18

19 **Abstract:**

20   Size distributions of inorganic and organic components in particulate matter (PM)

21 provide critical information on its sources, fate and pollution processes. Here, ions,

22 elements, carbon fractions, n-alkanes, polycyclic aromatic hydrocarbons (PAHs),

23 hopanes and steranes in size-resolved (9 stages) PM were analyzed during one year in

24 a typical northern Chinese industrial megacity (Tianjin). We found that the

25 concentrations of organic carbon fraction OC3, NO_3^- (or SO_4^{2-}) and the sum of crustal

26 elements were the highest in the pseudo-ultrafine (<0.43 µm), fine (0.41-2.1 µm) and

27 coarse (>2.1 µm) modes, respectively. The diagnostic ratios of organic components

28 consistently suggest that the traffic influence was stronger during summer and coal

29 combustion during winter. Nitrate and high molecular weight PAHs were concentrated

30 in the fine mode during winter, while nitrate and low molecular weight PAHs showed

31 bimodal distributions especially during summer due to repartitioning. Long-chain *n*-

32 alkanes showed a peak in the coarse mode during spring and summer, indicating a

33 relatively stronger vegetation source and resuspended dust. Furthermore, we found a

34 major difference in the size distribution of aerosol components during heavy pollution

35 episodes (PM_{10}>233 µg m^{-3}) in different seasons: in spring, OC fractions, 4- and 5-ring

36 PAHs, hopanes and C18-C33 n-alkanes were enhanced at 1.1-3.3 µm, implying that

37 they may arise from local combustion sources which emit relatively large particles; in

38 summer PM mass, SO_4^{2-}, NH_4^+, Al, and C26-C33 *n*-alkanes were enhanced mainly in

39 the coarse mode, peaking at 5.8-9.0 µm, indicating a large contribution from

40 resuspended dust or heterogeneous reactions on dusts; in the winter and autumn, NO_3^-

Atmospheric
Chemistry
and Physics
Discussions

41   was significantly enhanced followed by SO_4^{2-}, NH_4^+, OC and EC with their peaks

42   shifting from 0.43-0.65 µm to 0.65-2.1 µm, indicating strong atmospheric processing.

43   These results reveal that the size distributions of inorganic and organic aerosol

44   components are dependent on the seasons and pollution levels as a result of the differing

45   sources and physicochemical processes.

46

47

48   **1 Introduction**

49   Atmospheric particulate matter (PM) negatively affects human health and visibility,

50   influences global climate change and nutrient cycles within ecosystems (Burnett et al.,

51   2014; Wang et al., 2014; Zhang et al., 2017). Properties and effects of PM depend on

52   their chemical composition and particle sizes (Seinfeld and Pandis, 1998; Kanakidou et

53   al., 2005; Kompalli et al., 2020). PM cover a wide range of sizes from a few nanometers

54   to several hundreds of micrometers, and is composed of a complex mixture of inorganic

55   substances (such as water-soluble ions, elements, and elemental carbon) and hundreds

56   of organic compounds. Several studies have shown that the size distribution of chemical

57   components can provide evidence for examining the sources and formation pathways

58   (Guo et al., 2014; Yao et al., 2018; Hilario et al., 2020).

59   Non-polar organic compounds in PM, such as n-alkanes, polycyclic aromatic

60   hydrocarbons (PAHs), hopanes and steranes, can provide specific information to

61   identify PM sources (Oros and Simoneit, 2000; Wang et al., 2009; Han et al., 2018).

62   PAHs are mainly emitted from anthropogenic activities, such as biomass burning, coal

Atmospheric
Chemistry
and Physics
Discussions
Open Access
EGU

63 combustion, oil combustion and industrial processes (Mastral et al., 1996; Liu et al.,

64 2012). Hopanes and steranes are abundant in coal, crude oils and the lubricant oil

65 fraction, and are often found in traffic exhaust and coal combustion emissions (Oros

66 and Simoneit, 2000). n-Alkanes can arise from both natural and anthropogenic activities,

67 including abrasion products from vegetation leaf surfaces (characterized by the

68 predominance of > C29 odd n-alkanes) and fossil fuel combustion (Han et al., 2018).

69 Although these organic compounds are assumed to be relatively stable and nonreactive

70 (Feng et al., 2006; Ma et al., 2011), they can undergo complex physical and chemical

71 changes, like photochemical oxidation and gas-particle partitioning (Robinson et al.,

72 2006; Han et al., 2018). The size distributions of the organic compounds are strongly

73 associated with their sources, physical behavior and chemical reactions. Several studies

74 on size distributions of PM chemical components have been conducted for ions,

75 elements, and carbon fractions (Dillner et al., 2006; Huang et al., 2016; Tian et al., 2016;

76 Hilario et al., 2020), and for some organic compounds (Wang et al., 2009; Han et al.,

77 2018; Xu et al., 2020). These studies indicated that the size distributions of the inorganic

78 or organic components may vary with season and degree of pollution, so characterizing

79 the variations is valuable for understanding their sources and fate. However, the

80 combined analysis of seasonal variations of inorganic and organic components based

81 on whole year sampling has rarely been conducted.

82   Severe atmospheric PM pollution has been a recurring problem affecting developing

83 countries (Cheng et al., 2016; Zou et al., 2017). As one of the world's fastest-developing

84 economic zones, the Jing-Jin-Ji economic circle in China has experienced severe and

85   long-lasting haze episodes (Guo et al., 2014; Long et al., 2019). The "Jin" is Tianjin, a

86   megacity with a population of 15.6 million. With gross industrial production ranking

87   third among all Chinese provinces (TMSB, 2017), Tianjin is a typical industrial city.

