava et al., 2019) that can also be formed in association with combustion sources.

15 For the three submicron size modes analyzed at C1 and S1, N_{At} had the largest median and mean number concentrations, equating to 44% of the median and 31% of the mean for the total submicron aerosol concentrations, N_{tot} , when averaged from the different sites and seasons. N_{At} also had the highest deviation between the mean and median of the three size modes during the summer and winter. Median N_{At} at C1 were relatively constant at 245 cm^{-3} in the summer and 258 cm^{-3} in the winter. Median N_{At} at S1 was 78% of C1 with 190 cm^{-3} in the summer. While median N_{At} were relatively constant for the data shown
20 here at both seasons and sites, mean N_{At} varied with site and season. Mean N_{At} were 540 cm^{-3} (C1) and 330 cm^{-3} (S1) in the summer (Fig. 4a). In the winter at C1, the mean N_{At} was 800 cm^{-3} , which was 48% higher than what was observed in the summer (Fig. 4b).

The higher observed mean N_{At} at C1 during the winter indicated that the influence of nearby aerosol sources was likely to be
25 larger in the winter than in the summer. This result is supported by the earlier results from N_{tot} (Section 4. 1: Fig 3a, c) and the submicron size distributions (SI.3b). The reason for the higher fraction of N_{At} observed in the winter at C1 could have been due to additional seasonal sources that were not attributed here, such as the burning of wood or other fuels to heat homes, etc. Different meteorological conditions experienced in the winter versus the summer could also have contributed to the seasonal differences. For example, higher N_{At} from the known sources discussed in SI.3 might also be due to different winter
30 meteorological conditions, e.g. lower boundary height, higher wind speeds, etc.

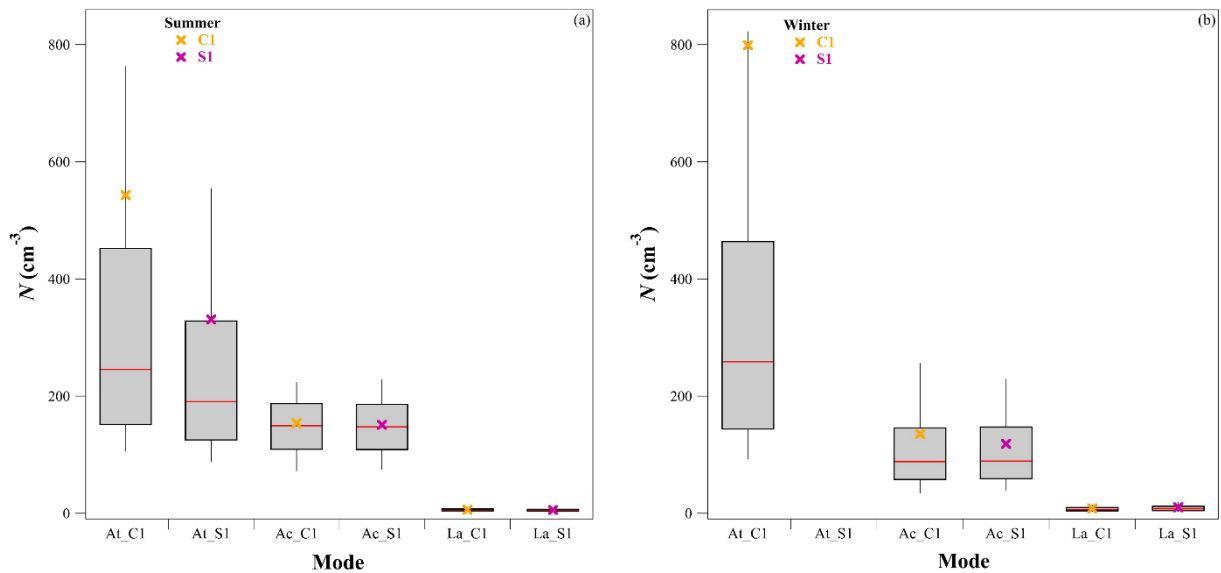

Figure 4. Box and whisker plot of At, Ac and La mode aerosol number concentrations at C1 (orange) and S1 (pink) in the (a) summer and (b) winter. Mean (x) and median (red line). Box bottom at 25%, box top at 75%, whisker bottom at 10%, and whisker top at 90%. No At mode data was available at S1 during the winter.

5

Mean and median N_{Ac} were lower than N_{At} during summer and winter at C1 and S1, yet still represented a significant fraction of N_{tot} . In the summer, C1 and S1 N_{Ac} had similar mean and median values, indicating low variability in the data. Mean N_{Ac} observed were 160 cm^{-3} (C1) and 151 cm^{-3} (S1). Median N_{Ac} were 156 cm^{-3} (C1) and 147 cm^{-3} (S1). The similar values between the mean and median N_{Ac} at both sites indicated that the mode was not largely affected by high concentration aerosol events.

10 In the winter, mean N_{Ac} were 13% (C1) and 22% (S1) lower than mean N_{Ac} in the summer. Mean N_{Ac} were 140 cm^{-3} (C1) and 118 cm^{-3} (S1). Median N_{Ac} were 91 cm^{-3} (C1) and 89 cm^{-3} (S1). Overall, N_{Ac} at C1 and S1 were more similar than N_{At} in summer and winter. However, there was a higher variability between the mean and median N_{Ac} observed during the winter that was not observed in the summer (see SI.3 and SI.4 for discussion).

