**Abstract.** There are few long-term datasets of volatile organic compounds (VOCs) in the High Arctic. Furthermore, knowledge about their source regions remains lacking. To address this matter, we report a multi-season dataset of highly time-resolved VOC measurements in the High Arctic from April to October 2018. We have utilized a combination of measurement and modeling techniques to characterize the mixing ratios, temporal patterns, and sources of VOCs at Villum Research Station at Station Nord, in Northeastern Greenland. Atmospheric VOCs were measured using Proton Transfer-Time of Flight-Mass Spectrometry (PTR-ToF-MS). Ten ions were selected for source apportionment with the receptor model, positive matrix factorization (PMF). A four-factor solution to the PMF model was deemed optimal. The factors identified were Biomass Burning, Marine Cryosphere, Background, and Arctic Haze. The Biomass Burning Factor described the variation of acetonitrile and benzene and peaked during August and September. The Marine Cryosphere Factor was comprised of carboxylic acids (formic, acetic, and C<sub>3</sub>H<sub>6</sub>O<sub>2</sub>) as well as dimethyl sulfide (DMS). This factor displayed peak contributions during periods of snow and sea ice melt. A potential source contribution function (PSCF) showed that the source regions for this factor were the coasts around Southeastern and Northeastern Greenland. The Background Factor was temporally ubiquitous, with a slight decrease in the summer. This factor was not driven by any individual chemical species. The Arctic Haze Factor was dominated by benzene with contributions from oxygenated VOCs. This factor exhibited a maximum in the spring and minima during the summer and autumn. This temporal pattern and species profile are indicative of anthropogenic sources in the mid-latitudes. This study provides seasonal characteristics and sources of VOCs and can help elucidate the processes affecting the atmospheric chemistry and biogeochemical feedback mechanisms in the High Arctic.

## 1 Introduction

The temperature in the Arctic has increased at twice the rate of the global average (IPCC, 2019), a phenomenon known as Arctic amplification. Increased CO<sub>2</sub> concentration and sea ice loss are responsible for the majority of this temperature increase (Dai et al., 2019). However, short-lived climate forcers (SLCFs; methane, ozone, black carbon (BC), and aerosol particles) are together responsible for half of the present temperature increase observed in the Arctic (Quinn et al., 2008). Atmospheric aerosol particles are the most important SLCF (due to their scattering, absorbing, and cloud modification properties) but their climate forcing is associated with the largest uncertainty, especially in the Arctic (Pörtner, 2019). Ozone is an important photochemical oxidant in the Arctic troposphere. Ozone precursors, e.g., volatile organic compounds (VOCs), nitrogen oxides (NO<sub>x</sub>), and peroxyacetyl nitrate (PAN), remained poorly characterized in the High Arctic (AMAP, 2015). Photochemical reactions including ozone and VOCs have important implications for the lifetime of methane, a major greenhouse gas. The identification and characterization of processes leading to precursor emissions of aerosols and ozone are therefore needed to improve the assessments of biosphere-aerosol-climate feedback mechanisms.

Several studies have reported on new particle formation (NPF) events, involving naturally emitted biogenic VOCs during the summer in the High Arctic. Dall'Osto et al. (2018b) recently demonstrated a negative correlation of NPF events at Villum Research Station, Station Nord, in Northeastern Greenland with sea ice extent. The authors suggested that ultrafine

aerosol formation is likely to increase in the future, given the projected increased melting of sea ice (Boe et al., 2009; Bi et al., 2018). Dall'Osto et al. (2017) hypothesized that NPF events during summer on Svalbard were linked to marine biological activities within the open leads and between the pack ice and/or along the marginal sea-ice zones. Further confirming the same processes are occurring for Northeastern Greenland (Dall'Osto et al., 2018a; Nielsen et al., 2019). Open leads and open pack  
45 ice emit dimethyl sulfide (DMS) that undergoes atmospheric oxidation leading to methanesulfonic acid (MSA), sulfur dioxide, and ultimately sulfuric acid, which helps form and grow particles (Nielsen et al., 2019). After formation, aerosols grow to sizes where they can act as cloud condensation nuclei (CCN) (Ramanathan et al., 2001). VOCs of marine biogenic origin greatly contribute to CCN activity during summer (Lange et al., 2018; Lange et al., 2019). The sources of NPF in the Arctic and its corresponding precursors are a topic of intense research, as uncertainty remains regarding the mechanism of aerosol  
50 production. For example, Burkart et al. (2017) found that the condensable vapors responsible for particle growth were more semi-volatile than previously observed in mid-latitudes, although they could not identify a source area for these vapors. Aerosol formation is one of the most important factors in determining the surface energy balance in the Arctic. Recently, it was estimated that NPF events could increase CCN concentrations by 2–5 fold over background concentrations (Kecorius et al., 2019). However, parametrization of the processes leading to aerosol formation is still a large source of uncertainty in global  
55 radiative forcing predictions (Haywood and Boucher, 2000). The characterization of these gas-phase precursors to particle formation is a key factor for understanding the dynamics of the Arctic troposphere and the corresponding effects on climate.

Ozone is an important pollutant at the surface and greenhouse gas in the mid to upper troposphere. Ozone can perturb radiation fluxes and modify heat transport to the Arctic (Shindell, 2007). In the Arctic, sources of ozone include long-range transport and photochemical production. Ozone and its precursors (VOCs, NO<sub>x</sub>, CO, and PAN) can be transported from  
60 anthropogenic sources in the mid-latitudes (Hirdman et al., 2009) and natural boreal forest fire emissions (Arnold et al., 2015), which have been increasing in recent years (Parrish et al., 2012). The major sink for ozone in the Arctic is photochemical loss, followed by minor contributions from dry deposition. Ozone largely controls the oxidative capacity of the atmosphere, as a chief precursor for OH, an oxidant for many compounds, and a major prerequisite for halogen explosion event (Simpson et al., 2007). Halogen explosion events can affect the lifetime and reaction rates for organic gases and the deposition of mercury in  
65 the Arctic ecosystem. Photochemical reactions involving VOCs can be a sink (by reactions with ozone) and a source (through reactions with NO<sub>x</sub>) of ozone. Increased anthropogenic activity in the Arctic (shipping and resource extraction) is expected to increase emissions of both NO<sub>x</sub> and VOCs (Law et al., 2017). Biomass burning emissions, which are expected to increase in the future, have been shown to increase ozone production by as high as 22 % in the Arctic (Arnold et al., 2015). Ozone levels have consequences for OH radical production, which is the main oxidant of methane, thus largely controlling its lifetime in  
70 the atmosphere. Therefore, the characterization of the interactions of ozone and VOCs have implications for climate effects and atmospheric chemistry.

Several factors, including chemical lifetime, local emissions, and long-range transport, govern the mixing ratios of VOCs in the Arctic atmosphere. The chemical lifetime of most VOCs in the Arctic is dependent on the oxidative capacity of the atmosphere, thus there is a strong seasonality (Gautrois et al., 2003). However, due to the low humidity in the Arctic

75 atmosphere, the concentration of OH is low (Spivakovsky et al., 2000). Therefore, halogen and ozone chemistry play an active  
role during the spring in the atmospheric chemistry of VOCs in Arctic regions (Simpson et al., 2015). However, atmospheric  
reactions alone seem unable to explain the VOC mixing ratios and dynamics observed at Arctic sites (Grannas et al., 2002;  
Guimbaud et al., 2002; Sumner et al., 2002), indicating missing sources other than photochemical production. Two potential  
80 uptake/release mechanisms and acts as a matrix for many photochemical and biological processes (Guimbaud et al., 2002;  
Grannas et al., 2004; Kos et al., 2014). For example, Dibb and Arsenault (2002) demonstrated that the snowpack is a source  
of formic and acetic acid through the oxidation of ubiquitous organic matter. Furthermore, Boudries et al. (2002) observed  
emission from the snowpack to the atmosphere of acetone, acetaldehyde, and formaldehyde, which were explained by  
photochemical production in the snowpack. Depositional fluxes of methanol were also observed, which they postulated as a  
85 source of formaldehyde. These observed gas-phase fluxes had a diurnal cycle following polar sunrise that correlated with the  
solar zenith angle. Sea surface microlayer emissions are important local sources of atmospheric VOCs, e.g. DMS, formic acid,  
and acetic acid (Mungall et al., 2017). Sea emissions have a pronounced seasonality because of sea ice preventing air-sea  
exchange during most of the year in the Arctic. The sea surface microlayer could play a role in the emission of VOCs due to  
photochemical processes (Chiu et al., 2017; Bruggemann et al., 2018) or heterogenic oxidation (Zhou et al., 2014). For highly  
90 water-soluble compounds, the ocean could also be an important sink (Sjostedt et al., 2012). Finally, transport of VOCs, such  
as benzene, methane, ethane, propane, and chlorofluorocarbons, has been observed from the mid-latitudes to the High Arctic  
(Stohl, 2006; Harrigan et al., 2011; Willis et al., 2018).

Few studies have reported VOCs in ambient air from Arctic sites with on-line techniques, usually during short-term  
campaigns. Hornbrook et al. (2016) utilized non-methane hydrocarbons measurements to derive time-integrated halogen  
95 mixing ratios during the OASIS-2009 campaign at Utqiagvik, AK (formerly known as Barrow, AK). Mungall et al. (2018)  
studied the sources of formic and acetic acid at Alert, NU during the summer of 2016. Sjostedt et al. (2012) and (Mungall et  
al., 2017) performed VOC measurements onboard the CCGS *Amundsen* in the Canadian Archipelago during the summer of  
2008 and 2014, respectively. There have been several campaigns exploring snowpack emissions of VOCs (Boudries et al.,  
2002; Dibb and Arsenault, 2002; Guimbaud et al., 2002; Barret et al., 2011; Gao et al., 2012). Gautrois et al. (2003) reported  
100 long-term VOC concentrations for Alert, NU, where a seven-year time-series of VOC mixing ratios has been generated,  
although with a 9-day time resolution, using off-line techniques (GC coupled to flame ionization and electron capture  
detectors). High time resolution measurements are of vital importance for the study of Arctic atmospheric chemistry. For  
instance, diurnal studies can only be accomplished with a fast response instrument, as grab samples and time-integrated  
samples (i.e., adsorbent tubes) will not capture the variability on short enough time scales (de Gouw and Warneke, 2007).  
105 Understanding the effects of meteorological parameters on VOCs levels requires an instrument response which is shorter than  
the transient event being observed. Also, flux measurements can only be achieved through fast responding instrumentation  
(Müller et al., 2010). The study of short-lived compounds, such as reactive halogen species, and their interactions with VOCs  
is only possible on short timescales. Finally, global networks have highlighted the need for a quick turnaround in the delivery

of atmospheric species for the validation of global atmospheric composition forecasting systems (Schultz et al., 2015). These  
110 previous studies call for higher time resolved and longer measurement campaigns, thus highlighting the importance of long-  
term high time-resolved measurements of VOCs in the Arctic.