88   Various anthropogenic emissions, including industrial emissions, coal combustion,

89   vehicle exhaust and resuspended dust, significantly contribute in this region.

90   Additionally, the chemical and physical characteristics of PM are complex during

91   different seasons. High reactivity due to relative humidity (RH) during winter has been

92   reported (Cheng et al., 2016), and strong dust and sea salt emissions during spring and

93   summer can increase the surfaces needed for heterogeneous reactions. The factors that

94   influence heavy pollution in different seasons remain unclear due to their complexity

95   (Cheng et al., 2016; Yao et al., 2018). The variation of size-resolved inorganic and

96   organic chemical component size distributions during periods of heavy pollution in

97   different seasons can throw light on the mechanisms of PM pollution (Tian et al., 2016;

98   Xu et al., 2020).

99   In this study, we conducted a comprehensive study of water-soluble ions, elements,

100   carbon fractions, n-alkanes, PAHs, hopanes and steranes in size-resolved PM (9 stages)

101   samples collected from May 2018 to April 2019 in Tianjin, China. The goal of this study

102   is to (1) determine size-resolved chemical composition, including inorganic and organic

103   components, (2) characterize seasonal variations of size distribution of inorganic and

104   organic markers, (3) explore the mechanisms of PM pollution during different seasons

105   through investigating the changes in composition as well as size distribution. The

106   results of this work will help researchers better understand the sources, physical process

Atmospheric

and Physics
Discussions

107 and chemical mechanisms of PM pollution during different seasons, which is crucial

108 for evaluating the effects of PM on human health, visibility and regional radiative

109 forcing, and for developing control strategies.

110

111 **2 Methods and materials**

112 **2.1 Study area and sampling**

113 Tianjin is located at 116°43'E~118°04'E, 38°34'N~40°15'N, in the northern part of

114 the North China Plain. It covers an area of 11947 km^2, near the Capital of China (Beijing)

115 and bordering on the Bohai Sea. The population is 15.6 million. As a municipality

116 directly under the Central Government and one of the first coastal open cities, Tianjin

117 is a typical industrial city and a major manufacturing base for some industrial products,

118 whose gross industrial production ranks third among all Chinese provinces (TMSB,

119 2017). The industries include petroleum and chemical, modern metallurgy, aerospace,

120 automobile and equipment manufacturing, amongst others. More than 20 million tons

121 of coal is consumed by industries and residential heating every year. The civil motor

122 vehicle fleet in Tianjin is about 2.8 million. The Tianjin Port is the largest

123 comprehensive port in northern China and a major port for foreign trade.

124 The PM samples were collected by an Andersen air sampler (Andersen Series E-0162,

125 USA) with 9-stage size ranges of >9.0, 9.0-5.8, 5.8-4.7, 4.7-3.3, 3.3-2.1, 2.1-1.1, 1.1-

126 0.65, 0.65-0.43, and < 0.43 μm. Quartz-fibre filters (81 mm in diameter) were used.

127 The sampling period was from May 2018 to April 2019, involving spring (May in 2018,

128 and March and April in 2019), summer (June and August in 2018), autumn (1

129   September to 15 November 2018) and winter (15 November 2018 to 15 March 2019,

130   when coal was consumed for residential heating). The sampling was conducted for 47

131   h during spring and summer, and for 23 h during autumn and winter, and was stopped

132   during rainy days. Overall, 153 sets of successfully size-resolved samples (total 1377

133   fraction samples) were obtained. Additionally, the $PM_{2.5}$ and PM_{10} mass concentrations

134   were continuously monitored by a Beta Particulate Monitor (BPM-200, Focused

135   Photonics, China) at the sampling site. The correlation plots between $PM_{2.1}$ and PM_{10}

136   mass concentrations sampled by the Andersen sampler (PM-measured) vs

137   corresponding means of continuous $PM_{2.5}$ and PM_{10} concentrations monitored by the

138   BPM (PM-monitored) were showed in Figure S1. High correlations (0.86 and 0.82)

139   were observed.

140   To explore the mechanisms of heavy pollution, the heavy pollution was defined as

141   the days with PM_{10} concentrations higher than the 3rd quartile of all the samples, which

142   was 233 $\mu g\ m^{-3}$.

143

144   **2.2 Chemical analysis of ions, elements and carbon fractions**

145   In this work, 7 ions, 17 elements, 7 carbon fractions, 18 PAHs, 2 cholestane, 7 hopane

146   and 24 n-alkanes were analyzed on each size range. For ion analyses, including Na^+,

147   K^+, Ca^{2+}, NH_4^+, Cl^-, NO_3^- and SO_4^{2-}, one eighth of each quartz filter was cut. The

148   sample was placed in a centrifuge tube which had been ultrasonically cleaned and dried,

149   before addition of 8 ml of distilled deionized water, then placed in an ultrasonic bath

150   for 20 minutes. The sonicated centrifuge tube was refrigerated for 24 hours. The clear

Atmospheric
Chemistry
and Physics
Discussions

151 liquid in the middle of the centrifuge tube was withdrawn with a needle tube, filtered

152 through two 0.2 μm filters, and injected into the sample bottle. Lastly the extraction

153 liquid was analyzed to determine the cation and anion concentrations with a Thermo

154 ICS900 Ion Chromatograph (Thermo Electron). For the elemental analysis, 17 elements

155 (Al, Ca, Ti, K, Mg, Na, V, Fe, Cu, Zn, Mn, Pb, As, Cd, Co, Cr, Ni) were analyzed by

156 inductively coupled plasma-mass spectrometry (ICP-AES) (IRIS Intrepid II, Thermo

157 Electron). We cut one eighth of each quartz filter into portions and extracted elements

158 into acid solution (HNO_3: HCl: H_2O_2 = 1: 3: 1) using a microwave digester (PyNN

159 Corporation). Carbon fractions were analyzed by a thermal/optical carbon aerosol

160 analyzer (DRI 2001A, Atmoslytic Inc.), which gives OC1, OC2, OC3, OC4, OP, EC1,

161 EC2, EC3 fractions. The instrument is based on heating and releasing organic carbon

162 and elemental carbon at different temperatures, and uses He-Ne laser to allow

163 quantification of the pyrolytic (OP) fraction. The IMPROVE-A thermal/optical

164 reflectance (TOR) protocol was used (Chow et al., 1993) with 140°, 280°, 480°, 580°,

165 740°, and 840°C to divide the carbon fractions.