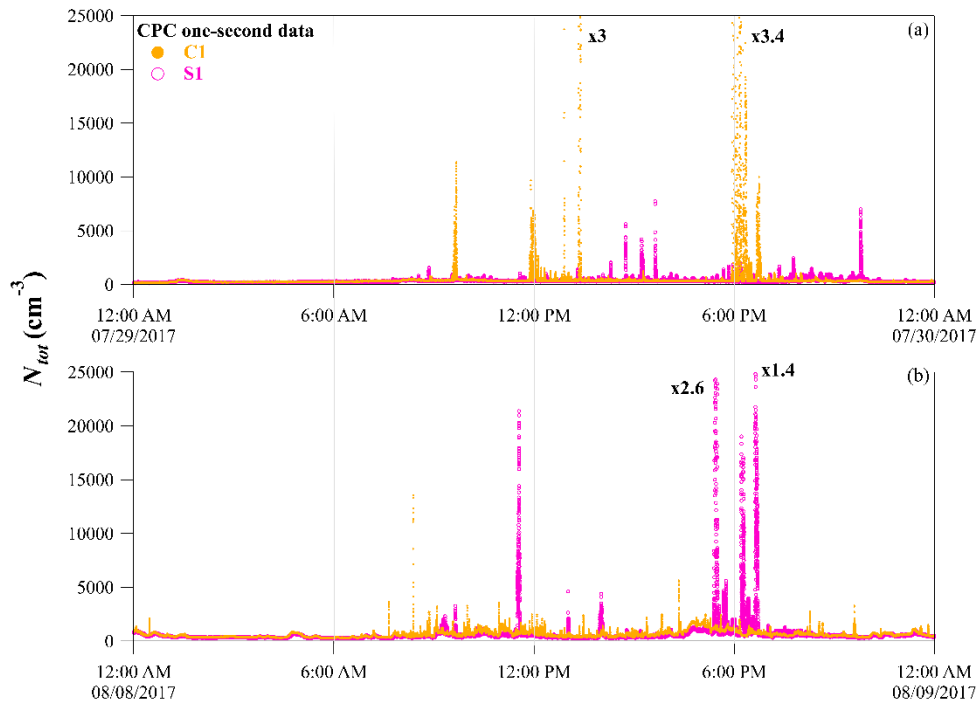

15 N_{LA} did not represent a significant fraction to N_{tot} at ENA for the data presented here. Mean N_{LA} during the summer were 6 cm^{-3} at C1 and S1. Similar N_{LA} were observed in the winter at 8 cm^{-3} at C1 and 10 cm^{-3} at S1. While N_{LA} is important in regard to mass concentrations, scattering properties, and cloud condensation nuclei, all properties measured by the AOS (Uin et al., 2019), N_{LA} are not generally attributed to local combustion aerosol sources, which is the focus here. Contributions and impacts to N_{LA} due to sea spray aerosol were beyond the scope of this work, yet were not considered to be a large contribution at C1 or
 20 S1 based on the low N_{LA} observed here.

4.3 High time-resolution data

Time series of N_{tot} at C1 and S1 indicated that both locations periodically sample high concentrations over time periods < 4 minutes. High N_{tot} such as these are typically the result of local sources due to their high concentrations and short durations which would become less evident at greater distances from the source. Since aircraft idling, taxiing, take-off, and landing are
 25 all potential times when high N_{tot} could be sampled at C1 and S1, we used the Graciosa airport flight logs and the AOS camera observations to validate high time-resolution N_{tot} data at ENA.

In Fig. 5, we present two one-day periods sampled at C1 and S1 during the summer. $N_{tot} > 25,000$ particles cm^{-3} were observed on a daily basis at C1 in the raw one-second data (Fig. 5a). Lower N_{tot} daily maximum concentrations $> 11,000 \text{ cm}^{-3}$ were
 30 observed at S1. Winter N_{tot} daily maximums at C1 were $> 20,000 \text{ cm}^{-3}$ with maximum concentrations occasionally $\sim 80,000 \text{ cm}^{-3}$. Figure 5b shows a time period when the overall trend is the reverse of Fig. 5a when higher N_{tot} were observed at S1 in

comparison to C1. While this period did not represent the overall trend in N_{tot} between C1 and S1, it is included to show that C1 and S1 both observed N_{tot} maximums at different times and that both sites were impacted by high concentration aerosol events in high time-resolution.

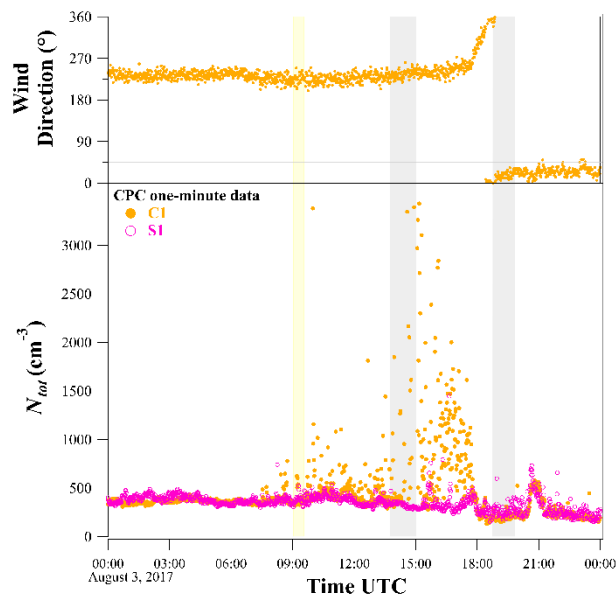

5

Figure 5. One-second N_{tot} during two one-day periods at C1 (orange) and S1 (pink) raw in the summer. (a) Typical day when C1 sampled higher N_{tot} than S1, (b) atypical day when S1 sampled higher N_{tot} than C1. To highlight the smaller peaks, the four highest peaks are off-scale by the factors indicated in the figure.

- 10 Graciosa airport on average hosts two flights a day, the first typically in the late morning/early afternoon, and the second in the late afternoon. The airport time tables for 2017 and 2018 reported that planes landed and took off from Graciosa Island during three distinct time periods throughout the day: ~17% of the planes arrive at Graciosa airport between 8:30 and 11:00 UTC, ~26% between 13:00 and 15:00 UTC, ~56% between 17:00 and 20:00 UTC. Taking into account the wind direction, planes typically land from the east and take off from the west. We confirmed that, during the summer, 97% of the flights
- 15 occurred in this direction by analysing the daily video from the AOS cameras at C1. However, due to the runway's limited length, planes often utilize the full length of the runway, which was observed in N_{tot} at C1 and S1. Such occurrences affected N_{tot} at C1 the most when the wind direction was between northeast and west, and S1 when the wind came from the east to southwest.
- 20 To further understand the potential influence of the airport operations on N_{tot} at C1 and S1, we examined a one-day time period in detail. In Fig. 6, we present C1 and S1 one-minute time-resolution N_{tot} on August 3, 2017. N_{tot} at S1 was largely unaffected by the short duration high concentration aerosol events as N_{tot} never was $> 1000 \text{ cm}^{-3}$. While this is only a one-day time period and was by no means representative of daily N_{tot} , we show it as an example of the complexity within N_{tot} at ENA.
- 25 Throughout the day, abrupt changes in wind direction were observed. Winds from the south, southwest and west dominated until 17:58 UTC. Starting at 18:00 UTC, the dominant wind directions were northwest, north and east. Analysis of the video from the AOS camera at C1 showed that diesel trucks were on the runway from 09:07 UTC to 09:27 UTC for daily maintenance. At two times during the afternoon, 13:42 to 15:02 UTC and 18:46 to 19:51 UTC, the aircraft was idling near the airport terminal (Fig. 6). During the first part of the day, when the wind directions were from the south and west, $N_{tot} > 1000$

cm^{-3} at C1 at numerous times. In the SI we identify these directions at C1 with the airport terminal, parking lot, and the road to the airport. Later in the day, when the winds were coming from the northwest to east, in the direction of the runway at C1, $N_{tot} < 1000 \text{ cm}^{-3}$ at C1 were similar to N_{tot} at S1.