In this study, we report several months of high time-resolved mixing ratios of selected VOCs measured at the high  
Arctic site Villum Research Station (Villum) at Station Nord (Northeastern Greenland). This study aims to provide a better  
insight into the dynamics, seasonal behavior, and potential sources of VOCs in the high Arctic. We accomplish this by  
115 combining VOC mixing ratios with meteorological data, air mass back trajectories, and the receptor model, positive matrix  
factorization (PMF). In Sect. 2, we describe our analytical instrumentation and models in detail. In Sect. 3, we cover the  
seasonal dynamics of VOC as well as each factor from the PMF model.

## 2 Methods

### 2.1 Field site

120 The sampling campaign took place at Villum Research Station (Villum), which is situated on the Danish military base, Station  
Nord, in Northeastern Greenland (81° 36' N, 16° 40' W, 24 m above mean sea level). Villum is situated in a region with a dry  
and cold climate where the annual precipitation is 188 mm and the annual mean temperature is -16 °C. The dominating wind  
direction is southwestern with an average wind speed of 4 m s<sup>-1</sup>. The sampling took place about 2.5 km southwest of the main  
facilities of the Station Nord military camp. The sampling location is upwind from the Station most of the time for all seasons  
125 (Fig. S1). An overview of the meteorological data is presented in Fig. S2. Statistics for meteorological data over the sampling  
campaign can be found in Table S1.

### 2.2 Gas-phase measurements and data processing

Gas-phase measurements of VOCs were obtained using a PTR-ToF-MS 1000 (Ionicon Analytik GmbH). The measurement  
campaign commenced after polar sunrise on April 4 and concluded before polar sunset on October 28, 2018. The PTR-ToF-  
130 MS was operated with hydronium ion (H<sub>3</sub>O<sup>+</sup>) as a reagent ion, a drift tube temperature of 70 °C, a drift pressure of 2.80 mbar,  
a drift tube voltage of 650 V leading to an *E/N* (Electric field/density of the buffer gas in the drift tube) value of around 120  
Townsend (Td). Mass spectra up to *m/z*=430 Da were collected at 5 second single spectra integration time. The instrument  
inlet consisted of a PEEK capillary tube heated at 70 °C and a built-in permeation unit (PerMasCal; Ionicon Analytik) which  
emitted 1,3-diiodobenzene, used for mass scale calibration. The inlet of the sampling line consisted of ¼" Teflon tubing  
135 extending through an insulated opening in the roof with a sampling cone at the tip to prevent water and debris from blocking  
the orifice. Ambient outdoor air was aspirated into the instrument at a rate of 100 ml min<sup>-1</sup>. Blank measurements were obtained  
every 4 hours for 15 minutes by automatic switching from the ambient outdoor air to indoor air pumped through a Zero Air  
Generator (Parker-Balston, Part #75–83). Due to technical issues (mainly electrical power failure), measurements were  
interrupted for short periods ranging from days to weeks in April, June, August, and September. Instrument parameters (*E/N*

140 ratio, drift tube temperature, pressure, and voltage) were inspected before and after power failures to ensure proper instrument functionality. Periods with abnormal parameter values were removed. Table S2 summarizes the total number of operational hours for each compound for each month of the campaign.

Data generated by the PTR-ToF-MS instrument were processed with the PTR-MS Viewer software v. 3.2.12 (Ionicon Analytik). Mass calibrations and VOC mixing ratios were calculated by the PTR-MS Viewer, based on the reaction kinetics  
145 quantification method (Sect. S1). The instrument quantification was validated against an external gas-phase calibration standard (Apel-Riemer Environmental), a comparison between standard and instrument mixing ratios yielded percent errors that were within the analytical uncertainties (Table 1), therefore we are confident in the quantification method (Holzinger et al., 2019). The PTR-MS technique allows to observe species with a proton-affinity higher than water, this encompasses most VOCs found in the atmosphere with the important exception of alkanes. It does not allow for the distinction between isomers  
150 to be made. Compound names were assigned based on comparison with the libraries from the PTR-MS Viewer and Pagonis et al. (2019), and references therein. Inspection of the mass spectrum yielded ten protonated masses from which an empirical formula was calculated, and compound names were assigned for nine masses, as discussed in Sect. 3.1. Output files were further processed with MATLAB R2018B for time averaging and blank subtraction. The limit of detection (LOD) for each identified species was calculated as three times the standard deviation (s.d.) of the blank values for each day. For calculation  
155 of statistics, mixing ratios below LOD were set to  $\frac{1}{2}$  the LOD. The data were time-averaged to a 30-minute means. Uncertainty in VOC measurements accounted for the reaction rate coefficient as well as primary ion counts and blank corrected ion counts, for a detailed description see the Sect. S1. The data set has been rigorously quality controlled, through analysis of particle number size distributions (PNSD), meteorological data (wind direction and speed), and internal activity logs, to remove the influence of local pollution, for a detailed description see Sect. S2. Ozone ( $O_3$ ) was measured using an API photometric  $O_3$   
160 analyzer M400, data is quality assured and controlled via standard EN14625:2012, with calibrations every six months (Skov et al., 2004; Skov et al., 2020).

### 2.3 Positive Matrix Factorization (PMF) analysis

The PMF model was operated using the US EPA PMF version 5.0 software, which uses the second version of the multilinear-engine 2 (ME-2) platform (Paatero and Tapper, 1994). The goal of PMF is to identify the number of factors or sources  $p$ , the  
165 species profile  $f$ , and the mass contributed by each factor to each sample. PMF accomplishes this by decomposing a data matrix  $X$  into two matrices  $G$  and  $F$ . The input data matrix  $X$  consists of dimensions  $i$  and  $j$ , where  $i$  is the number of samples and  $j$  is the measured chemical species. The source profile matrix  $f$  is of dimensions  $p$  and  $j$ . The source contribution matrix  $g$  is composed of  $p$  and  $i$  dimensions. This is expressed in Eq. (1), below.

$$X_{ij} = \sum_{k=1}^p g_{ik} \times f_{kj} + e_{ij} \quad (1)$$

170 Where  $e_{ij}$  is the residual matrix and  $k$  is the individual sources. PMF uses measurement uncertainties  $u_{ij}$  and the residual matrix to minimize the Objective Function  $Q$ , Eq. (2) below:

$$Q = \sum_{i=1}^n \sum_{j=1}^m \left[ \frac{e_{ij}}{u_{ij}} \right]^2 \quad (2)$$

Where  $n$  is the total number of samples and  $m$  is the total number of species. There are three versions of the objective function:  $Q_{true}$  that includes all data points,  $Q_{robust}$  that excludes outliers, and  $Q_{theo}$  that is approximately equal to the number of degrees of freedom. The ME-2 platform performs iterations via the conjugate gradient method until convergence to minimize  $Q$ . Each good data point contributes a value of approximately one to the value of  $Q$ ; therefore,  $Q$  and the ratio of  $Q_{true}$  to  $Q_{theo}$  are the goodness of fit parameters for the appropriate number of factors (Paatero et al., 2014).

The following data preparation protocol was developed according to standard practice in the field (Polissar et al., 1998; Reff et al., 2007; Hopke, 2016) which allows PMF analysis to be performed effectively. In certain cases, discussed here, the data set was modified before modeling via PMF. Data with concentrations below the LOD were replaced with a value equal to half of the LOD. The associated uncertainty was set to 5/6 of the LOD. Missing concentrations from a sample were replaced with the median concentration of the data set and the uncertainty was set as a multiple (3) of median concentration (Polissar et al., 1998; Reff et al., 2007). It is worth noting that the operational protocols used to estimate the uncertainties and treatment of data are based on extensive testing to find an approach that provided useful results (Hopke, 2016). Numerous sensitivity runs were performed to evaluate the validity of this data preparation protocol including varying the treatment of data below the LOD (replacing with half of the LOD or leaving as is), treatment of missing values (removing the sample or replacing missing species with the median), treatment of the uncertainty matrix, number of species included in the model (species were systematically removed or added to observe their influence on the model solution), threshold values for species categorization, and the number of factors. Each variation of the input data, of course, produced a unique solution, however, the overall shape of the time series and factor contributions profile was consistent with the solution present in this study. The optimal model solution, for the configuration present here, was therefore deemed robust to these variations of the input data and provided acceptable diagnostics.

Two methods for evaluating modeling uncertainty in PMF were performed: bootstrapping (BS) and displacement of factor elements (DISP) (for a description see Paatero et al. (2014)). BS uncertainty includes effects from random errors and partially includes the effects of rotational ambiguity. DISP explicitly captures uncertainty from rotational ambiguity (Brown et al., 2015). Another method of estimating rotational ambiguity is the Fpeak function. Fpeak evaluates  $Q$  under different rotational strengths, in this study Fpeak strengths from -5 to 5 in intervals of 1 and from -1 to 1 in intervals of 0.1.

## 2.4 Ancillary data

Meteorological data including temperature, relative humidity, wind speed, wind direction, pressure, radiation, and snow depth were generated by an automatic weather station placed ~44 meters away from the measurement site. Using the local wind direction and wind speed, a conditional probability function (CPF) was calculated using the source contributions for each factor. CPF is defined as  $CPF = m_{\theta}/n_{\theta}$ , where  $m_{\theta}$  is the number of occurrences that a source contribution exceeds a predetermined threshold criterion (75<sup>th</sup> percentile) while arriving from a wind sector and  $n_{\theta}$  is the total number of occurrences

wind arrived from the same wind sector. A wind sector was defined as 30° and wind speeds below 0.5 m s<sup>-1</sup> were excluded to  
205 account for uncertainty in wind direction at low wind speeds. Daily polar gridded sea ice concentrations for the measurement  
period were obtained through the Nimbus-7 SMMR and DMSP SSM/I-SSMIS Passive Microwave Data (Cavalieri et al.,  
1996). Time series of local sea ice concentrations were calculated from the gridded daily average sea ice concentrations (%)  
by masking an area of ± 2° longitude and +8°/-4° latitude around Villum (Greene et al., 2017; Greene, 2020).

## 2.5 Back Trajectory Analysis

210 To investigate source regions, the R package Openair (Carslaw and Ropkins, 2012) was utilized to produce a potential source  
contribution function (PSCF). Trajectories in Openair were calculated using the HYSPLIT model (Draxler and Hess, 1998;  
Rolph et al., 2017) at 100 m altitude and 120 hours backward in time using Global NOAA-NCEP/NCAR reanalysis data  
archives on a 2.5° resolution. A PSCF, shown in Eq. (3), calculates the probability that an emission source is located in a grid  
cell of latitude  $i$  and longitude  $j$ , on the basis that emitted material in the grid cell  $ij$  can be transported along the trajectory and  
215 reach the receptor site.

$$PSCF = \frac{m_{ij}}{n_{ij}} \quad (3)$$

Where  $n_{ij}$  is the number of times a trajectory has passed through grid cell  $ij$  and  $m_{ij}$  is the number of times that a concentration  
was above a certain threshold value, in this case, the 90<sup>th</sup> percentile. To account for uncertainty in cells with a small number  
of trajectories passing through, a weighting function was applied (Carslaw and Ropkins, 2012).