166

167 **2.3 Chemical analysis of organic components**

168 Organic compounds in half of total sample filters were analyzed by gas

169 chromatography-mass spectrometry (GC-MS). The full names and corresponding

170 abbreviations of organic compounds were summarized in Table 1.

171 **Table 1**

172 For extraction, the filters were cut into portions and put into tubes. Then 10 ml of

8

173 dichloromethane (DCM) and 10 ml of n-hexane (1:1, v:v) were added into each tube

174 which was then put in an ultrasonic bath at 30 ℃ for 15 minutes. The solution was

175 filtered with a silica column to clean up the extract. The silica column was eluted with

176 20 ml of DCM/hexane (1:1) and the extract was collected. After reduction to less than

177 5 ml (about 2 or 3 ml) by rotary evaporator, the extract was solvent-exchanged to n-

178 hexane. Finally, the volume was reduced to 1 ml. Calibrations of PAHs, hopanes,

179 steranes and n-alkanes were used to test chromatographic conditions before analysing

180 samples. A DB-5MS fused-silica capillary column (30 m × 0.25 mm, 0.25 mm film

181 thickness, Agilent Technology) was used in the GC separation procedure. The carrier

182 gas was pure helium (purity of 99.99% or more) at a constant flow rate of 1.0 mL min^{-1}

183 ^{1}. For PAHs, hopanes and steranes, inlet and transfer line temperatures were set to 230 ℃

184 and 280 ℃ respectively. EI mode was used and the ionization energy level was 70eV.

185 For n-alkane analysis, inlet and transfer line temperatures were set to 300 ℃.

186

187 **2.4 Quality assurance and quality control (QA/QC)**

188   Throughout the whole process, much attention was given to ensure quality assurance

189 and control. All samples were collected by one instrument and analyzed by the same

190 methods. When it rained, we stopped the sampling campaign. The air flow rate was

191 corrected by a flowmeter before each sampling period. Before use, the quartz filters

192 were baked in an oven at 400-500 ℃ to eliminate any organic matter that may exist on

193 the filters. All the filters were equilibrated at room temperature for 48 h in desiccators

194 before weighting. Each filter was weighted by a sensitive microbalance with balance

195   sensitivity ±0.010 mg. The quartz filters were kept in aluminum foil bags before and

196   after sampling until analysis, and stored at −4 °C. The samples were analyzed within

197   30 days.

198   Field and laboratory blanks were measured to correct the corresponding data.

199   Standard reference materials were analyzed with the same procedure every day and the

200   recovered values for all the target components showed low relative standard deviations.

201   Additionally,, the first sample of every ten samples was re-examined with the precision

202   found to be within 10%. The recoveries were 79-106% for elements, and 96-110% for

203   ions. For carbon fractions, a system stability test (three-peak detection) is required

204   before and after detecting samples and the relative standard deviation should not exceed

205   5%. For organic compounds, all extractions were conducted two times so that the

206   samples were extracted adequately, with the tubes sealed by foil and ice added to the

207   ultrasonic bath. The internal standards (naphthalene-d8, acenaphthene-d10,

208   phenanthrene-d10, chrysene-d12, and perylene-d12; hexamethylbenzene; n-

209   tetracosane-d50) were used for the samples to qualify actual volumes of the target

210   compounds present. The calibration curves were strongly linear. The recoveries of most

211   organic compounds ranged from 70%-130%, except for Nap, Any, Ana, C10, and C11

212   with recoveries below 50%.

213

214   **2.5 Diagnostic ratios**

215   Diagnostic ratios were used to identify the sources. The Ant/(Ant+Phe) ratio for

216   PAHs is used to differentiate petroleum origins or pyrogenic sources, and IPY/BghiP

217   is for different fossil fuels. The ratio of C29αβ/C30αβ for hopane can also be used to

218   judge fossil fuels. The homohopane index C34[S/(S+R)] can distinguish fuel maturity,

219   which is defined as:

220     $$C34[S/(S+R)] = \frac{C34\alpha\beta S}{C34\alpha\beta S + C34\alpha\beta R}$$ (1)

221   For n-alkanes, the carbon preference index (CPI) can reflect the comparison between

222   natural and anthropogenic contributions, which is defined as the ratio of the total

223   concentration of odd n-alkanes to that of even n-alkanes:

224     $$CPI = \frac{\sum_{i=5}^{16} C_{2i+1}}{\sum_{i=5}^{16} C_{2i}}$$ (2)

225   where i is the carbon number. Due to that plant wax n-alkanes show strong odd carbon

226   number predominance, biogenic n-alkanes should have CPI values greater than unity,

227   whereas anthropogenic n-alkanes should have CPI values close to unity (Han et al.,

228   2018).

229   Contributions from natural wax n-alkanes (WNA%) and petrogenic n-alkanes

230   (PNA%) can directly present the origins. The negative value of $[C_i - (C_{i-1} + C_{i+1})/2]$

231   should be replaced by zero.