- 5 The high N_{tot} events at C1 and S1 were associated with the airport activities and increased road traffic that generally occurred before the arrival and after the departure of the aircraft, based here on visual observations, airport flight logs, and wind degree direction analysis. The aircraft and vehicle impacts were observed by sharp peaks occurring on timescales on the order of minutes when N_{tot} was an order of magnitude above the baseline signal. In contrast, the airport operations tended to cause periods of elevated N_{tot} that occurred over longer timescales on the order of hours. Therefore, the impact of the airport, its operation and associated traffic on the AOS data at ENA could not be constrained to the arrival and departure times of the aircraft since it was also impacted by airport operations that occurred throughout the day and the wind direction in relation to C1 and S1.

- 15 **Figure 6.** N_{tot} and wind direction at C1 (orange) and S1 (pink) on August 3, 2017. Yellow and grey periods indicate when the AOS cameras observed trucks on the runway (yellow) and planes near the terminal building (grey).

- While the influence of the airport operations may not be readily apparent from the short duration high concentrations observed at C1 and S1 (Fig. 5), further information constraining this influence was obtained by looking at the diurnal cycle of mean and median N_{tot} at C1 (Fig. 7). The three hourly periods with highest mean N_{tot} were observed during 9:00 to 10:00 UTC at 916 cm^{-3} , 13:00 to 14:00 UTC at 860 cm^{-3} , and 17:00 to 18:00 UTC at 1,595 cm^{-3} . These three elevated mean N_{tot} periods occurred during the three time periods when the airport flight logs on average observed flights. These periods were identified using the airport flight logs and are shown as the black boxes in Fig. 7. Mean N_{tot} from 7:00 to 8:00 UTC reached a value of 615 cm^{-3} . The highest mean N_{tot} was observed during the third time period identified by the airport to host on average half of the daily flights, while the two earlier time periods were only associated with ~25% of the flights each. Two other high mean N_{tot} periods were observed during the diurnal profile at C1. Mean N_{tot} were 615 cm^{-3} from 7:00 to 8:00 UTC, that occurred during a similar time that the AOS cameras observed the daily maintenance of the runway with diesel trucks from 7:45 and 8:30 UTC. The second period from 20:00 to 21:00 with mean $N_{tot} > 800 \text{ cm}^{-3}$ was attributed to unknown potential aerosol sources at this time.

The diurnal variation observed in the mean N_{tot} at C1 in the summer was not observed in the median N_{tot} . Hourly averaged medians exhibited low variability throughout the day with a minimum of 380 cm^{-3} during the night between 23:00 and 24:00 UTC. A maximum of 506 cm^{-3} was observed in the late afternoon between 17:00 and 18:00 UTC.

- 5 At ENA, the periods with the largest deviation between the median and mean N_{tot} were the three periods when most of the flights occurred at the airport. A diurnal variation was observed in the mean N_{tot} , yet was not statistically relevant for the median N_{tot} of the same data at C1 and S1. While not shown here, S1 had a similar trend in the diurnal profile to what was observed at C1 in the summer. The main difference was that the mean N_{tot} were all $< 1,000 \text{ cm}^{-3}$. Winter data at C1 also had the highest mean N_{tot} and their deviations from the medians during the hours of airport operations. We use the information from the diurnal profiles at ENA to validate the statement that the airport operations and associated activities were the largest sources of high concentration N_{tot} observed at ENA.
- 10

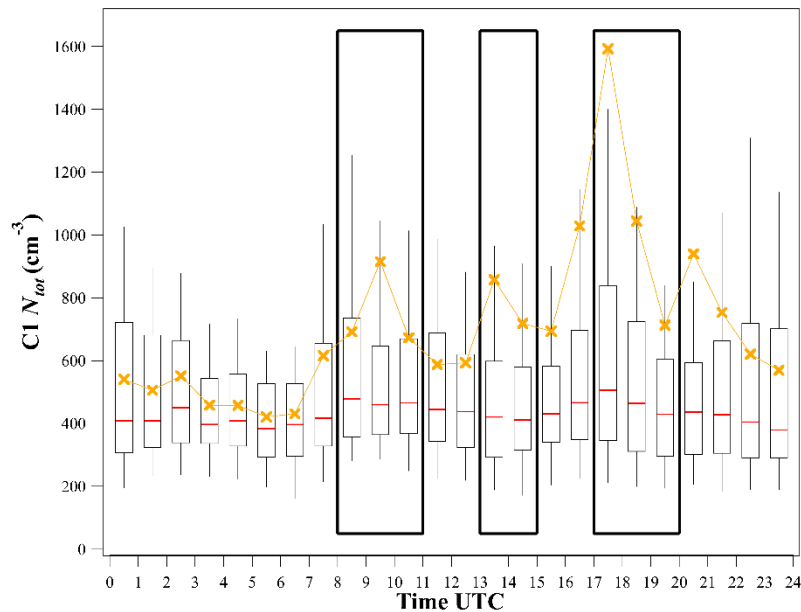

Figure 7. Box and whisker diurnal profile of N_{tot} at C1 during summer. N_{tot} mean (orange x) and median (red line). Black boxes from 08:00-10:00, 13:00-15:00 and 17:00-20:00 UTC indicate the three daily time periods when aircraft were present at the Graciosa airport.