## 220 3 Results and discussion

### 3.1 VOC temporal patterns and mixing ratios

The ten selected masses monitored by the PTR-TOF-MS and their assignments to species names are presented in Table 1.  
Assignments are made by choosing the most plausible contributions to an observed mass but each measured ion may have  
contributions from several different isomeric molecules. The assignment of masses in the table to protonated molecules of  
225 formaldehyde, acetonitrile, formic acid, acetic acid, and benzene appears to be unproblematic as no meaningful alternatives  
are found. For the remaining molecules, alternative assignments are possible. The mass assigned to acetone could be propanal  
as well, but propanal has a shorter atmospheric residence time and acetone is known to be one of the dominating VOCs  
observed in the atmosphere (Jacob et al., 2002), further, it has been found to have sources in the Arctic (Guimbaud et al.,  
2002). The mass assigned to DMS could be ethanethiol as well, but the large marine source of DMS makes it the most plausible  
230 assignment. Methyl ethyl ketone is isomeric with butenal, but being the second most abundant ketone in the atmosphere with,  
among others, apparently an oceanic source (Brewer et al., 2020) it appears to be the best assignment. C<sub>3</sub>H<sub>6</sub>O<sub>2</sub> may stem from  
propionic acid but also hydroxyacetone, methyl acetate, and ethyl formate. While it seems unlikely that ethyl formate could  
give a major contribution to this signal, the other three species are all plausible candidates: Low molecular weight organic

acids are commonly found in the atmosphere (Lee et al., 2009), methyl acetate has been found in emissions from biomass  
235 burning (Andreae, 2019) and hydroxyacetone is known to be formed by the atmospheric degradation of isoprene (Karl et al.,  
2009). For what concerns the  $C_5H_8OH^+$  ion we prefer not to make an assignment, possible isomers include, among others,  
pentalenals and pentalenones.

For the ten selected VOCs, time series of mixing ratios during the entire measurement period are displayed in Fig.  
1a-f. During the spring (April–May), certain compounds (benzene and  $C_5H_8O$ ) exhibited a maximum and thereafter a  
240 decreasing pattern, similar to the timing and profile of the Arctic Haze phenomena. During the spring, compounds did not  
display a diurnal profile except for acetic acid (Fig. S3) Whilst in summer (June–August), OVOCs revealed a diurnal cycle  
that closely follows radiation (Fig. 2 and S4). Compounds of non-photochemical origin (benzene and acetonitrile) also  
displayed a slight diurnal pattern, which could possibly be due to entrainment from aloft (Fig. S4). Interestingly, several  
compounds (formaldehyde, formic acid, and acetone) peaked in the spring with decreasing levels until the summer when a  
245 diurnal pattern following sunlight was observed (Fig. 1, 2, S4). During the autumn (September–October), all compounds were  
low except for acetone and acetonitrile (Fig. 1) and only acetic acid displayed a diurnal profile (Fig. S5). The levels, seasonal  
patterns, and comparison with other studies of these compounds will be discussed below.

Formaldehyde, formic acid, MEK, and acetone, and to a lesser extent acetic acid and  $C_5H_8O$ , displayed a decreasing  
pattern in the spring. For formaldehyde, formic acid, acetic acid, acetone, MEK, and  $C_3H_6O_2$  a diurnal variation was observed  
250 in the period July–August, with peak mixing ratios occurring around midday (Fig. 2 and S4), highlighting their dependence  
on sunlight. Acetone showed the highest mean mixing ratio  $\pm$  s.d. ( $0.608 \pm 0.196$  ppbv). Mean mixing ratios of acetone  
measured at Utqiagvik, AK during the OASIS-2009 field campaign (March–April 2009) were  $0.900 \pm 0.300$  ppbv (range of  
 $0.364$ – $2.21$  ppbv) (Hornbrook et al., 2016), and in the Canadian Archipelago in August–October was  $0.424$  ppbv (Sjostedt et  
al., 2012), which is within the same range observed at Villum ( $0.608 \pm 0.196$  ppbv, Table 1). The average mixing ratio of  
255 formaldehyde in the present study ( $0.220 \pm 0.128$  ppbv) is similar to those measured at Utqiagvik, AK ( $0.204$  ppbv) and Alert,  
NU ( $0.166$  ppbv) in March–April (Grannas et al., 2002; Barret et al., 2011). Formic acid ( $0.454 \pm 0.371$  ppbv) and acetic acid  
( $0.201 \pm 0.149$  ppbv) mean mixing ratios were within the range of those measured at Summit, Greenland ( $0.4$  ppbv) by Dibb  
and Arseneault (2002), although considerably lower than those measured by Mungall et al. (2018) during the early summer at  
Alert, NU (formic acid  $1.23 \pm 0.63$  ppbv, acetic acid  $1.13 \pm 1.54$  ppbv). MEK displayed a mean mixing ratio of  $0.031 \pm 0.021$   
260 ppbv, which is slightly lower than the median concentrations of  $0.190$  ppbv measured in March–April 2009 at Utqiagvik, AK  
(Hornbrook et al., 2016) and  $0.054$  ppbv measured at Alert, NU in April–May 2000 (Boudries et al., 2002).

The two main non-oxygenated compounds measured were acetonitrile and benzene. Benzene mixing ratios followed  
the expansion of the polar dome with high mixing ratios in the spring period and lowest in the summer period (Fig. 1f), similar  
to sulfate and BC measured (Massling et al., 2015; Skov et al., 2016) and accumulation mode aerosols (Lange et al., 2018).  
265 The mean mixing ratio of benzene measured at Villum was  $0.027 \pm 0.016$  ppbv, which is a factor of two higher than those  
measured in the Canadian Archipelago ( $0.013$  ppbv) by Sjostedt et al. (2012). Benzene has shown a seasonal pattern at Alert,  
NU with a higher mixing ratio in winter due to no or limited photochemistry and long-range transport from lower latitudes

(Gautrois et al., 2003). They reported mean winter and summer mixing ratios of 0.200 and 0.034 ppbv, respectively; when compared to the present study there is good agreement during the summer. Acetonitrile followed a similar pattern to benzene during the spring with decreasing values, as well as exhibiting minima in the summer and maxima during the autumn (Fig. 1b). The mean mixing ratio of acetonitrile observed at Villum is  $0.067 \pm 0.025$  ppbv, which is a factor of two higher than reported by Sjostedt et al. (2012) (0.030 ppb). The range of acetonitrile mixing ratios (0.023–0.156 ppbv) corresponds to the upper and lower limits of background levels over the Atlantic Ocean (0.10–0.15 ppbv) reported by Hamm et al. (1984) and Hamm and Warneck (1990). The main source of acetonitrile in the atmosphere has been found to be biomass burning (Singh et al., 2003).

DMS was the only sulfur-containing compound detected, with a mean  $\pm$  s.d. of  $0.046 \pm 0.043$  ppbv. The mixing ratios of DMS observed in this study are a factor of two lower than those reported by Sjostedt et al. (2012) (0.093 ppbv). DMS mixing ratios were near LOD during the spring and autumn, however, were significantly elevated levels during the summer periods of sea ice melt (Fig. 1e and 2).

### 280 3.2 Springtime VOC correlations

Elevated DMS mixing ratios were observed for two short periods of a few days' duration in May (1–5 May and 16–19 May), where DMS mixing ratios increased an order of magnitude from  $\sim 0.02$  to  $>0.2$  ppbv (Fig. 3a and b). In May, most of the ocean surrounding Villum is still frozen. However, satellite images from the area (available at <http://ocean.dmi.dk/arctic/nord.php>) showed that there were open leads in the frozen sea surface. Back trajectory calculations (Fig. S6a and b) confirmed that, during the DMS emission episodes, the air masses experienced extensive surface contact, traversed near areas containing open leads (as identified from satellite images) before reaching the station. During DMS emission episodes, the acetone mixing ratios decreased correspondingly. Sjostedt et al. (2012) found moderate anti-correlation ( $R=0.37$ ,  $p<10^{-4}$ ) for DMS with acetone. Minimum values of acetone were observed when DMS reached its maximum values, and the short photochemical lifetime of DMS suggests a localized biological sink for acetone associated with the production of DMS. Certain microorganisms can consume acetone as well as produce DMS from DMSP (Taylor et al., 1980; Kiene et al., 2000). At Villum, the relationship between acetone and DMS showed seasonal changes with a moderate negative correlation in April ( $R=-0.55$ ), a weak positive correlation in July ( $R=0.23$ ), and a moderate negative correlation in September ( $R=-0.68$ ). Possible reasons for these variations may be changes in the biological conditions of the seawater, photochemical activity, and source regions. Pearson correlation coefficients for chemical species, radiation, and temperature for April, July, and September are tabulated in Table S3, S4, and S5, respectively.

As illustrated in Fig. 3a and b, acetone is anti-correlated with ozone during periods of elevated DMS. This relationship is particularly evident during situations with abrupt changes in the mixing ratios of the species as on 1, 2, and 5 May. These changes in mixing ratios are accompanied by a change in meteorological conditions, illustrated here by changes in wind speed and to a less extent wind direction (Fig. 3). Guimbaud et al. (2002) found a similar relationship between acetone and ozone during different field campaigns at Alert, Canada with elevated acetone levels during ozone depletion episodes accompanied

by a concomitant decrease in the propane mixing ratios. However, it was found that the increase in acetone could not be explained by gas-phase chemistry but possibly by photochemically induced emissions from the snowpack. This phenomenon was also observed by Boudries et al. (2002). The anti-correlation between ozone and acetone observed at Villum may also be explained by a similar influence of photochemistry that causes destruction of ozone as well as the formation of acetone by gas phase and surface reactions. Also, the possible influence of vertical air exchange must be considered as well. During pristine atmospheric conditions at Villum, ozone is destroyed but not produced within the boundary layer, due to low NO<sub>x</sub> concentrations (Nguyen et al., 2016). Exchange with the free troposphere will lead to increases in the ozone concentrations and possibly a reduction of acetone concentrations at ground level due to dilution by air from aloft with a lower acetone concentration. The anti-correlation between ozone and acetone supports the hypothesis that acetone is not brought down from aloft to a significant extent but has surface or boundary layer chemistry as its main source.