232     $$WNA\% = \frac{\sum_{i=10}^{32}[C_i - (C_{i-1} + C_{i+1})/2]}{\sum_{n=10}^{33} C_n}$$ (3)

233   PNA%=100%- WNA%   (4)

234

235   **3 Results and discussion**

236   **3.1 Size distribution of PM mass concentrations**

237   Figure 1 describes the size distribution of PM mass concentrations in spring, summer,

238   autumn and winter. The average concentrations of PM were the greatest during winter,

239   followed by spring, autumn and summer at most sizes. The size distribution of the PM

240   mass concentrations was bimodal, with one peak at 0.43-0.65 µm (fine mode) and the

241   other at 4.7-5.8 µm (coarse mode). Particles at small sizes may be mainly influenced

242   by secondary formation and anthropogenic sources (such as vehicle emissions, coal

243   combustion, industrial emissions, etc.), while particles at large sizes may be more

244   associated with natural sources, resuspended dust (such as road dust, construction dust,

245   mechanical abrasion processes, etc.) and industrial emissions (Hilario et al., 2020). In

246   this work, the peaks in the coarse mode were very strong during spring due to the

247   influences of resuspended dust and natural sources. The enhancement of PM in the fine

248   mode during winter is associated with unfavorable meteorological conditions for the

249   dispersion of fine particles, and increased emissions from coal combustion for heating

250   (Cheng et al., 2016; Tian et al., 2016). The broader peak in the fine mode during winter

251   should be noted.

252   **Figure 1**

253   To explore the causes of heavy pollution, size distributions of PM during the heavy

254   pollution days were compared with less polluted days (all the rest of the days).

255   According to the temporal variations of the size-segregated particle concentrations in

256   Figure S1, most heavy pollution cases occurred in winter and there were only a few

257   days in other seasons. Figure 1 also describes the size distribution of particle mass

258   concentrations for less polluted days and heavy pollution days during four seasons. PM

259   concentrations in the fine mode increased during heavy pollution in all of the seasons.

260   It was also found in several previous studies that fine particles significantly

Atmospheric
Chemistry
and Physics
Discussions
Open Access
EGU

261 accumulated during the haze pollution period (Wang et al., 2014; Tian et al., 2016). In

262 spring, the peak in the coarse mode was weaker during heavy pollution than during less

263 polluted days, while the concentrations in the coarse mode significantly increased

264 during summer heavy pollution. Thus, the spring heavy pollution may be associated

265 with sources or processes that engender small particles (like combustion, secondary

266 formation, etc.), while summer heavy pollution was strongly linked with large particle

267 sources (like resuspended dust, dust storms, etc.). During winter and autumn, it is

268 interesting to find that peaks in the fine mode shifted to a larger size, from 0.43-0.65

269 μm during less polluted days to 0.65-1.1 μm during heavy pollution. This result is

270 consistent with the previous studies, which showed that the peak mass concentration of

271 fine mode particles shifted to larger sizes during heavily polluted days (Tian et al., 2016;

272 Guo et al., 2014). The causes and mechanisms of heavy pollution will be further

273 explored according to the variations of inorganic and organic components.

274

275 **3.2 Size-resolved chemical compositions and diagnostic ratios**

276 Correlations among size-segregated chemical composition (percentages of 4 ions, 17

277 elements and 7 carbon fractions accounting for PM concentrations) have been

278 calculated and are summarized in Table S1(a). It is noticeable to find that the

279 compositions were similar in each mode (size<0.43 μm considered as the pseudo-

280 ultrafine mode; 0.43-0.65, 0.65-1.1 and 1.1-2.1 μm as the fine mode; and 2.1-3.3 3.3-

281 4.7, 4.7-5.8, 5.8-9.0 and >9.0 μm in the coarse mode), while they showed relatively

282 high differences between different modes. Additionally, the correlations among size-

Atmospheric
Chemistry
and Physics
Discussions

283 segregated composition of organic compounds (percentages of 18 PAHs, 2 cholestane,

284 7 hopane and 24 n-alkanes accounting for PM concentrations) showed similar trends

285 (Table S1(b)), indicating that both main component composition and organic

286 composition were similar in each mode. Thus, the sizes were aggregated into three

287 modes to investigate the size-segregated compositions: coarse (>2.1 μm), fine (0.43-

288 2.1 μm), and pseudo-ultrafine (< 0.43 μm) modes.

289 **3.2.1 Size-segregated main species**

290   Concentrations of chemical species in the pseudo-ultrafine, fine and coarse modes

291 during the four seasons are shown in Figure 2. The composition of main species were

292 similar during spring, autumn and winter: in the pseudo-ultrafine mode, the primary

293 component was organic carbon fraction OC3 (2.4, 2.0 and 3.2 μg m^{-3} during spring,

294 autumn and winter, respectively); in the fine mode, the primary component was NO_3^-

295 (8.0, 12.7 and 15.1 μg m^{-3}, respectively); and in the coarse mode, the CE (crustal

296 elements, defined as sum of Al, Ca, Fe and Ti) was highest with concentrations of 17.2,

297 16.0 and 20.2 μg m^{-3}. During summer, the highest components were SO_4^{2-} in the

298 pseudo-ultrafine (1.6 μg m^{-3}) and fine modes (8.2 μg m^{-3}), and CE in the coarse mode

299 (14.8 μg m^{-3}). The sums of OC fractions were higher than other components in most

300 modes and seasons. NO_3^-, SO_4^{2-} and OC are mainly from secondary formation,

301 combustion sources and industrial emissions, and crustal elements are linked with

302 resuspended dust (except during dust storm periods).