15

4.4 High number concentration aerosol event mask

4.4.1 Algorithm parametrization and validation

- To apply a mathematical algorithm to mask high N_{tot} events at C1 and S1, we first calculated the standard deviation of the data below the median (σ_b). We found σ_b values of 298 cm^{-3} and 264 cm^{-3} for C1, respectively in the summer and winter, and σ_b values of 234 cm^{-3} for S1 in the summer. Then, we conducted a sensitivity test to select the optimal parametrization of the algorithm to apply to the one-minute resolution N_{tot} data at ENA using the combination of the α parameter and thresholding method shown in Table 1, Section 3.2. First, we analyzed the efficiency of six parametrizations to detect high N_{tot} aerosol events that were independently validated using additional collocated measurements at C1 (AOS camera and airport flight logs).
- 20
- 25 Subsequently, we assessed the percentage of data removed and the R^2 generated between masked N_{tot} at C1 and S1. Finally, we evaluated the ability of the best parametrizations to discriminate short-lived high N_{tot} events from periods when ENA was affected by long-range transported continental aerosol. In our analysis, we use one-month time periods as the utilization of longer periods was found to bias the characterization of the regional baseline due to seasonality, which could accentuate long-

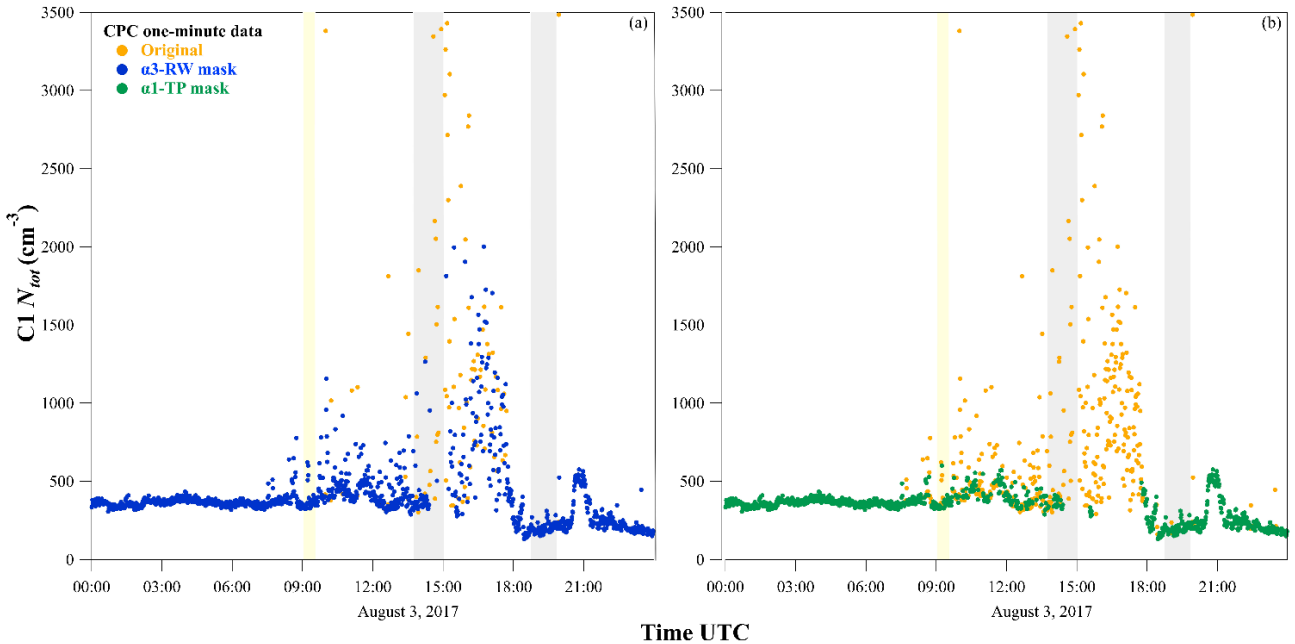

term variabilities and confuse the high signal of local events (El Yazidi et al., 2018). Previous studies use the random walk (RW) threshold for aerosol data. Drewnick et al. (2012) proposed using $\alpha = 3$ to remove sharp and short peaks lasting a few seconds in N_{tot} from CPC and gas-phase CO measurements from a mobile aerosol research laboratory. The authors found that the application of the $\alpha 3$ -RW parameterization worked well when the density of the high concentration events was low.

5 Similarly, El Yazidi et al. (2018) used $\alpha 1$ -RW with gas-phase CO₂ and CH₄ data at four different stations in Europe that were affected by sharp events over time periods of a few minutes. The $\alpha 1$ -RW parameterization was able to detect ~96% of the events that were visually identified by the station manager. Therefore, we began at ENA by testing three α values with the RW threshold that were used in these two studies.

10 We present, in Fig. 8, the results from the application of the algorithm over the same twenty-four-hour period that we analyzed in Section 4.3, Fig. 86. The first three parameterizations selected, $\alpha 05$ -RW, $\alpha 1$ -RW and $\alpha 3$ -RW, were able to identify the first data points during a high N_{tot} event, but were not able to identify events that occurred for extended periods of time on the order of hours, as is shown in Fig. 8a for the application of $\alpha 3$ -RW at C1. While $\alpha 05$ -RW and $\alpha 1$ -RW are not included in the figure for simplicity, similar results were produced from these parameterizations. Next, we constrained the threshold more by applying the TP method with the same α values. For both C1 and S1 sites and seasons, the $\alpha 05$ -TP (not shown for simplicity)

15 and the $\alpha 1$ -TP parameterization were the only parameterizations able to identify longer duration events that lasted from minutes to hours, as were experienced due to airport operations as shown in Fig. 107b. Results from $\alpha 3$ -TP were not included in the figure as the combination of the relaxed α and constrained two point threshold parameters, $\alpha 3$ -TP, yielded similar results to the RW threshold parameterizations tested previously. The $\alpha 3$ -TP parameterization was not able to identify the longer duration

20 high N_{tot} events. In conclusion, when high N_{tot} events had durations on the order of hours, the difference in the signal between the adjacent points was not high enough to be identified by either the RW threshold or the higher $\alpha=3$ parameter combinations tested at C1.

25 **Figure 8.** Original (orange points) and masked N_{tot} at C1 using (a) $\alpha 3$ -RW (blue points) and (b) $\alpha 1$ -TP (green points) parameterizations over a twenty-four-hour period on 8/3/2017. Yellow and grey boxes indicate periods when the AOS cameras at C1 detected trucks and planes, respectively, on the runway.

Similar results were obtained when we tested the six parameterizations of the algorithm on N_{tot} at S1, not shown. As we

30 observed at C1, the tightest combinations of parameters, $\alpha 05$ -RW and $\alpha 1$ -TP, were able to most accurately identify all of the high N_{tot} events of all the parameterizations tested here. The higher α values and the random walk threshold relaxed the

algorithm such that the number of data points identified was likely to underestimate the number and duration of high N_{tot} events observed at ENA.