During the summer, the behavior of acetone is different. In addition to the previously mentioned dependence on the diurnal variations of sunlight (Fig. 2 and S4), providing strong evidence of a local photochemical source, a positive correlation with ozone was observed. In June, an anti-correlation is still seen, but in July and August, the two species are correlated (R=0.69 for July and R=0.46 for August). The fact that ozone is also positively correlated to other OVOCs (particularly formaldehyde, R=0.86 for July) suggests that the correlation is due to the influence of transport of air containing ozone and acetone formed by the photochemical degradation of air pollutants. During the summer period, acetone is correlated with acetonitrile (R=0.73 for June–August), in September and October this correlation becomes very strong (R=0.96). Acetonitrile is considered an atmospheric tracer of biomass burning as the global budget of this compound, as previously mentioned, is dominated by emissions from biomass burning (Holzinger et al., 2001). Thus, biomass burning and atmospheric degradation of biomass burning products seem to be an important source of acetonitrile and acetone during this period. The correlation with ozone is also positive during these months, most likely because the photochemistry of biomass burning emissions is also a source of ozone brought to Villum. The different temporal patterns and correlations suggest the behavior and sources of VOCs in the Arctic are seasonally dependent. Therefore, a detailed, statistical investigation of the sources affecting VOC levels is warranted.

### 3.3 Source Apportionment via PMF

VOCs exhibited distinct temporal patterns that are seasonally dependent and suggest different processes contributing to ambient mixing ratios. Therefore, the source apportionment model, PMF, was employed to provide an in-depth examination of these VOC sources. The base model was executed 100 times with a random start seed. Species were categorized based on their S/N, species with an  $S/N \geq 1$ ,  $0.2 < S/N < 1$ ,  $S/N < 0.2$  were categorized a ‘Strong’, ‘Weak’, and ‘Bad’, respectively. The uncertainties of ‘Weak’ species were tripled, and ‘Bad’ species were excluded from the analysis. Two species deviated from this categorization; benzene (S/N = 0.3) was classified as ‘Strong’ since it serves as a tracer for anthropogenic emissions from fossil fuel combustion and formic acid (S/N =1.0) was classified as ‘Weak’ since there was substantial variability of blank measurements in the spring. Rather than down-weighting spring samples, the entire dataset for formic acid was down-weighted

to minimize bias for the spring period. The species included in the analysis were those shown in Table 2. Expanded  
335 uncertainties for model input were estimated as described in the Sect. S1. The two periods of elevated DMS mixing ratios were  
removed from the model input matrix since these periods were considered an anomaly compared to the rest of the measurement  
period (appearance of open leads, wind direction directly from these leads, and air masses with extensive surface contact).  
Therefore, these periods violated one of the assumptions of PMF; that sources do not change significantly over time or do so  
in a reproducible manner. The inclusion of these two periods did not improve model performance. Instead, we argue that their  
340 exclusion allows us to model the ambient behavior of VOCs devoid of episodic influence due to certain meteorological  
conditions.

A four-factor solution was deemed optimal based on  $Q_{\text{true}}/Q_{\text{theo}}$  ratios,  $R^2$  values between modeled and measured  
mixing ratios, and physical interpretation of the factor time series and profiles. Figure S7 displays the  $Q_{\text{true}}/Q_{\text{theo}}$  ratios against  
the factor number. Increasing the factor number from two to three produces the largest decrease in the  $Q_{\text{true}}/Q_{\text{theo}}$  ratio, which  
345 is often taken as the optimal solution for the number of factors. However, the mean  $R^2$  values for the 3-factor solution (0.8)  
were lower than for the four-factor solution (0.85) and the physical interpretation of the four-factor solution yielded more  
robust analysis. Therefore, a four-factor solution was deemed optimal. The large discrepancy between  $Q_{\text{true}}$  and  $Q_{\text{theo}}$  can be  
explained by the large analytical uncertainties (32–64 %, Table 1), which is due to the extremely low mixing ratios observed,  
causing  $Q_{\text{true}}$  to be small, the large number of samples which produces a large  $Q_{\text{theo}}$ , as well as co-variation in the species (see  
350 Sect. 3.1). While these uncertainties are high, they are reasonable for a kinetic quantification of organics at these instrument  
parameters and extremely low mixing ratios based on Holzinger et al. (2019).

Displacement on the four-factor solution yielded no errors in the model and zero factor swaps, illustrating the solution  
is valid and free of rotational ambiguity. Bootstrapping was performed for 100 runs and mapped >85 % of the boot factors to  
the base factor. This high percentage indicates the model solution is free of random error. Variations of the  $F_{\text{peak}}$  strength  
355 consistently returned the lowest change in  $Q$  at  $F_{\text{peak}} = 0$ , indicating the model is free of rotational ambiguity. The inspection  
of G-space plots produced no visible correlations between factors. Together these error estimation methods show the model  
solution is robust, valid, and free of random errors and rotational ambiguity.

Based on their chemical composition and their temporal variation the four factors were assigned to likely sources  
including Biomass Burning, Marine Cryosphere, Background, and Arctic Haze, which will be explained in detail below.

### 360 3.3.1 Biomass Burning Factor

The most prominent species in the profile of the Biomass Burning Factor is acetonitrile, explaining 63 % of the variation, and  
benzene, explaining 33 % of the variation (Fig. 4b). As mentioned above, acetonitrile is a characteristic tracer for biomass  
burning emissions. Biomass burning is also an important source of benzene, with an estimated global strength of about half of  
the anthropogenic sources (Lewis et al., 2013) and it is a source of methyl acetate as well (Andreae, 2019), one of the  $C_3H_6O_2$   
365 isomers. The chemical species profile (Fig. 4b) of this factor, therefore, points to a biomass-burning source. The time series  
(Fig. 4a), shows this factor to decrease in the spring to a minimum in the summer, and slowly increase to a maximum at the

beginning of September. The decrease in the spring is reflective of decreasing concentrations of benzene and acetonitrile; in the case of benzene this can be ascribed to anthropogenic emissions during this period as the polar dome is expanded during winter and spring allowing for emissions to be entrained from the mid-latitudes. In the case of acetonitrile, the reason is more uncertain, there are anthropogenic sources of acetonitrile, particularly wood burning for residential heating and solvent use (Languille et al., 2020), but they appear to be of very minor importance compared to forest fires (de Gouw et al., 2003). The height of the biomass burning season in North America and Northern Eurasia is July (Lavoue et al., 2000), although due to the contraction of the polar dome during summer, minimum contributions from this factor are observed. Increased areas of open water in the Arctic also act as a sink for acetonitrile during the summer (de Gouw et al., 2003). The Biomass Burning Factor peaks in August/September when the polar dome starts to expand thus allowing biomass burning emissions to reach the High Arctic.

To examine the geographical origin of this factor, air mass back trajectories from the HYSPLIT model were calculated every hour during the peak of the Biomass Burning Factor (15 August–15 September 2018) and extending 336 hours (two weeks) backward in time. The trajectory length of two weeks was selected to account for the long lifetime of acetonitrile. Active fires during the period 15 August–15 September 2018 were provided by NASA's Fire Information for Resource Management System (FIRMS) (Schroeder et al., 2014). Active fires occurring within one hour and one-degree latitude/longitude of a trajectory endpoint was used to access the influence of active fires on the Biomass Burning Factor. While there was evidence of active fires in North America and Eurasia occurring near a trajectory endpoint within one hour, the uncertainty of a trajectory with a length of 336 hours is quite large (Stohl, 1998). Therefore, no meaningful conclusions can be drawn from this analysis other than the transport time of emissions influencing the Biomass Burning Factor is greater than two weeks, and that we are unable to capture these emissions with the current trajectory models with any confidence.

The influence of biomass burning was observed at other High Arctic sites during this period. (Lutsch et al., 2020) used fourier-transform infrared spectroscopy (FTIR) measurements of CO, HCN, and ethane at several High Arctic sites coupled with aerosol optical depth data and the GEOS-Chem model to detect the influence of wildfires and attribute their sources. They observed fire-affected enhancements in the tropospheric CO column at Eureka, NU from September 9 to the 25, 2018, and at Thule, Greenland from 24 August through 26 September 2018. The GEOS-Chem simulated the source regions for the fire-affected enhancements in the tropospheric CO column measurements to be boreal forests in North America and Asia at both sites (Lutsch et al., 2020). These observations of biomass burning at other High Arctic sites are in good agreement with the Biomass Burning Factor presented here, adding robustness to this factor assignment and can offer insight into the geographical origins of the Biomass Burning Factor.

Biomass burning is known to be an important source of BC, and it has been estimated to account for about 35 % of the BC emissions in the Northern Hemisphere (Qi and Wang, 2019). Despite this, the observed time profile of BC (not shown) at Villum did not show an increase during the autumn of 2018. This is likely to be explained by the fact that the emissions from biomass burning sources have been transported over long distances with corresponding long transport time (> two weeks), as BC is removed much faster from the atmosphere than acetonitrile due to wet deposition. The atmospheric residence time of

BC is below 5.5 days, according to a recent estimate (Lund et al., 2018), while that of acetonitrile is several months (de Gouw et al., 2003). Using meteorological parameters calculated along the trajectory path using HYSPLIT (see above), the mean accumulated precipitation for the peak of the Biomass Burning Factor was 14 millimeters (mm). Raut et al. (2017) used a combination of in situ observations from aircraft, satellite remote sensing, and modeling simulations to calculate the transport efficiency of BC during 2012. They concluded that the transport efficiency of BC was low (<30 %) when accumulated precipitation was large (5–10 mm). These previous observations combined with the accumulated precipitation data along each trajectory during the peak of the Biomass Burning Factor support the lack of BC loading during this time. While biomass burning is a source of BC globally, which is expected to increase in the future (Westerling et al., 2006), the results presented here indicate meteorological parameters encountered during transport can play a role in the levels observed in the High Arctic atmosphere. While biomass-burning emissions may increase in the future, increased precipitation patterns might counterbalance this increase although more research is needed to elucidate the relationship between these feedback mechanisms.

### 3.3.2 Marine Cryosphere Factor

The Marine Cryosphere Factor was characterized by formic acid, acetic acid,  $C_3H_6O_2$ , and DMS, explaining over 50 % of the variability of each of these compounds (Fig. 5b). The contribution of this factor is near zero in the spring and autumn and maxima during the summer months (Fig. 5a). This factor shows an enhanced diurnal variation with a correlation to sunlight during the summer months (Fig. 6). The high content of DMS points to a marine origin of this factor, while carboxylic acids have been demonstrated to be emitted from the snowpack (Dibb and Arsenault, 2002). Analysis of snow depth and sea ice concentrations ( $\pm 2^\circ$  longitude and  $+8^\circ/-4^\circ$  latitude area around Villum) illustrate the onset of this factor coincides with the snowmelt and sea ice decline. Therefore, a combination of marine and cryosphere sources appears to contribute to the species observed in this factor. The  $C_3H_6O_2$  is in this case assigned to propionic acid as the alternative isomers seem less probable, considering their typical origins (biomass burning for methyl acetate and isoprene oxidation for hydroxyacetone).