303   The concentration of SO_4^{2-} is the highest among all measured species in the fine

304 mode during summer, while NO_3^- was the primary component during other seasons.

305   During summer, photochemical processes can be more efficient. However, due to the

306   thermodynamic instability of ammonium nitrate, it may decompose under high

307   temperature (Hasheminassab et al., 2014). It is interesting to find that the NO_3^-

308   concentration in the coarse mode was higher during summer (5.7 μg m^{-3}) than during

309   other seasons, which may result from the deposition of nitric acid vapour upon coarse

310   particle surfaces.

311   **Figure 2**

312   **3.2.2 Size-segregated organic compounds and diagnostic ratios**

313   PAHs arise mainly from anthropogenic sources. According to the concentrations of

314   organic compounds in Figure 2, the concentrations of $\sum_{18}$PAHs (summed

315   concentrations of 18 PAHs) were 22, 19, 31 and 49 ng m^{-3} during spring, summer,

316   autumn and winter, respectively. The 5 and 6-ring PAHs (mainly BbF, BeP, BaP, DBA,

317   IPY and BghiP) showed higher concentrations than other PAHs during all four seasons

318   (Figure S2a). High molecular weight PAHs are emitted under a high temperature

319   condition as from vehicles and they are more stable in the particle phase. It is interesting

320   to observe an obvious increase of 4-ring PAHs in the fine mode during winter, which

321   may be caused by coal combustion for residential heating, and the low wintertime

322   temperature favouring partition into the condensed phase. Tianjin is a typical city in

323   northern China with considerable coal burning for house heating during winter, which

324   emits more 4-ring PAHs (Zhang et al., 2017). Moreover, some low-molecular-weight

325   PAHs can be emitted by volatilization and low to moderate temperature combustion,

326   such as during coking (Khalili et al., 1995), biomass combustion (Zhang et al., 2008)

327 and residential utilization of electricity or gas for heating and cooking (Yadav et al.,

328 2018). Thus, the results suggest that vehicle exhaust, coal combustion, industrial

329 emission and biomass burning had mixed effects on the atmospheric PAH pollution,

330 and that coal burning was one of major sources of PAHs in northern China, especially

331 during winter.

332   Additionally, diagnostic ratios of organic compounds are may be indicative of

333 sources, so the ratios in size-resolved PM during each season and their ranges for

334 sources are summarized in Table 2. The Ant/(Ant+Phe) ratios were greater than 0.1,

335 confirming an influence from pyrogenic emissions (Han et al., 2018). The IPY/BghiP

336 ranged from 0.66 to 2.51, indicating mixed effects of vehicle emissions and coal

337 combustion (Grimmer et al., 1983). The IPY/BghiP values were lower in the pseudo-

338 ultrafine fraction, implying that vehicle emissions impact was stronger in the pseudo-

339 ultrafine than in other modes. Enhancement of IPY/BghiP ratios during autumn and

340 winter indicates that PAHs derived from coal combustion increased, consistent with the

341 results of 4-ring PAH variations. Due to the low concentrations of organic compounds,

342 the diagnostic ratios are subject to uncertainty, especially for the seasons and modes

343 with lower concentrations.

344   **Table 2**

345   Hopanes and steranes are often used to determine the fuel maturity (Oros and

346 Simoneit, 2000). As shown in Figure 2, the total concentrations of 2 steranes and 7

347 hopanes ranged from 1 to 5 ng m^{-3} for the pseudo-ultrafine mode, from 4 to 25 ng m^{-3}

348 for fine mode and from 3 to 27 ng m^{-3} for the coarse mode. The maximum occurred in

Atmospheric
Chemistry
and Physics
Discussions

349 winter and the minimum occurred in summer. The 17α(H),21β(H)-30-norhopane

350 (C29αβ) and 17α(H),21β(H)-30-hopane (C30αβ) showed the highest levels of the

351 hopanes and steranes during four seasons in all modes, as shown in Figure S2b. The

352 C30αβ mass concentration was higher than C29αβ during spring, summer and autumn,

353 while the contrary occurred during winter. C34αβS and C34αβR concentrations were

354 significantly enhanced during autumn and winter in the fine and coarse modes.

355   The molecular composition of hopanes are further assessed by their mass ratios. As

356 shown in Table 2, diagnostic ratios of C29αβ/C30αβ indicate a strong traffic influence

357 during summer (C29αβ/C30αβ=0.59-0.69) and a strong coal combustion contribution

358 during winter (ratio=1.32-1.38). The hopane C34[S/(S+R)] ratio, which is an indicator

359 of the maturity of combusted fossil fuel, ranged from 0.27 to 0.75. Hopane [S/(S+R)]

360 ratios increase with increasing fuel maturity. When the level of the R isomer is much

361 higher than the concentration of the S isomer, PM is mainly influenced by emissions

362 from coal combustion, while the similar concentrations of R and S isomer indicate

363 traffic emissions. It was reported that the homohopane index [S/(S+R)] for coal smoke

364 samples increases with coal rank (lignite 0.05; brown coal 0.09; sub-bituminous coal

365 0.20; bituminous coal 0.35) (Oros and Simoneit, 2000). The C34[S/(S+R)] ratios in this

366 study were more indicative of coal burning during autumn and winter. And we notice

367 that the C34[S/(S+R)] values were generally in the order of pseudo-ultrafine mode >

368 fine mode > coarse mode, indicating that the maturity of the fossil fuel decreased with

369 the increase of particle size. Obvious low values of C34[S/(S+R)] in the coarse mode

370 during winter may indicate an influence of combustion of immature coals.