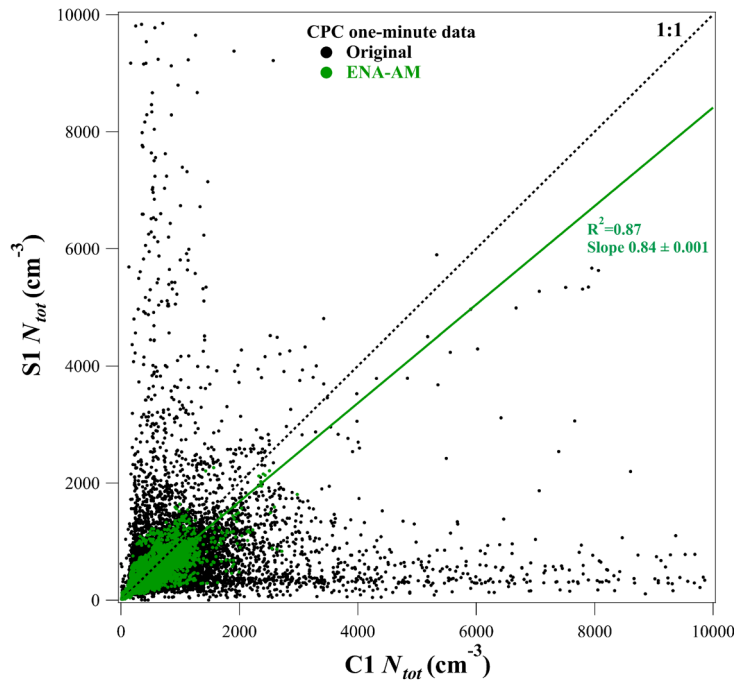

5 Due to the diverse high N_{tot} events and local sources at ENA, the R^2 value between N_{tot} measurements collected at C1 and S1 in the summer was minimal (Fig. 9, $R^2 = 0.03$, slope = 0.05 ± 0.001). In Table 2, we show a comparison of the percentage of data that was masked and the R^2 values with corresponding slopes after applying the parametrizations of the algorithm.

Table 2. R^2 values and percentage of masked N_{tot} data during summer at C1 and S1 using six different combinations of the α parameter and thresholding methods.

ENA Site		RW			TP		
		$\alpha = 0.5$	$\alpha = 1$	$\alpha = 3$	$\alpha = 0.5$	$\alpha = 1$	$\alpha = 3$
R^2		0.71	0.76	0.72	0.88	0.87	0.79
Slope $\pm \sigma$		0.80 ± 0.001	0.78 ± 0.001	0.75 ± 0.001	0.86 ± 0.001	0.84 ± 0.001	0.79 ± 0.001
Data Masked	C1	19.3%	12.5%	5.4%	35%	26%	10.6%
	S1	12.4%	7%	3%	23%	15%	5.6%

10

Application of the RW threshold generated R^2 values ≤ 0.8 between C1 and S1 independent of α . The highest α value ($\alpha = 3$) with the TP threshold generated similarly low regressions between the two ENA sites ($R^2 = 0.79$, slope = 0.79 ± 0.001) confirming that the $\alpha 3$ -TP parameterization was not able to detect all of the local aerosol events. After applying the $\alpha 0.5$ -TP and the $\alpha 1$ -TP parameterizations, the linear regressions and slopes were closer to unity. $\alpha 0.5$ -TP generated a $R^2 = 0.88$ with a slope = 0.86 ± 0.001 and $\alpha 1$ -TP a $R^2 = 0.87$ with a slope = 0.84 ± 0.001 (data fit through zero by orthogonal distance regression).
 15 The percentages of masked data were 35% ($\alpha 0.5$ -TP) and 26% ($\alpha 1$ -TP) at C1 and 23% ($\alpha 0.5$ -TP) and 15% ($\alpha 1$ -TP) at S1. C1 retained a higher N_{tot} , likely due to incomplete removal of sources discussed in Section 4.1 and in SI.4. The variability in the original N_{tot} s due to high concentration aerosol events was removed and a regional baseline was able to be identified based on the agreement between the two locations within measurement and mask uncertainties.

20

Figure 9. Scatter plot of N_{tot} at C1 and S1 in the summer. Original one-minute data (black) is shown with ENA-AM masked data (green).

Furthermore, we evaluated the ability the $\alpha 0.5$ -TP and the $\alpha 1$ -TP parameterizations to mask short-lived high N_{tot} events during periods when ENA was sampling long-range transported aerosol. Periods with elevated aerosol concentrations due to long range-transported continental sources have been observed to occur at ENA for durations on the order of days to weeks (Zheng et al. 2018). Through the analysis of back trajectories and aerosol optical properties, here we identify and present an episode of transported aerosol from Central Africa and the Canary Islands from January 7 to 12, 2017 (Fig. 11a). During this time, N_{tot} at ENA remained above 700 cm^{-3} . The transported aerosol was likely due to a mixture of mineral dust and carbonaceous aerosol species from biomass burning sources (Logan et al., 2014), as have been observed from other continental sources at ENA. After applying the two parametrizations of the algorithm, we observed that during the long-range transported aerosol event, at C1, the $\alpha 05$ -TP approach removed 47% versus 29% of the data with $\alpha 1$ -TP. The $\alpha 05$ -TP algorithm was not able to discriminate between variations in the baseline due to regional processes, e.g. entrainment of particles from the free troposphere due to long-range transport events shown in Fig. 10, from weak local aerosol events from unattributed local sources. After applying the $\alpha 1$ -TP parameterization to N_{tot} at C1 we observed that the majority of the data associated with the multiday event were retained with the baseline N_{tot} . Simultaneously, the short duration high N_{tot} events, attributed to local sources, were also removed (Fig. 10b). We use the results from this case study to further validate the application of ENA-AM using $\alpha 1$ -TP with one-minute N_{tot} data during periods when multi-day entrained long-range transported aerosol were sampled at ENA.

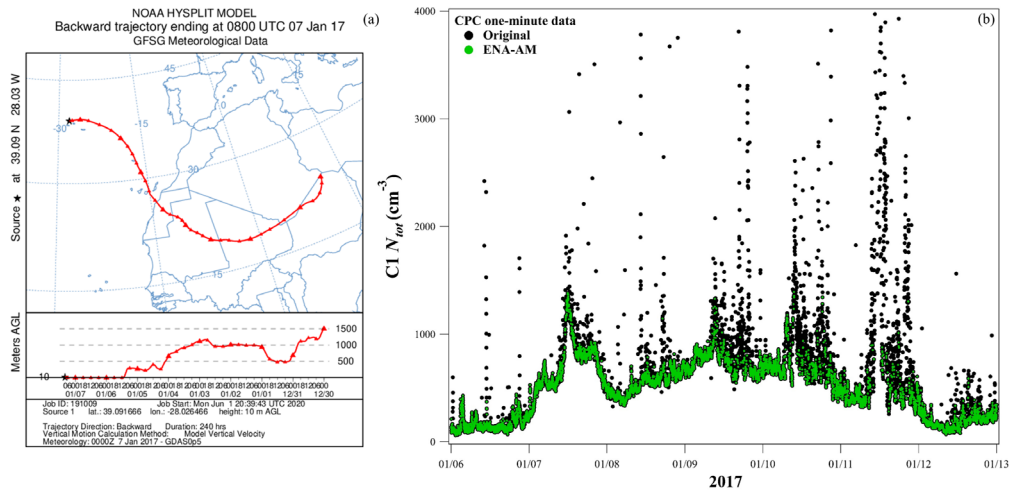

Figure 10. An episode of long-range transported of continental aerosol at C1 determined (a) with an 8-day back trajectory arriving at 10 m a.g.l. and (b) elevated N_{tot} with original (black) and masked (green) data using ENA-AM.