The sources of the organic acids are much less well characterized than those of DMS; in fact, model simulations have not been able to reproduce the mixing ratios of formic and acetic acid, particularly in the Arctic and northern mid-latitudes (Paulot et al., 2011; Mungall et al., 2018). As the lifetimes of formic acid and acetic acid against photochemical oxidation by reaction with the OH radical are relatively long (about 25 and 10 days, respectively, for  $[OH]=10^6$  molecules/cm<sup>3</sup>), dry and wet deposition is thought to be the main removal pathways (Seinfeld and Pandis, 2016). Estimated globally averaged atmospheric lifetimes against deposition for both formic and acetic acid in the boundary layer are between 1 and 2 days (Paulot et al., 2011). Thus, it is unlikely that direct long-range transport plays a relevant role in determining the mixing ratios of these species at Villum. Analysis of <sup>14</sup>C isotopes in formic and acetic acid in air and rainwater have shown that outside of urban and semi-urban areas the dominating (>80 %) source is modern carbon (Glasius et al., 2001). This analysis is consistent with model simulations showing that atmospheric oxidation of biogenic hydrocarbons is the largest source (Paulot et al., 2011; Millet et al., 2015). Even though vegetation in the High Arctic is sparse, contributions from precursor emissions or direct emissions of

formic acid and acetic acid from vegetation cannot be excluded, as discussed by Mungall et al. (2018). Emissions from the soil are also a possible but highly uncertain source of these species (Mungall et al., 2018). However, the Marine Cryosphere Factor is largely absent when snow is completely melted, exposing the bare ground and vegetation to the atmosphere, thus soil emissions and vegetation are improbable sources of these compounds. Instead, enhancements in these species and this factor is observed during periods of snowmelt and sea ice melt.

A comparison of the contribution of the Marine Cryosphere Factor to sea ice concentration, calculated as described in Sect. 2.3, and snow depth can further shed light on the origin of this factor (Fig. 5a). Periods of high contributions and diurnal pattern by the Marine Cryosphere Factor starts on 22 June (Fig. 6), where the local sea ice concentration and snow depth are starting to decline. Diurnal patterns were observed during this period of melting (Fig. 5a and 6). This continues until 9 August, when the measurements were interrupted due to technical issues. When measurements resumed on 16 August, the contribution from the Marine Cryosphere Factor had returned to the low levels found during springtime. Note that instrument parameters were monitored before and after interruptions to ensure proper functionality of the instrument, and periods that deviated from nominal values were removed. The Marine Cryosphere Factor appears not to be strongly dependent on the extension of the open sea, as sea ice concentrations/extensions reach a minimum, and consequently, the open sea area reaches a maximum by the beginning of September, but rather depends on active melting of snow and sea ice. Thus, it seems that emissions of VOCs from melting snowpacks and newly exposed sea ice areas could offer a viable explanation for the observed dependence of this source.

Previous work has shown that emissions from the sea in the Arctic area can be caused by a surface microlayer enriched in organic substances that acts as a source of formic acid and other oxidized VOCs (Mungall et al., 2017). This occurs either via heterogeneous chemistry or by photochemically driven reactions within the surface layer (Vlasenko et al., 2010; Chiu et al., 2017). Mungall et al. (2017) performed factor analysis of VOCs in the Canadian Archipelago finding four factors. One factor (Ocean Factor; containing formic acid, isocyanic acid, and oxo-acids) was highly correlated with dissolved organic carbon (DOC), fluorescent chromophoric dissolved organic matter (fCDOM), and radiation. However, DMS was poorly correlated with this factor. They concluded the source to be photochemical or heterogeneous oxidation from sources on the sea surface microlayer. While formic and acetic acid, as well as the carbonyl compounds, show daily variations correlating with radiation, as mentioned above, DMS shows a less clear correlation. The emission of DMS from the open ocean has been demonstrated to be dependent on horizontal wind speed (Bell et al., 2013). Although, the variation of the Marine Cryosphere Factor seems not to be driven mainly by the dependence on horizontal wind speed ( $R=-0.04$ ). Marine microorganisms produce DMS (Stefels et al., 2007; Lévassieur, 2013), and given the distance of the measuring site from open water (taking sea ice into account the, station is approx. 25 km distance from open water), it is proposed that the majority of DMS produced is already oxidized to MSA and other products when reaching the station. The presence of gas-phase MSA has been indicated by the observation of the methanesulfonate ion, which has been previously measured in the particle phase at Villum in February–May 2015 (Dall'Osto et al., 2018b; Nielsen et al., 2019).

Several studies have demonstrated the emission of VOCs from the snowpack; Gao et al. (2012) observed photo enhanced release of VOCs from both Arctic and mid-latitude snow; Grannas et al. (2002) obtained similar results by applying a box model to simulate observed emissions of carbonyl compounds from an Arctic surface layer at Alert. They found that  
470 diel cycles of carbonyl compounds are impacted by snowpack exchange characterized by nighttime adsorptive uptake from the snowpack and the largest release around noon, similar to the observations in this study. Anderson et al. (2008) found a high concentration of water-soluble organic compounds (presumably mainly formic and acetic acid) in the surface layer of polar snow, and Dibb and Arsenault (2002) measured levels well above 1 ppbv of formic and acetic acid in firm air. Gao et al. (2012) also observed enhanced release of acetone, formic acid, and acetic acid from snow coinciding with radiation, which  
475 they explained by oxidation of organic matter, e.g., humic substances present within the snowpack, perhaps by photochemically produced OH radicals (Nguyen et al., 2014). This experimental evidence that Arctic snow and areas of open sea are a relevant source of VOC emissions adds credence to this factor assignment.

The spatial origin of the Marine Cryosphere Factor was investigated via a PSCF, calculated with the R package Openair (Carslaw and Ropkins, 2012). Figure 7 displays the PSCF for air masses arriving every hour during the measurement  
480 campaign, which provides increased statistical robustness to the results over calculating a PSCF just for the summer period. From Fig. 7, two areas with a relatively higher probability of being a source region for the Marine Cryosphere Factor can be discerned, the coast around Southeastern and Northeastern Greenland. This analysis is supported by the CPF for the Marine Cryosphere Factor (Fig. S8b), which shows the dominant wind direction for this factor to be the south and south-south-east. Lee et al. (2020) used monthly chlorophyll-*a* derived from the MODIS satellite to demonstrate the coasts around Northeastern  
485 Greenland to contain high chlorophyll-*a* concentrations during June, which has been supported by previous studies (Degerlund and Eilertsen, 2010; Galí and Simó, 2010). Lee et al. (2020) also used a PSCF to determine this area to be the source regions for total particle number concentrations in the nucleation size range (3–25 nm). This area has been demonstrated to be a source region for MSA during the summer months (Heintzenberg et al., 2017). Thus, we propose the biologically active coasts around Eastern Greenland to be the source region for the Marine Cryosphere Factor.

The properties of the Marine Cryosphere Factor (composition, temporal variation, and spatial origins) helps confirm the work of previous studies in the High Arctic. We propose this factor (although not necessarily these exact species) as responsible for the biogenic precursor emissions of particles observed in other studies (Nguyen et al., 2016; Burkart et al., 2017; Dall'Osto et al., 2017; Freud et al., 2017; Dall'Osto et al., 2018a; Dall'Osto et al., 2018b; Dall'Osto et al., 2019; Nielsen et al., 2019). For example, Nguyen et al. (2016) identified the area southeast of Villum as having a high probability of observing  
495 an NPF event when air masses originating from this sector. One of the source areas identified in Fig. 7 is southeast of Villum, and a CPF analysis indicated high contributions of the Marine Cryosphere Factor were observed when the wind direction was south of Villum (Fig. S8b). While the species identified using this analytical technique might not be responsible for particle formation and growth, other high molecular weight compounds originating from the same sources could well be. Therefore, this factor has important climatic implications, as sea ice and snowmelt are expected to start earlier due to warming

500 temperatures. Increased contributions from this factor can be expected, which will alter the CCN budget and occurrence in the summer and thus alter the radiative balance.

### 3.3.3 Background Factor

The Background Factor explains the majority (>50 %) of the variation of acetone and C<sub>5</sub>H<sub>8</sub>O as well as 37 % of formaldehyde (Fig. 8a). It explains approximately 30 % of the variation of acetonitrile and MEK, followed by minor (< 20 %) variations of  
505 acetic acid, benzene, and C<sub>3</sub>H<sub>6</sub>O<sub>2</sub>. C<sub>3</sub>H<sub>6</sub>O<sub>2</sub> may in this case result from all three of the isomers: propionic acid, methyl acetate, and hydroxyacetone. Acetone and formaldehyde are known to have photochemical oxidation of precursor compounds in the atmosphere as an important source. The chemical profile of this factor does not point to a specific, known source (Fig. 8b). Its contributions start increasing in the middle of April and reach a maximum by the end of the month, then decrease until the summer period (Fig. 8a). During the autumn, contribution levels are similar to the summer period; however, the temporal  
510 pattern is quite similar to the one observed for the Biomass Burning Factor. The temporal correlations of the Background Factor to the Marine Cryosphere and Biomass Burning Factor during their respective periods of peak contributions indicate this factor does not arise from one identifiable source but rather from a myriad of sources, hence the assignment as a background factor. The species profile for the Background Factor corresponds to mixing ratios of 0.355 ppbv for acetone, 0.090 ppbv for formaldehyde, and less than 0.050 ppbv for all other compounds. These mixing ratios can be interpreted as the  
515 background mixing ratios for these compounds in the High Arctic.

The Background Factor has its highest period of mean contributions during the spring when solar intensity increases but before the emissions related to open sea or melting snow become relevant. This factor likely represents a source of VOCs caused by the increasing rate of photochemical oxidation of labile organic carbon naturally present in the air and on surfaces. Photo-oxidation of alkanes present in the air and deposited during the winter is a possible source of labile organic carbon  
520 (Boudries et al., 2002; Guimbaud et al., 2002; Gao et al., 2012). For example, acetone (a major component of the Background Factor) is primarily formed from reactions of OH and Cl with propane, isobutane, and pentane (Hornbrook et al., 2016). This slow decrease during the spring could be due to the decreasing supply of labile organic carbon in the snowpack. The weak diurnal pattern of this factor in the summer (Fig. 6) could be due to increased available organic matter for oxidation from the open ocean and melting snowpack. Further measurements, especially during the polar night to day transition, are required to  
525 test this hypothesis.

Given the lack of a peak period for contributions from this factor, we were unable to locate the source regions of this factor through air mass back trajectory analysis. Therefore, local wind direction and normalized contributions for this factor were used to create a conditional probability function (see Sect. 2.3). During the spring and autumn, the dominant wind direction at Villum is from the southwest, while during the summer it is from the east (Nguyen et al., 2016). The CPF can give  
530 information regarding the directional dependence of a factor or compound. Figure 9 shows the CPF for the Background Factor. There is a lack of directional dependence for this factor, indicating this factor does not arise from one specific source area, but rather it is spatially ubiquitous.

The Background Factor likely represents natural processes occurring in the Arctic. This factor can serve as a baseline for comparison with future VOC measurements and source apportionment analysis. These comparisons can help expound upon the effects of climate change on the natural processes occurring in this pristine and sensitive region. This, however, requires more long-term VOC measurements, especially across all seasons.