371   n-Alkanes are mainly emitted in vehicle emissions, coal combustion, tire-wear

372   particles and particulate abrasion products from leaf epicuticular waxes, and it has been

373   reported that they have unique signatures for different sources (Han et al., 2018). N-

374   alkanes were the most abundant organic compounds, with the total concentrations

375   ranging from 2187 during summer to 4452 ng m^{-3} during winter (Figure 2). As shown

376   in Figure S2 and Table 2, the values of the carbon number of the most abundant n-

377   alkane (Cmax) in this study were C23 in the fine mode and C31 in the coarse mode

378   during spring and summer, and were generally C28 in all modes during autumn and

379   winter. Cmax represents the carbon number of the most abundant n-alkane, which is

380   regarded as an important indicator of biogenic inputs. C23 has been reported as

381   indicative of vehicle emissions (Lyu et al., 2017). C31 mainly comes from a vegetation

382   source (plant wax) and tire-wear source which can be caused by resuspended dust (Han

383   et al., 2018). Thus, the Cmax values in this work suggest a strong fuel combustion

384   influence in the fine mode, and contributions of vegetation sources and resuspended

385   dust in the coarse mode during spring and summer. During autumn and winter, the

386   Cmax=28 was considered to come from local emissions, especially coal combustion

387   (Han et al., 2018).

388   The CPI (carbon preference index) ranged from 0.73 to 1.48, suggesting a

389   predominant contribution from anthropogenic sources (Han et al., 2018). WNA% and

390   PNA% provide a direct insight that above 75% of n-alkanes were originated from

391   anthropogenic sources. CPI and WNA% consistently demonstrate that n-alkanes were

392   mainly contributed by anthropogenic activities, and the natural source was higher in the

393 coarse mode during spring and summer, consistent with the interpretation of other ratios

394 above.

395

396 **3.3 Seasonality of size distributions**

397 **3.3.1 Size distributions of main components**

398   The size distributions of main chemical species (ions, elements and carbon fractions)

399 during spring, summer, autumn and winter are shown in Figure 3a. NO_3^-, SO_4^{2-} and

400 NH_4^+ mass concentrations were abundant in the fine mode, which exhibited maxima at

401 0.43-0.65 or 0.65-1.1 μm during most seasons, except for SO_4^{2-} in winter (1.1-2.1 μm)

402 and NO_3^- in summer (3.3-4.7 μm). Except for primary sources, the fine mode NO_3^- and

403 SO_4^{2-} can be formed from the gaseous and aqueous phase reactions, and the coarse

404 mode NO_3^- and NH_4^+ can origin from repartitioning and heterogeneous reactions with

405 sea salt and crustal dust (Liu et al., 2017). A strong peak of NO_3^- was observed at 3.3-

406 5.8 μm during summer. Due to the thermodynamic instability, fine mode NH_4NO_3 can

407 be dissociated into vapour at high ambient temperatures and then shifted onto coarse

408 particles by the condensation, reaction, dissolution or coagulation. During spring and

409 summer, the weak peaks of NH_4^+ in the coarse mode may partly derive from suspended

410 soil containing fertilizer. The size distributions of Cl^- showed obvious seasonal

411 variations, which strongly peaked in the fine mode during winter and autumn

412 corresponding to emissions of HCl from combustion sources which can form semi-

413 volatile ammonium chloride (Pio and Harrison, 1987); and peaked in the coarse mode

414 during summer because of sea salt.

Figure 3

415

416   Carbon fractions generally exhibited typical bimodal distributions with peaks in fine

417 and coarse modes. The levels of OC2, OC4 and EC1 in the fine mode and those of OC3

418 in both fine and coarse modes were significantly enhanced during winter. The OC

419 fractions and EC1 primarily come from coal combustion, vehicle exhaust, and biomass

420 burning, while EC2 and EC3 mainly originate from diesel and oil combustion (Kim and

421 Hopke, 2004; Shi et al., 2016). Thus, the enhancement of these carbon fractions in the

422 fine mode during winter is strongly linked with coal combustion for residential heating.

423 The OC3 in the coarse mode may be influenced by complex emissions and reactions. It

424 has been shown that PM emissions in northern China are complex during winter (Tian

425 et al., 2016), like scattered (area source) coal combustion. Shi et al. (2020) indicated

426 that scattered coal is the largest source of ambient volatile organic compounds during

427 the heating season in Beijing, which are important precursors for secondary organic

428 carbon (SOC). Thus, SOC generation may be another reason for OC enhancement in

429 both fine and coarse modes. Photochemical reactions may be generally weak during

430 winter, but high precursor concentrations, high humidity and high PM concentrations

431 during winter may enhance the aqueous phase and heterogeneous reactions.

432   The crustal elements (Al, Ca, Fe, Ti, etc.) were primarily concentrated in the coarse

433 mode at 4.7-5.8 or 5.8-9.0 μm. The high wind speed during spring can facilitate the

434 resuspension of dust (such as road dust, soil dust) into the atmosphere and result in the

435 high level of the crustal elements in the coarse mode. K showed a bimodal distribution:

436 the peak in the fine mode may be associated with biomass or coal combustion, and that

Atmospheric
Chemistry
and Physics
Discussions

Open Access

EGU

437 in coarse mode associated with natural sources from soil dust and sea salt. Figure S3

438 shows the ratios between water-soluble ions and corresponding elements in each size.

439 Peaks of K^+/K and Ca^{2+}/Ca were generally in the fine mode, indicating that K and Ca

440 may be contributed by industrial or combustion sources in the fine mode and strongly

441 associated with crustal dust in the coarse mode. A strong peak of Na^+/Na in the coarse

442 mode during summer may indicate impacts of sea salt, consistent in explaining the peak

443 of Cl^- in the coarse mode during summer.