Therefore, we used the $\alpha 1$ -TP parameterization to create an aerosol mask at ENA, heretofore referred to as the ENA Aerosol Mask (ENA-AM), using one-minute resolution N_{tot} . At ENA the one-minute N_{tot} had sufficient time resolution to mask the high N_{tot} events. Application to the higher time-resolution one-second N_{tot} data was not necessary based on the validation of ENA-AM presented here and saves computational time when analyzing continuous data.

4.4.2 Identification of a regional baseline and impact of ENA-AM on N_{tot} and N_{Ac}

After the application of ENA-AM, we observed that mean, deviation between mean and median, and standard deviation N_{tot} all experienced reductions. In Table 3 we show mean, median and standard deviations for the original and ENA-AM masked N_{tot} and N_{Ac} measurements at C1 and S1 in the summer and winter. After applying ENA-AM to C1 N_{tot} , mean and standard deviation values dropped from $707 \pm 2780 \text{ cm}^{-3}$ to $428 \pm 228 \text{ cm}^{-3}$ in the summer and from $537 \pm 630 \text{ cm}^{-3}$ to $347 \pm 223 \text{ cm}^{-3}$ in the winter. At S1, the decrease was lower yet still significant, from $489 \pm 370 \text{ cm}^{-3}$ to $384 \pm 355 \text{ cm}^{-3}$. In the summer, ENA-AM mean N_{tot} was 9.1% higher at C1 than at S1. Satellite images and analysis of local aerosol sources (see SI) show that C1

is located ~ 1 km closer to urbanized areas and to the town of Santa Cruz than S1. The N_{tot} generated from these more distant and diffuse sources is likely too weak to be completely masked by ENA-AM as discussed in Section 4.5.1.

Contrarily to N_{tot} , in the summer, N_{Ac} mean, median and the deviation between them remained largely unchanged after the application of ENA-AM. This is in agreement with Section 4.3.2, where we showed summer N_{Ac} was only minimally affected by local aerosol events. However, in the winter, mean, deviation between mean and median, and standard deviation N_{Ac} at C1, experienced a higher reduction when masked with ENA-AM (25% for the mean, 51% for the deviation between mean and median, and 73% for the standard deviation). These results are likely related to the presence of additional sources in the winter (e.g. burning of wood for home heating) which might affect N_{Ac} in a way that was not masked completely by ENA-AM.

10

Table 3. Mean, median and standard deviations (σ) of original and ENA-AM masked one-minute N_{tot} at C1 and S1 during the summer and winter.

		Summer C1			Summer S1			Winter C1		
		Original	ENA-AM	Reduction	Original	ENA-AM	Reduction	Original	ENA-AM	Reduction
N_{tot} (cm^{-3})	Mean	707	428	39%	489	384	21%	537	346	36%
	Median	427	387	9%	370	355	4%	366	290	21%
	σ	2,780	228	92%	1,012	193	81%	630	223	65%
N_{Ac} (cm^{-3})	Mean	160	150	6%	151	149	1%	140	105	25%
	Median	156	152	3%	147	147	-	91	81	11%
	σ	142	60	58%	79	75	5%	296	79	73%

To estimate the influence of local aerosol events on daily N_{tot} and N_{Ac} , we investigated the deviation between the original and ENA-AM masked N_{tot} and N_{Ac} daily means at C1 in the summer and winter in Figure 11. We observed that after applying ENA-AM, depending on the day, N_{tot} daily means experienced reductions varying between 7% and 81% in the summer and between 2% and 67% in the winter. N_{Ac} reductions were lower than 27% in the summer and 40% in the winter (with the exception of two days, December 16 and 22, when N_{Ac} daily means experienced reductions of 61% and 80%). As already observed in Section 4.2, at ENA, especially in the summer, local sources are mainly responsible for the emission of small particles in the At mode, while the Ac mode is generally only minimally impacted. Thus, in general, the reduction in N_{Ac} after masking the data does not impact the daily mean values as much as it does for N_{tot} . The higher daily mean reductions observed for N_{tot} in comparison to N_{Ac} after the utilization of ENA-AM demonstrated that the algorithm was able to selectively detect and isolate periods impacted by local aerosol events without having to use size distribution data. The high original N_{tot} and N_{Ac} daily means and the large deviation after application of ENA-AM (80%) observed on December 22 were exceptions likely related to a poor-efficiency combustion source, a bulldozer, not normally present at C1 that was observed by the AOS cameras. The time series plots highlight N_{Ac} up to 11,000 cm^{-3} between 14:50 and 18:30 UTC. Thus, while N_{tot} and N_{Ac} measurements were impacted, ENA-AM was able to mask the data.