### 3.3.4 Arctic Haze Factor

The Arctic Haze Factor exhibits high contributions at the beginning of April and it rapidly decreases until the middle of May where it remains low and stable for the remaining of the measurement campaign (Fig. 10a). This factor accounts for 56 % of the variation of benzene and zero percent of acetonitrile, which suggests fossil fuel combustion processes as the source of this factor (Liu et al., 2008) (Fig. 10b). Interestingly, the other species apportioned to this factor with significant contributions, i.e., MEK, formic acid, formaldehyde, and  $C_5H_8O$  (Fig. 10b) are all oxygenated compounds that exhibit decreasing patterns in the spring as well as diurnal variation in the summer (Fig. 2). Much like for the Background Factor, the source of these OVOCs is the oxidation of labile organic carbon transported from the mid-latitudes.

The high levels of anthropogenic pollutants transported to the High Arctic during this period give the well-known ‘Arctic Haze’ phenomenon (Barrie et al., 1981). The decrease in mixing ratio during the spring is characteristic of the seasonality for long-range transport for this region (Willis et al., 2018). The mixing ratio of compounds emitted from sources outside the Polar dome is drastically reduced in the summer (Klonecki et al., 2003). Also, the faster oxidation rates due to higher OH radical concentrations as well as increased wet scavenging during transport in summer will reduce VOC and BC mixing ratios (Browse et al., 2012). Gautrois et al. (2003) reported benzene mixing ratios for 7 years at Alert, NU, and found an annual variation similar to observations for the Arctic Haze Factor in this study. The enhanced levels of BC (not shown) during this period (and lack thereof during summer and autumn) supports the assignment of this factor to anthropogenic combustion sources.

The Arctic Haze Factor presented in this study can be compared to other Arctic Haze Factors previously found using factor analysis or clustering of either aerosol composition or PNSD data. It is worth noting that the Arctic Haze Factor from this study is only for spring, while the other studies present data from the winter/spring, therefore any comparisons we make are from our spring Arctic Haze Factor to other Haze factors during winter and spring. While this is not a perfect comparison, it is one worth making, as Arctic Haze is the main source of anthropogenic pollution in the Arctic. Lange et al. (2018) used k-means clustering of aerosol size distribution to classify the accumulation mode aerosol population from Villum. The authors found three accumulation mode clusters, one of which they named ‘Haze’ occurred predominately in the winter/spring and was largely absent in the summer. The Haze cluster contained the largest amounts of refractory BC, sulfate, and organics as well as the highest concentrations of CCN. Extending this analysis into the chemical composition of aerosols, Nielsen et al. (2019) utilized PMF to find three factors. The factor deemed ‘Arctic Haze Organic Aerosol’ was closely correlated with sulfate and temporally followed the pattern exhibited by the Haze cluster from Lange et al. (2018) and the Arctic Haze Factor (this study), due to the contraction of the Polar Dome in spring. These similar factors/clusters resolved from different data sources

(PNSD, aerosol chemical composition, and VOCs) and different statistical methods (k-means and PMF) highlight the extent to how anthropogenic pollution can influence the characteristics of the High Arctic atmosphere. Given recent trends in emission reductions across Europe and Eurasia, these factors/clusters are expected to decrease in magnitude, although the extent and occurrence of this anthropogenic pollution will ultimately be governed by several factors including transport patterns, precipitation patterns, and expansion of anthropogenic pollution sources within the Arctic Circle (resource extraction and shipping) (Law et al., 2017).

#### 4 Conclusions

VOC mixing ratios were measured during April–October 2018 at the High Arctic station Villum Research Station, located at Station Nord in Northeast Greenland. We identified 10 compounds by PTR-ToF-MS and provided time series of VOCs in the High Arctic covering several months. Generally, the mixing ratios observed in the present study are in accordance with other VOC measurements carried out in Arctic locations. We apportioned sources of these VOCs using PMF, finding four factors: Biomass Burning, Marine Cryosphere, Background, and Arctic Haze. The Biomass Burning Factor exhibited maxima during the autumn and the chemical profile was dominated by acetonitrile with contributions from benzene. Interestingly, BC did not show enhancements during the peak of the Biomass Burning Factor, which we show is due to washout during transport. The Marine Cryosphere Factor was described by carboxylic acids (formic and acetic acid and possibly propionic acid from  $C_3H_6O_2$ ) and DMS. This factor displayed maxima in the summer during periods of snow and sea ice melt. A PSCF analysis yielded the coasts of Southeastern and Northeastern Greenland as source regions for this factor. The Background Factor showed maxima in the spring and autumn, and minima during the summer. While acetone was the dominating species in this factor, the chemical profile did not resemble any known processes or sources. Oxidation of labile organic carbon is proposed as the source of the OVOCs present in this factor. The Arctic Haze Factor peaked in April, decreased until mid-May, and was absent during the summer. This factor was driven by benzene as well as OVOCs. The source of OVOCs present in this factor is postulated to be the oxidation of precursor emissions during transport from the mid-latitudes to the Arctic.

This study has several important results that have implications for the Arctic climate. Recent studies have highlighted the importance of natural emissions to aerosol formation and their contribution to CCN concentrations in the summer (Leaith et al., 2016; Lange et al., 2019; Nielsen et al., 2019). The Marine Cryosphere Factor presents an important source of condensable vapors necessary for this formation and growth to CCN sizes. Due to increasing temperatures in the Arctic, the snowpack and sea ice are expected to experience increased melting in the coming years, which could increase the flux of DMS and carboxylic acids from the surface to the atmosphere. With the onset of the melt season in the Arctic expected to begin earlier in the future, we also expect that the timing of this onset can also affect NPF events and their subsequent growth as well as ozone photochemistry. While biomass burning is expected to increase in the future, the year-to-year variability is still highly uncertain. The Biomass Burning Factor was characterized by acetonitrile, benzene, and correlated temporally with ozone. Due to washout during transport, there were no enhancements in BC during the peak of the Biomass Burning Factor. The inter-

annual variability of biomass burning events and meteorological conditions can, therefore, have a substantial impact on atmospheric pollution levels at ground level.

600 While this research provides valuable insight into the atmospheric chemistry and sources of VOCs in the High Arctic, future work is still needed. While calculated mixing ratios using a kinetic quantification are reliable, they are inherently uncertain, therefore external calibration with gas-phase standards would greatly improve the accuracy and reduce the analytical uncertainty. This work presents a multi-season time series of VOC mixing ratios; however, these measurements are only during polar day. A full seasonal cycle including polar night, dark to light transition periods, and polar day would help elucidate the importance of transport of anthropogenic emissions in the absence of photochemical reactions. This work expounds on the understanding of the atmospheric chemistry and sources of VOCs in the High Arctic; however, future research is needed to fully understand the biogeochemical feedback mechanisms and their implications for a changing Arctic.

610 *Data availability.* All data used in this publication are available at <https://doi.org/10.5281/zenodo.4299817> or by request to the corresponding authors Jakob Boyd Pernov ([jbp@envs.au.dk](mailto:jbp@envs.au.dk)) and Rossana Bossi ([rbo@envs.au.dk](mailto:rbo@envs.au.dk)).

*Author contributions.* JBP, RB, and RH collected the measurements. JBP and RB processed the data. JBP, JH, RB, and TL analyzed the data. JBP, JKN, and TL performed the PMF analysis. JBP and JH wrote the manuscript. HSK provided initial project funding and idea for VOC measurements at Villum. All co-authors proofread and commented on the manuscript.

615 *Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgments.* Villum Foundation is gratefully acknowledged for financing the establishment of Villum Research Station and the instrumentation used in this study (PTR-ToF-MS). Thanks to the Royal Danish Air Force and the Arctic Command for providing logistic support to the project. Christel Christoffersen, Bjarne Jensen, and Keld Mortensen are gratefully acknowledged for their technical support. We acknowledge the use of data from the NASA FIRMS application (<https://firms.modaps.eosdis.nasa.gov/>) operated by the NASA/Goddard Space Flight Center Earth Science Data and Information System (ESDIS) project and NASA's Earth Science Data and Information System (ESDIS) with funding provided by NASA Headquarters. We thank NOAA for use of the HYSPLIT model. We thank David Carslaw for developing the Openair function. We acknowledge Chad Greene for use of MATLAB functions (Greene et al., 2017). We acknowledge Francesco Canonaco for helpful discussions on the PMF analysis as well as Ksenia Tabakova and Paul Glantz for help with HYSPLIT and MATLAB.

630 *Financial support.* This research has been financially supported by the Danish Environmental Protection Agency and the Danish Energy Agency with means from MIKA/DANCEA funds for environmental support to the Arctic region (project nos. Danish EPA: MST-113-00-140; Ministry of Climate, Energy, and Utilities: 2018-3767) and ERA-PLANET (The European

Network for observing our changing Planet) Projects; iGOSP and iCUPE, and finally by the Graduate School of Science and Technology, Aarhus University.

1030 **Table 1.** Overview of measured protonated masses included in PMF analysis. Mean refers to the arithmetic average of the mixing ratio for each compound. Mean, Mean LOD, and % < LOD were calculated after quality control of data influenced by local pollution. % QC represents the percentage of data removed due to the Quality Control Procedure (Sect. S2).

Measured mass ( <i>m/z</i> )	Empirical Formula	Assigned Compound	Mean (ppbv)	Mean LOD (ppbv)	% < LOD	Mean Relative Uncertainty (%)	% QC
30.997	CH <sub>2</sub> OH <sup>+</sup>	Formaldehyde	0.220	0.176	0.6	41	5
42.019	C <sub>2</sub> H <sub>3</sub> NH <sup>+</sup>	Acetonitrile	0.067	0.045	0	46	5
47.011	CH <sub>2</sub> O <sub>2</sub> H <sup>+</sup>	Formic Acid	0.454	0.250	17	37	7
59.062	C <sub>3</sub> H <sub>6</sub> OH <sup>+</sup>	Acetone	0.608	0.037	0	32	0
61.047	C <sub>2</sub> H <sub>4</sub> O <sub>2</sub> H <sup>+</sup>	Acetic Acid	0.201	0.096	5	39	8
63.034	C <sub>2</sub> H <sub>6</sub> SH <sup>+</sup>	Dimethyl Sulfide	0.046	0.043	4	57	25
73.068	C <sub>4</sub> H <sub>8</sub> OH <sup>+</sup>	Methyl Ethyl Ketone	0.031	0.023	0.1	56	0
		Propionic Acid /					2
75.058	C <sub>3</sub> H <sub>6</sub> O <sub>2</sub> H <sup>+</sup>	Hydroxyacetone/ Methyl Acetate	0.025	0.031	0.1	61	
79.057	C <sub>6</sub> H <sub>6</sub> H <sup>+</sup>	Benzene	0.027	0.031	0.5	64	0
85.066	C <sub>5</sub> H <sub>8</sub> OH <sup>+</sup>	N/A	0.027	0.030	0.03	61	0

1035 **Table 2.** Input species for PMF model along with species categorization, S/N, and R<sup>2</sup> value for modeled versus measured values.