444 **3.3.2 Size distribution of organic markers**

445 Figure 3b describes the size distribution of organic compounds during different

446 seasons. The size distribution varied with seasons and congeners. About 66-79% PAHs

447 were in the pseudo-ultrafine and fine modes, which were higher than the cumulative

448 percentages of hopanes (64-71%) and n-alkanes (56-60%). The sum of 2- and 3-ring

449 PAHs showed a bimodal distribution, while the summed concentrations of 6- and 7-

450 ring PAHs was strongly concentrated in the fine mode. High molecular weight PAHs

451 are less volatile and predominantly formed on smaller particles where they condense

452 immediately after combustion. However, low molecular weight PAHs are more volatile,

453 so they are easily adsorbed on larger particles as the emissions cool down, or can

454 evaporate from the particle-phase into the air and subsequently adsorb/condense onto

455 pre-existing coarser particle (Offenberg and Baker, 1999). The 4- and 5-ring PAHs were

456 found with a unimodal distribution peaking in the fine mode (0.43-1.1 μm) during

457 winter, while they were bimodal during other seasons, due to their repartitioning being

458 enhanced under higher ambient temperatures.

459   Most sterane and hopanes detected in this work were observed with a bimodal

460   distribution. It is interesting to observe the enhancement of 17β(H),21β(H)-hopane

461   (C30ββ) and 17α(H),21β(H)-22R-tetrakishomohopane (C34αβR) in the coarse mode

462   during winter. C30ββ and C34αβR have been regarded as markers of less mature coals,

463   such as lignite and sub-bituminous coal combustion (Oros and Simoneit, 2000). Thus,

464   their increase indicates a contribution from immature coal combustion to coarser PM

465   during winter. For most n-alkanes, a bimodal size distribution was found at 0.43-0.65

466   or 0.65-1.1μm in the fine mode and 3.3-47 or 4.7-5.8 μm in the coarse mode. Total

467   concentrations of C26-C33 showed a strong peak in the coarse mode during spring and

468   summer, indicating a relatively stronger vegetation source and a resuspended dust

469   contribution to PM in the coarse mode.

470   In previous publications, a bimodal distribution of low molecular weight PAHs and

471   a strong peak in the fine mode of high molecular weight PAHs were reported (Lv et al.,

472   2016; Han et al., 2018). The bimodal distribution of most n-alkanes was observed by

473   Wang et al. (2009), Lyu et al. (2017) and Xu et al. (2017). The size distributions of

474   hopanes were reported as unimodal in the fine mode (Kleeman et al., 2008; Han et al.,

475   2018), and can be bimodal during summer (Wang et al., 2009). Through comparing

476   these publications with this work, we find that the size distributions of most organic

477   compounds were consistent, but the peaks in the coarse mode are often stronger in this

478   work. The difference can be due to variations in their sources, increased fine particle

479   coagulation at high particle concentrations, and organic compound repartitioning.

480   Tianjin is an important heavily populated megacity in northern China, which has large

481 emissions from industry and traffic, and high resuspended dust due to strong human

482 activities (such as construction and heavy trucks activity). The stronger peaks in the

483 coarse mode, especially during spring and summer, may be linked with the high

484 resuspension of dust from coal combustion, industrial emissions, traffic emissions,

485 construction dust, and mechanical abrasion processes.

486

487 **3.4 Size distributions during less polluted and heavy pollution periods**

488 To explore which sizes and which components are significantly enhanced during

489 heavy pollution periods, the enhancement ratios, which are defined as ratios of

490 component concentration during heavy pollution days to that during other days

491 ($ER_{H/C}=C_H/C_C$), are calculated and shown in Figure 4. There are different formation

492 mechanisms for heavy pollution episodes during different seasons. During spring heavy

493 pollution days, the $ER_{H/C}$ of OC3 and OC4 at 1.1-3.3 μm were significantly high, along

494 with the enhancement of 4- and 5-ring PAHs (Flt, Pry, BbF, BkF, Bap), hopane and

495 C18-C33 at these sizes. Further, Figure 5 compares the size distributions of species

496 which were significantly enhanced during heavy pollution. During the spring heavy

497 pollution, the peaks of the OC3 shifted to 2.1-4.7 μm, and the peaks of 4-ring PAHs,

498 C29αβ-HP, C30αβ-HP and sum of C26-C33 also changed to a larger size. The results

499 imply that this heavy pollution may be caused by local combustion sources which

500 emitted relatively larger particles.

501 Figure 4

502 Figure 5

503   The summer heavy pollution was characterized by strong enhancement of SO_4^{2-},

504   NH_4^+, Al, EC2 and C26-33 mainly in the coarse mode (Figure 4). The peak of Al in the

505   coarse mode changed from 4.7-5.8 μm for less/average polluted days to 5.8-9.0 μm for

506   heavy pollution (Figure 5). And SO_4^{2-}, NH_4^+ and C26-33 increased in size to 3.3-4.7 and

507   5.8-9.0 μm respectively. Consistent with the discussion on size distribution of PM mass

508   concentrations, this heavy pollution may be caused by resuspended dust or long-range

509   transported dust and heterogeneous reactions. Suspended soil containing fertilizer can

510   contribute to alkaline conditions and enhance the heterogeneous reactions on coarse

511   particles (Shen et al., 2011). Additionally, the increases of the low molecular weight

512   PAHs and short chain n-alkanes demonstrate the repartitioning and suspension.

513   Heavy pollution during autumn and winter was strongly associated with significant

514   enhancement of NO_3^- and moderate enhancement of SO_4^{2-}, NH_4^+, OC and EC at most

515   sizes especially at 0.65-3.3 μm, as shown in Figure 4. NO_3^-, SO_4^{2-}, NH_4^+, and OC can

516   be from chemical reactions and partly from primary emissions, while EC is from

517   primary emissions. The enhanced EC demonstrates that the meteorological conditions

518   during heavy pollution caused accumulation of particles and precursors. Referring to

519   Figure 5, peaks of NO_3^-, SO_4^{2-}, OC3 and EC1 in the fine mode shifted from 0.43-0.65

520   μm during less polluted days to 0.65-1.1 or 1.1-2.1 μm during heavy pollution. Heavy

521   pollution during autumn and winter in northern China is usually characterized by large

522   emissions and specific meteorological condition with a stable boundary layer, weak

523   winds, an increase in temperature, and high relative humidity (RH) (Cheng et al., 2016).