25

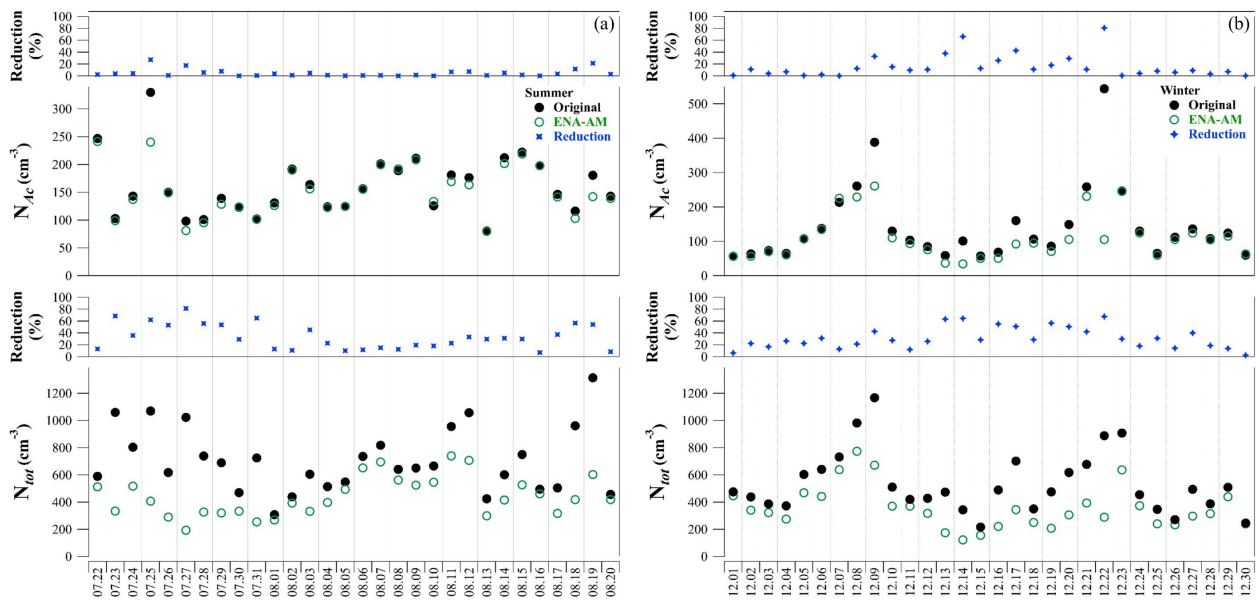

Figure 11. Original (black) and ENA-AM masked (green) N_{tot} and N_{Ac} daily means at C1 and corresponding reduction (%) (blue) in the (a) summer and (b) winter.

5 4.4.3 Comparison of ENA-AM to other masks

We tested using wind direction to mask local aerosols by applying a meteorological mask to remove C1 and S1 N_{tot} measurements as a function of the wind directions associated with the airport (west to northwest and southeast to south at C1 and east to south at S1). After applying the meteorological mask at C1, 38.9% in the summer and 62.0% in the winter of the AOS data was removed. Similarly, at S1 43.4% of the data in the summer were masked. Only 9.8% of the C1 and S1 N_{tot} datasets remained for comparison between C1 and S1, which limited our ability to determine the regional background. The linear regression generated an R^2 of 0.18, likely due the paucity of data. Therefore, masking AOS data based on wind direction resulted in the rejection of too much data to define a regional baseline aerosol.

Masking AOS data at ENA utilizing the associated metadata, such as AOS motion-activated cameras and airport flight logs, was not able to identify all of the periods impacted by local aerosol sources. However, analysis of videos and airport flight logs were useful to confirm the presence of the aircraft at the airport to validate the application of an aerosol mask. These observations and metadata were therefore used to validate the application of ENA-AM as discussed in Section 3.2.

Application of smoothing algorithms have been shown to be effective in filtering measurements affected by events lasting less than 1 hour (Liu et al., 2018) and that are associated with rapid increases in N_{tot} (up to $8,520 \pm 36,780$ cm⁻³) and cloud condensation nuclei concentrations $> 1,000$ cm⁻³. While signals with these characteristics are present at ENA, there are also longer events that last several hours due to the complex sources associated with the local airport operations. When we applied the method at ENA, 98% of the C1 N_{tot} data in the summer was masked (see SI Section SI.5 and Figure SI.5 for further information). Further optimization would be required for locations such as ENA as the method is better suited for more remote locations with less pervasive local sources, such as are encountered on a ship or remote island (Goring and Nikora, 2002)

We tested a different mathematical algorithm to filter aerosol data based on previous work by Hagler et al. (2012). The authors applied the coefficient of variation algorithm to ultra-fine particle concentrations and greenhouse gas data. At ENA, this method masked the dominant fraction of the data, 72% at C1 in the summer. We were not able to validate the additional

reductions in comparison to ENA-AM with other observations or collocated measurements. Periods with known long-range transported aerosol were also removed. Therefore, the application of this method was not pursued further at ENA.

Comparison was also made between ENA-AM and the one-second time base filter developed by Zheng et al. (2018) at ENA.

5 Conducted at C1 over two three-month periods in the summer (June to August 2017) and winter (December 2016 to February 2017), the authors found similar baseline values for N_{tot} measurements ($513 \pm 314 \text{ cm}^{-3}$ in the summer and $383 \pm 300 \text{ cm}^{-3}$ in the winter). They also reported similar N_{Ac} mean and standard deviation values ($143 \pm 81 \text{ cm}^{-3}$ in the summer and $92 \pm 89 \text{ cm}^{-3}$ in the winter) after the additional step of lognormal fitting the size distributions to what we report here with ENA-AM. We validate the original Zheng et al. (2018) algorithm with the additional Supplementary site data using the data from our summer
10 ENA-AM period. We recreated the Zheng et al. (2018) mask on the original one-second time base and applied it to our summer period at C1. We found that it agreed with ENA-AM 68% of the time (see section SI.5 in the SI). ENA-AM removed less data than the Zheng et al. (2018) method when mapped onto a one-minute time base (26% versus 41%). ENA-AM was also developed to operate on a longer time base (one-minute versus one-second) to reduce computational requirements.

15 4.4.4 Masked AOS data and AAF overflights

After determining the regional baseline for N_{tot} from the ground AOS measurements at ENA, we compare ENA-AM masked C1 N_{tot} with AAF N_{tot} data in Figure 12. We restricted our comparison of N_{tot} from the AAF to an area within a 10 km diameter box centered at C1 at altitudes ≤ 500 m. Before applying ENA-AM, the R^2 value obtained from comparing the original C1 N_{tot} and AAF measurements from seven overflights (data not shown) was poor ($R^2 = 0.26$). After applying ENA-AM at C1, we
20 obtained an R^2 of 0.71 and a slope of 1.04 ± 0.01 , which indicated a good agreement between the AOS and AAF data. The largest deviations from the 1:1 line occurred during two flights, on June 21 (RF1) and June 29 (RF6). On June 21 the AAF flew over Graciosa Island at two distinct times (12:00 and 13:30) during the day that we represent as two different periods in Fig. 12. While the AAF and C1 N_{tot} data fell on the 1:1 line within measurement uncertainties for the first period during RF1, C1 sampled an average of 43% more N_{tot} than the AAF during the second flyover. The second flyover might have coincided
25 with a period of time when C1 was affected by local events that ENA-AM was not able to identify and mask, as discussed in the paragraph above. Unfortunately, due to a lack of data at S1 during this time, this could not be verified. The largest deviation from the 1:1 line of all flights was observed on June 29 when higher N_{tot} was observed by the AAF. The mean N_{tot} was $659 \pm 17 \text{ cm}^{-3}$ at C1 and $1,141 \pm 828 \text{ cm}^{-3}$ at AAF. The flight trajectory indicated that the AAF flew south of C1 over the center of the island and around the town of Santa Cruz and two smaller towns, Guadalupe and Vitoria, on an ascending path. The AAF
30 N_{tot} measurements might be affected by local aerosol when the AAF flew over these urbanized areas. AAF N_{tot} measurements might also have been biased by AAF emissions sampled through the aerosol inlet while the aircraft was gaining altitude. The standard deviation of the AAF data was also significantly greater than what was observed at C1, indicating the AAF likely intercepted plumes not observed at C1 during this time. Further analysis of the AAF data from RF6 would be required to determine the source of the discrepancy with the AOS data.