Species	Categorization	S/N	R <sup>2</sup> (Modelled vs Measured)
Formaldehyde	Weak	0.9	0.83
Acetonitrile	Strong	1.1	0.97
Formic Acid	Weak	1.0	0.67
Acetone	Strong	2.2	1.00
Acetic Acid	Strong	1.0	0.67
Dimethyl Sulfide	Weak	0.4	0.62
Methyl Ethyl Ketone	Weak	0.5	0.95
C <sub>3</sub> H <sub>6</sub> O <sub>2</sub>	Weak	0.2	0.91
C <sub>5</sub> H <sub>8</sub> O	Weak	0.2	0.62
Benzene	Strong	0.3	0.96

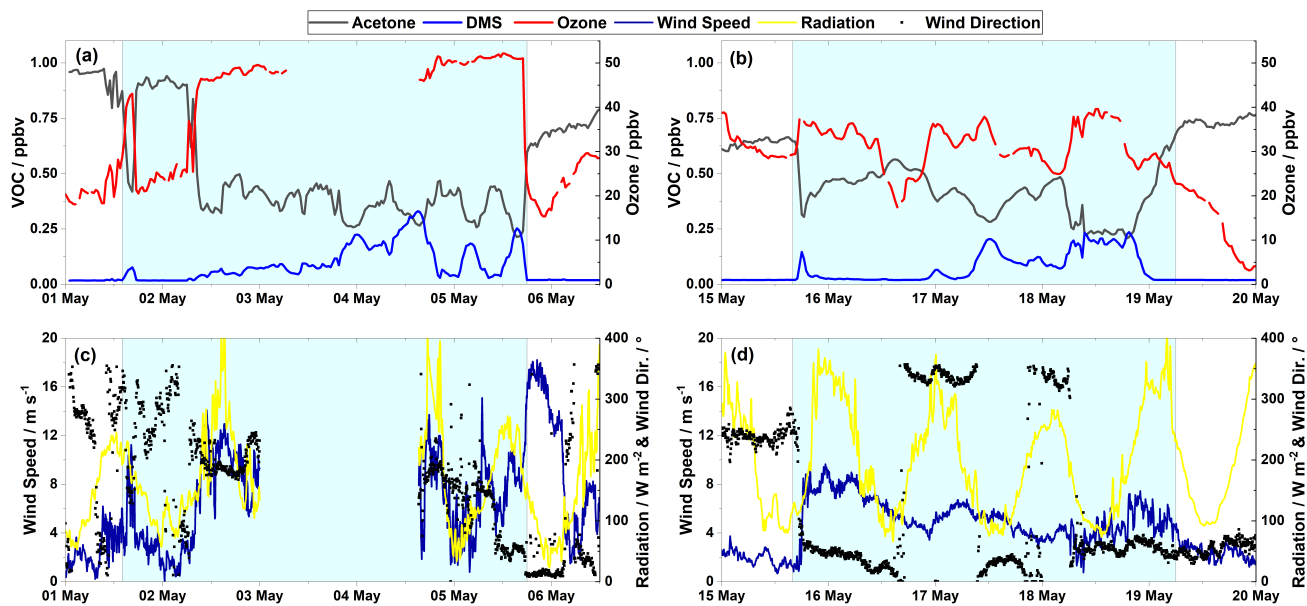

**Fig. 1.** Time series of mixing ratios (ppbv) for (a) formaldehyde, (b) acetonitrile, (c) formic acid and acetic acid, (d) acetone and MEK, (e) DMS and C<sub>3</sub>H<sub>6</sub>O<sub>2</sub>, and (f) benzene and C<sub>5</sub>H<sub>8</sub>O during the entire measurement period.

1040

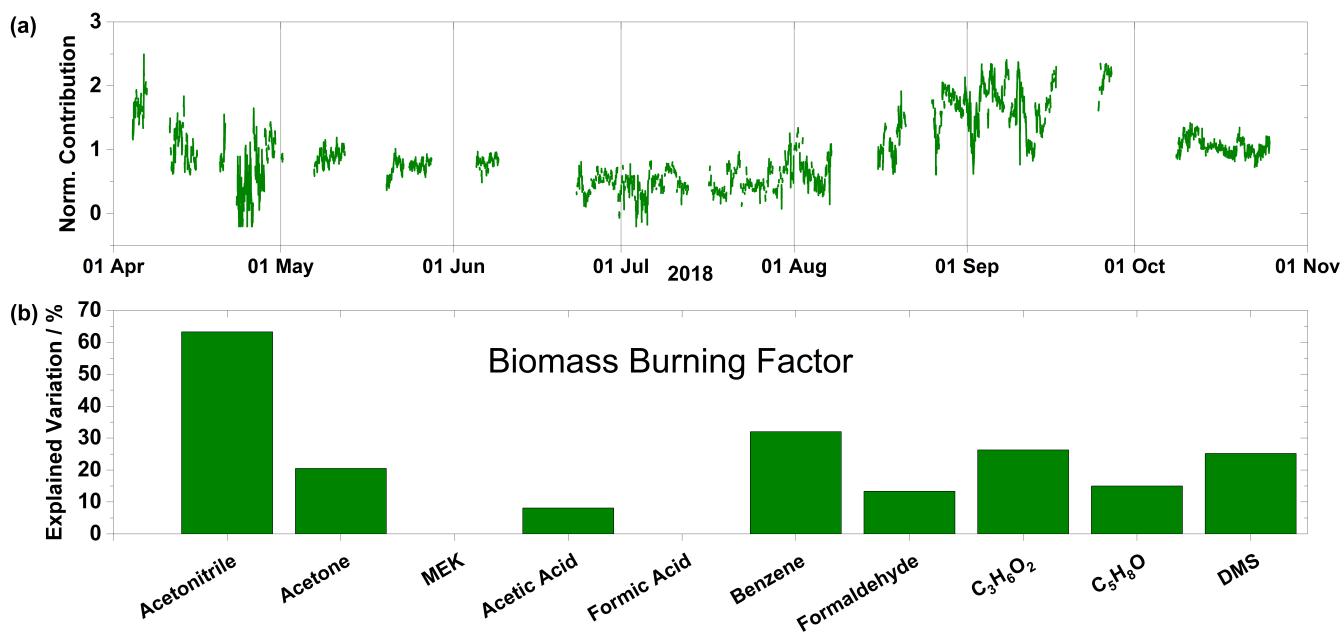

**Fig. 2.** Time series for (a) formic acid, acetone, acetic acid, and radiation and (b) MEK, formaldehyde, C<sub>3</sub>H<sub>6</sub>O<sub>2</sub>, DMS, and radiation during the period 22 June–09 August displaying the diurnal profile for each species.

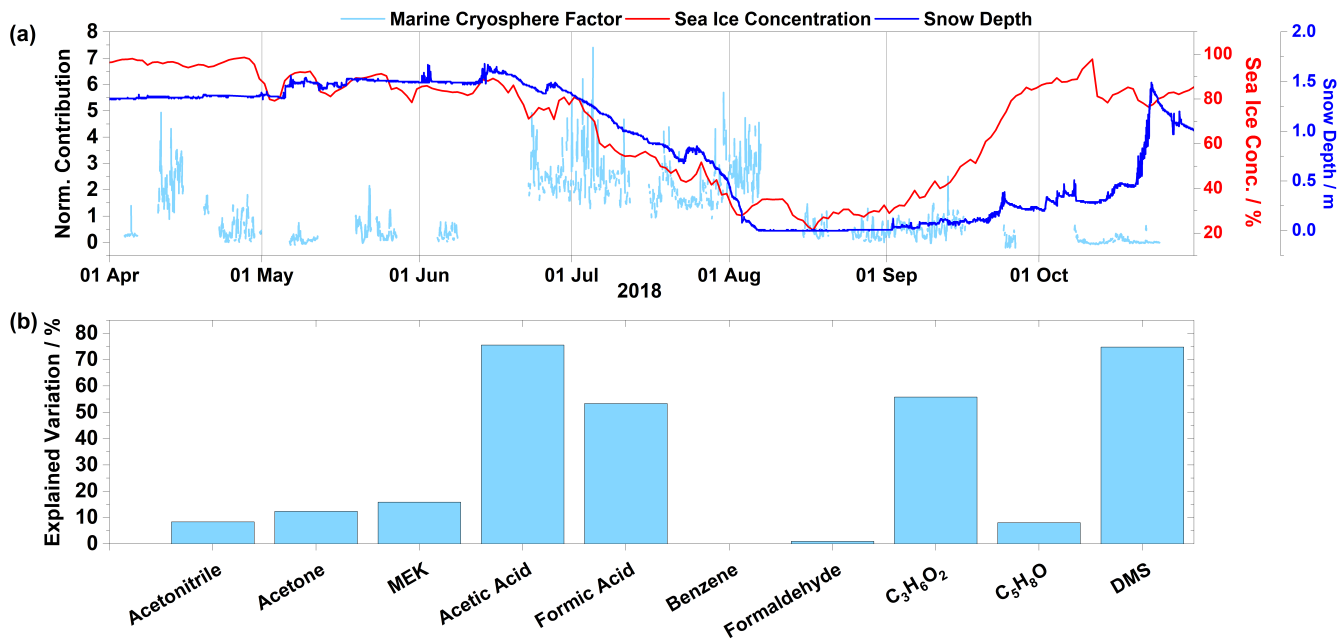

1045

**Fig. 3.** Left: The first period of elevated DMS mixing ratios (May 1–5). Right: The second period of elevated DMS mixing ratios (May 15–19); (a) and (b) mixing ratios of acetone, DMS (left axis), and ozone (right axis); (c) and (d) wind speed (left axis) and radiation and wind direction (right axis). The shaded area represents episodes of elevated DMS mixing ratios.