524   The meteorological condition was unfavorable for the dispersion of particles and

525   precursors and favours secondary particle formation, hygroscopic growth and stronger

526   coagulation. Lower temperature, high RH and high precursors increase the formation

527   of ammonium nitrate by facilitating the aqueous phase chemical reactions which was

528   more likely to occur at 0.65-2.1 µm (Zhang et al., 2013; Tian et al., 2016). In addition,

529   as discussed above, the emissions during winter were more complex and emitted

530   coarser EC-containing particles (such as domestic coal combustion), which can rapidly

531   accumulate during heavy pollution conditions. The EC at a coarser size can strength the

532   reaction at these sizes, because EC could provide sites for adsorption and reaction due

533   to its large surface area, and it has the catalytic properties for redox chemistry reactions.

534   Stronger relationship between black carbon (BC)-containing particles and secondary

535   species during more polluted periods were also observed by Wang et al. (2019).

536

537   **4. Summary and conclusions**

538   A comprehensive study on water-soluble ions, elements, carbon fractions, n-alkanes,

539   PAHs, hopanes and steranes in size-resolved PM samples were conducted during 1 year

540   in a typical northern Chinese industrial megacity. Size distributions of the inorganic and

541   organic components during different seasons and pollution levels were analyzed.

542   The size distribution of the PM mass concentrations was bimodal during all four

543   seasons peaking at 0.43-0.65 µm and 4.7-5.8 µm; and the coarse mode peak was large

544   during spring and the fine mode peak was more substantial during winter. Both main

545   component composition and organic composition were similar within each mode, but

546   relatively different for the different modes. The OC3, NO_3^- and sum of crustal elements

547   showed the highest concentrations in the pseudo-ultrafine, fine and coarse modes,

548   respectively, except that SO_4^{2-} became the largest component in the pseudo-ultrafine

549   and fine modes during summer. For organic markers, PAHs, C29αβ/C30αβ and

550   C34[S/S+R] ratios consistently indicate stronger traffic influence during summer and

551   increased coal combustion during winter; and imply that the maturity of the fossil fuel

552   source decreased with the increase of particle size. The enhancement of C30ββ and

553   C34αβR in the coarse mode during winter indicate a contribution from immature coal

554   combustion. The profile of *n*-alkanes suggests a dominant fuel combustion influence in

555   the fine mode, and contributions of a vegetation source and resuspended dust in the

556   coarse mode especially during spring and summer.

557   For the size distributions, NO_3^-, SO_4^{2-} and NH_4^+ concentrations were large in the fine

558   mode during most seasons, while SO_4^{2-} peaked at 1.1-2.1 μm during winter probably

559   due to a large contribution of aqueous phase reactions, and NO_3^- peaked at 3.3-4.7 μm

560   during summer due to repartitioning. Carbon fractions generally exhibited typical

561   bimodal distributions. The crustal elements (Al, Ca, Fe, Ti, etc.) were primarily

562   concentrated in the coarse mode at 4.7-5.8 or 5.8-9.0 μm. Most sterane, hopane and n-

563   alkanes were observed to have a bimodal distribution. High molecular weight PAHs

564   were concentrated at small sizes during winter, while low molecular weight PAHs were

565   frequently bimodal due to repartitioning.

566   During the spring heavy pollution periods, OC3, OC4, 4- and 5-ring PAHs, hopane

567   and C18-C33 n-alkanes were enhanced at 1.1-3.3 μm, and their peaks shifted to a larger

568   diameter, implying that the heavy pollution may be caused by a local combustion source

569   which emitted relatively larger particles. During the summer heavy pollution periods,

570   the PM, SO_4^{2-}, NH_4^+, Al, EC and C26-33 concentrations in the coarse mode

571   significantly increased, and their peaks in the coarse mode changed from 3.3-5.8 μm

572   for less polluted days to 5.8-9.0 μm for heavy pollution days, indicating a high

573   contribution of resuspended dust and/or heterogeneous reactions. During winter and

574   autumn, heavy pollution was strongly associated with significant enhancement of NO_3^-

575   and moderate increases for SO_4^{2-}, NH_4^+, OC and EC. Peaks of PM, NO_3^-, SO_4^{2-}, OC3

576   and EC1 in the fine mode shifted from 0.43-0.65 μm during less polluted days to 0.65-

577   1.1 or 1.1-2.1 μm during heavy pollution.

578   The data from this work will be used for quantitative source apportionment, which

579   will be further reported in a subsequent paper.

580

581   **Authors contributions**. YZT designed the research and wrote the draft of the

582   manuscript with contributions from all coauthors. RMH designed and reviewed the

583   manuscript. YCF take part in designing the research. ZBS assisted with data analysis

584   and manuscript edit. YLL, YXL and QQX performed sampling and experiments. JSX

585   assisted with data analysis.

586   **Competing interests.** The authors declare that they have no conflict of interest.