35

The high R^2 obtained from the masked C1 and AAF N_{tot} demonstrated that aerosol in the summer were well-mixed within the first 500 m of the marine boundary layer. This is likely due to the high sea level pressure system and advection in the summer at ENA which might enhance submicron aerosol mixing within the MBL (Davis et al., 1997). Since our focus here was on summer data at ENA due to the deployment of S1 to constrain C1 measurements, the winter season and vertical characterization
40 of the MBL was beyond the scope here. During the winter, aerosol in the MBL are expected to be less well-mixed due to a strong polar front activity and low pressure system (Barbosa et al., 2017). Therefore, we expect less correlation between the AOS data and the AAF in the winter than what was observed in the summer.

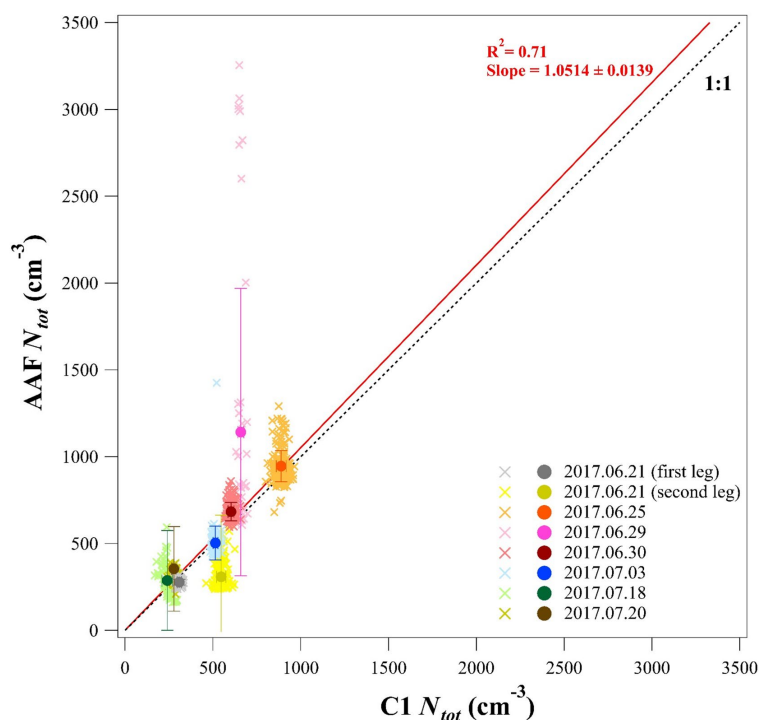

Figure12. Scatter plot of ENA-AM masked C1 N_{tot} and AAF N_{tot} collected within 10 km from C1 and at altitudes ≤ 500 m.

5 Conclusions

5 High concentration aerosol events were observed in the AOS data at the ENA Central Facility. Analysis of the submicron aerosol concentrations and size distributions were used with collocated meteorological data (wind direction) to associate high concentration aerosol events with potential local aerosol sources. Total submicron and Aitken mode aerosol were the most affected as determined by wind direction and should be masked before conducting ambient aerosol process studies at ENA. Accumulation mode aerosol was less impacted, especially in the summer. Ac mode might then be used without applying an
 10 aerosol mask as representative of the regional aerosol.

We developed a novel aerosol mask at ENA called ENA-AM and validated its application by using two measurement locations located within 1 km of each other. The temporary Supplementary site was deployed to validate the new aerosol mask at the Central Facility with the AOS. Time periods impacted by high concentration aerosol events were removed, and we were able
 15 to define a regional baseline for the submicron number concentration data at ENA during the summer and winter. The masked submicron aerosol number concentrations from the ground site were compared with the AAF aircraft data during flights over the facility. It was possible to determine a well-mixed regional aerosol within the first 500 m of the marine boundary layer for the data presented here collected during the summer ACE-ENA IOP.

20 Application of ENA-AM required measurements in which: 1) the time resolution of the dataset was shorter than the typical length of the event, and 2) the variation within the baseline data was smaller than the variation during the periods containing local aerosol. The CPC one-minute submicron number concentration data satisfied these requirements at ENA. Therefore, we developed an algorithm using the CPC data at ENA that could be applied to the AOS data for studying regional aerosol processes. After the application of ENA-AM, 26% of the one-minute data at C1 and 15% at S1 were masked in the summer.
 25 ENA-AM masked a lower percentage of the data than the wind direction mask, which masked 39% of the data at C1 data and 43% at S1. Compared to the meteorological method, ENA-AM removed approximately half of the data than the mask based

on wind direction and, more importantly, resulted in a higher R^2 between the sites, 0.87 versus 0.18. Minimal deviations between the original median N_{tot} and ENA-AM mean values at C1, respectively, were 427 and 428 particles cm^{-3} (summer), and 370 and 384 particles cm^{-3} (winter). Therefore, it is possible that median values might be used to study longer term trends in the data without applying an aerosol mask. While useful, for example, to study seasonal trends, this approach would not be suitable for studying short time period aerosol variability on the order of minutes to hours as is required in ambient aerosol process research. For this reason, application of an aerosol mask such as ENA-AM is recommended even at remote locations, when studying high time-resolution submicron aerosol processes, especially those focused on Aitken mode particles. Application of ENA-AM, or other aerosol masks, is possible at other locations with AOS or similar data. Validation should include comparison with other collocated measurements, observations and metadata when available.

10

Data availability: data were obtained from the Atmospheric Radiation Measurement (ARM) User Facility, a U.S. Department of Energy Office of Science user facility sponsored by the Office of Biological and Environmental Research (available at <https://www.archive.arm.gov/discovery>).

15

ACA and FG conceptualized the analysis and wrote the manuscript. FG led the analyses with additional input from JU, SRS, RW and FM. ACA was the project administrator. All authors were involved in helpful discussions and contributed to the manuscript.