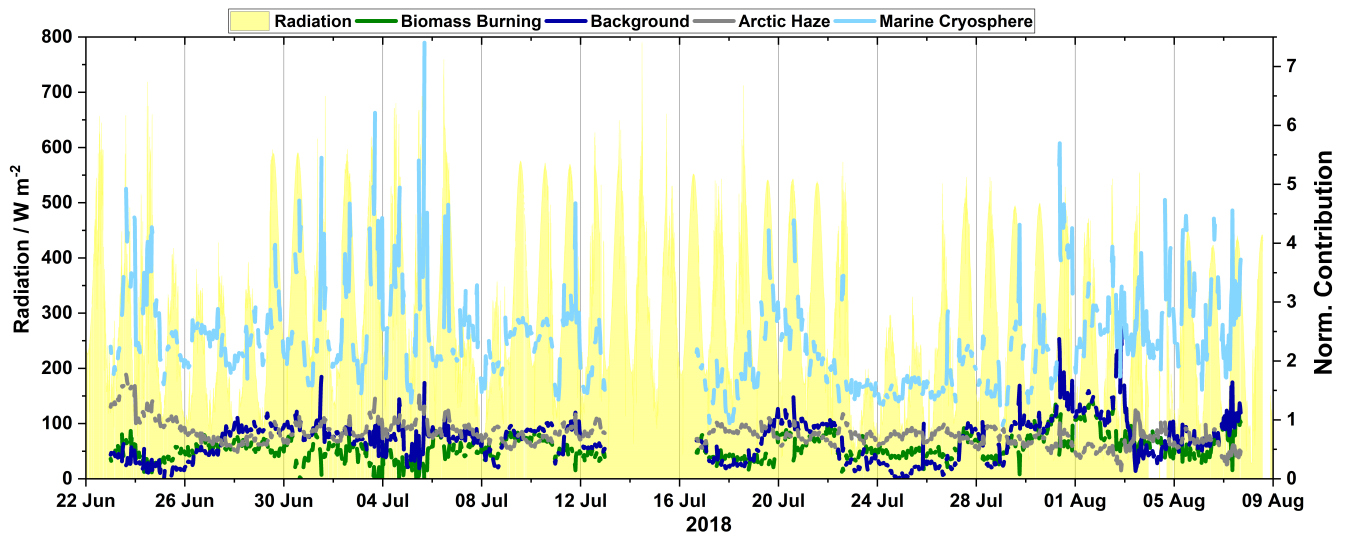

1050

**Fig. 4.** (a) Time series of normalized contributions and (b) species profile for the Biomass Burning Factor. Factor contributions are normalized to give a mean contribution of unity.

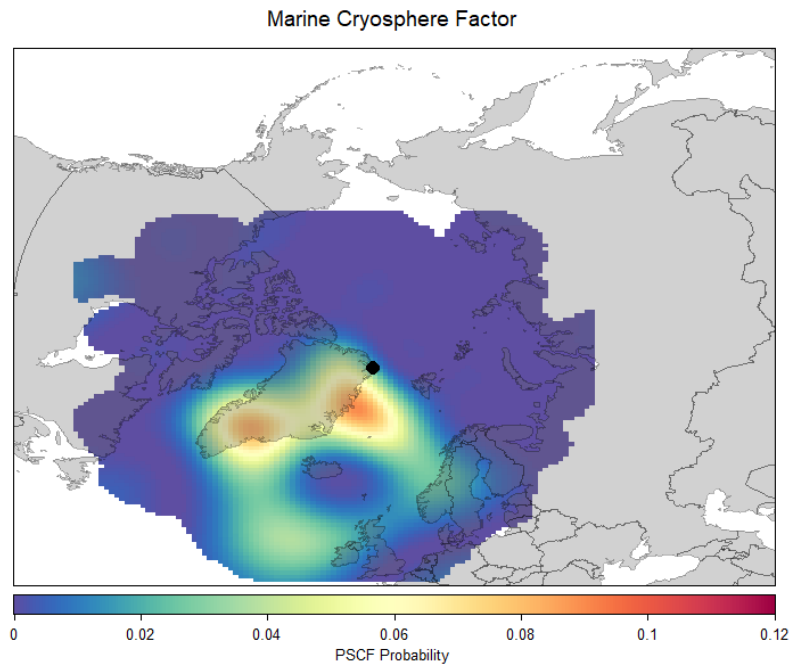

1055

**Fig. 5** (a) Time series of normalized contributions in light blue, left axis, and sea ice concentrations in red and snow depth in blue, right axes, and (b) species profile for the Marine Cryosphere Factor. Factor contributions are normalized to give a mean contribution of unity.

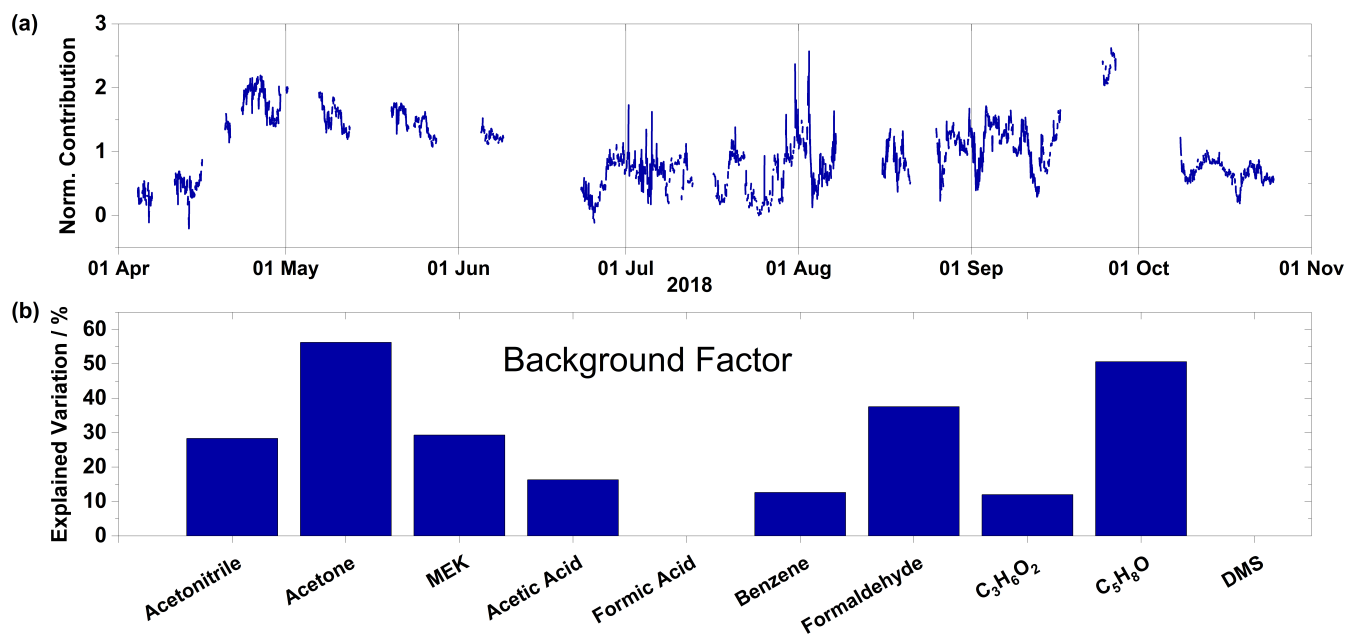

1060

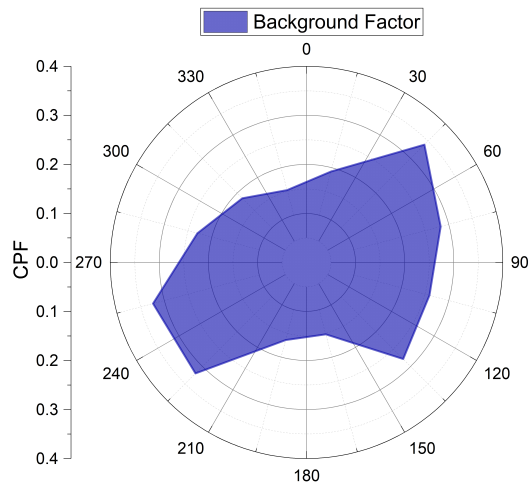

**Fig. 6.** Time series of the four factors from 22 June–09 August displaying the diurnal profile together with radiation.

**Fig. 7.** PSCF for the Marine Cryosphere Factor and air mass back trajectories arriving at 100 m altitude, extending backward 120 hours in time. This plot and analysis method were produced in R and R Studio programs (R Foundation for Statistical Computing, Vienna, Austria, and R Studio Inc, MA, USA) and the OpenAir suite of analysis tools (Carslaw and Ropkins, 2012).

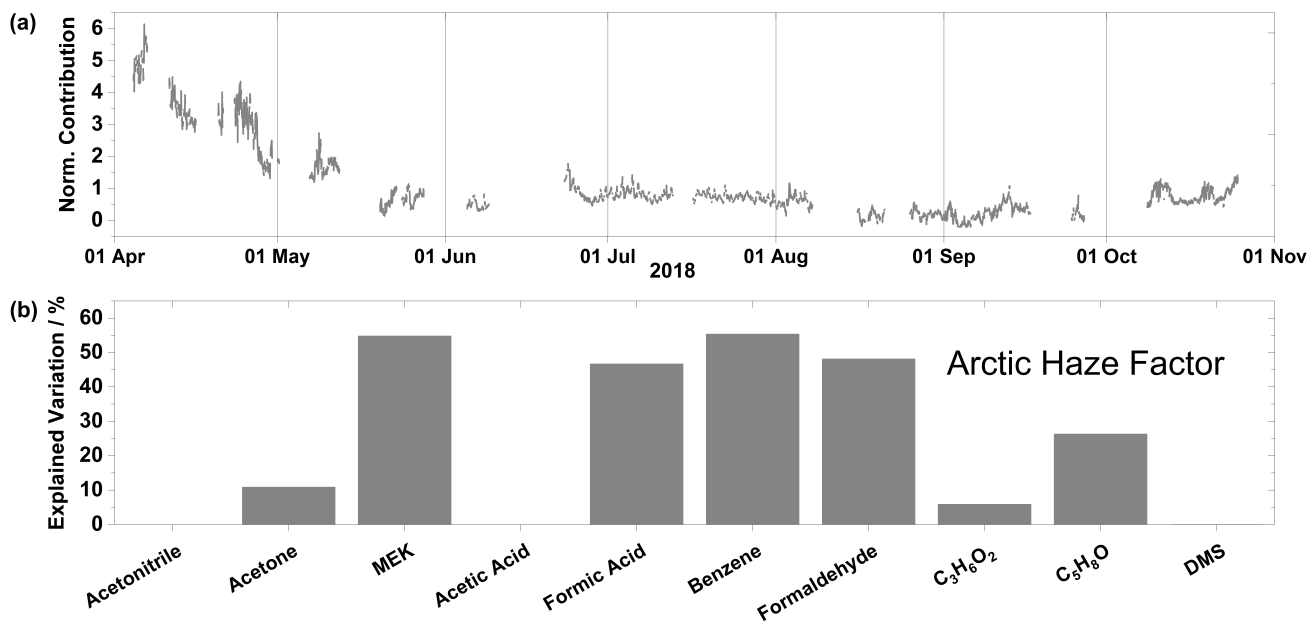

1070 **Fig. 8.** (a) Time series of normalized contributions and (b) species profile for the Background Factor. Factor contributions are normalized to give a mean contribution of unity.

**Fig. 9.** Conditional Probability Function for the Background Factor from the PMF analysis. CPF was calculated as described in Sect. 2.3.

**Fig. 10.** (a) Time series of normalized contributions and (b) species profile for the Arctic Haze Factor. Factor contributions are normalized to give a mean contribution of unity.
