Abstract. Different types of pollution boundary layer structures form via the coupling of different synoptic systems and local mesoscale circulation in the boundary layer; this coupling contributes toward the formation and continuation of haze pollution. In this study, we objectively classify the 32 heavy haze pollution events using integrated meteorological and environmental data and ERA-Interim analysis data based on the rotated empirical orthogonal function method. The thermodynamic and dynamic structures of the boundary layer for different pollution weather types are synthesized, and the corresponding three-dimensional boundary layer conceptual models for haze pollution are constructed. The results show that four weather types mainly influence haze pollution events in the Beijing area: (a) type1: southerly transport, (b) type2: easterly convergence, (c) type3: sinking compression, and (d) type4: local accumulation. The explained variance in the four pollution weather types are 43.69% (type1), 33.68% (type2), 16.51% (type3), and 3.92% (type4). In persistent haze pollution events, type1 and type2 surpass 80% on the first and second days, while the other types are present alternately in later stages. The atmospheric structures of type1, type2, and type3 have typical baroclinic characteristics at mid-high latitudes, indicating that the accumulation and transport of pollutants in the boundary layer is affected by coupled structures in synoptic-scale systems and local circulation. The atmospheric structure of type4 has typical barotropic characteristics, indicating that the accumulation and transport of pollutants is primarily affected by local circulation. In type1, southerly winds with a specific thickness and intensity prevail in the boundary layer, which is favorable for the accumulation of pollutants in plain areas along the Yan and Taihang Mountains, whereas haze pollution levels in other areas are relatively low. Due to the interaction between weak easterly winds and the western mountains, pollutants accumulate mainly in the plain areas along the Taihang Mountains in type2. The atmospheric vertical structure is not conducive to upward pollutant diffusion. In type3, the heights of the inversion and boundary layers are the lowest due to a weak sinking motion while relative humidity is the highest among the four types. The atmosphere has a small capacity for pollutant dispersion and is

31 favorable to particulate matter hygroscopic growth; as a result, the type3 has highest PM_{2.5} concentration. In type4, the
32 boundary layer is the highest among the four types, the relative humidity is the lowest, and the PM_{2.5} concentration is
33 relatively lower under the influence of local mountain–plain winds. Different weather types will shape significantly different
34 structures of the pollution boundary layer. The findings of this study allow us to understand the inherent difference among
35 heavy pollution boundary layers; in addition, they reveal the formation mechanism of haze pollution from an integrated
36 synoptic scale and boundary layer structure perspective. We also provide scientific support for the scientific reduction of
37 emissions and air quality prediction in the Beijing-Tianjin-Hebei region of China.

38 1 Introduction

39 Over the past 40 years, rapid industrialization and urbanization have caused serious haze pollution problems in China,
40 especially in the North China Plain (NCP). Beijing, located in the NCP region, suffers from frequent haze pollution, which
41 has become one of the greatest issues of concern for the public and government (Huang, et al., 2018). High concentrations of
42 fine particulates not only affect the climate system but also reduce visibility, affect city operation (Wang et al., 2015; Luan et
43 al., 2018; Li et al., 2020), and have a significant negative impact on human health (Gong et al., 2019; Han et
44 al., 2019, 2020a, 2020b, 2020c). Haze pollution creates health costs for residents (Dockery et al., 1993; McDonnell et al., 2000)
45 and emissions reductions costs (Hou et al., 2016). Governments must play a more flexible role and adopt an optimized
46 strategy between health costs and economic costs of controlling emissions based on national or local economic affordability
47 to reduce emissions (Lee et al., 2016). From an operability perspective, the timings of different emissions reductions
48 strategies are largely dependent on trends in atmospheric pollution dispersion conditions (Zhai et al., 2016). Haze pollution is
49 the combined effect that excessive emissions and adverse meteorological conditions have on the dispersion of pollutants (He
50 et al., 2013; Li et al., 2017). With relatively few changes in the emission source, the diffusion conditions largely determine
51 the duration and pollution level of a haze event.

52 First, from an atmospheric circulation perspective, persistent haze pollution generally corresponds to persistent adverse
53 meteorological conditions for pollutant dispersion (Zheng et al., 2015), where persistent anomalies in atmospheric
54 circulation are an important contributing factor (Inness et al., 2015). These conditions cause stabilized vertical stratification
55 and low horizontal wind speeds (Chamorro et al., 2010; Park et al., 2014), such that the combination of these two conditions
56 form "calm weather." From a large-scale climate circulation perspective (Markakis et al., 2017; Zou et al., 2017), previous
57 studies have suggested that, if global warming trends continue, the probability of adverse atmospheric pollutant dispersion
58 will continue to increase (Cai et al., 2017). The reduction in sea ice can lead to the weakening of the Rossby wave activity
59 south of 40°N, rendering the lower layer colder and a reduced moisture content, a stable atmosphere, weaker wind speeds,
60 and an increased chance of heavy haze pollution (Wang et al., 2015; Chen et al., 2015). These results show that the troposphere
61 in the Beijing-Tianjin-Hebei area can produce a continuous deep downdraft under flat circulation or a weak high-pressure
62 system, along with the boundary layer's southerly wind yielding the temperature inversion height and decrease in the

63 atmospheric capacity, which provides a favorable dynamic condition for the maintenance and aggravation of haze pollution
64 (Wu et al., 2017). Zhang et al. (2016) used the Kirchhofer technique (El-Kadi et al., 1992) to classify the circulation patterns
65 during the time period of 1980-2013, examining the air quality associated with those patterns clarify. The circulation patterns
66 were classified into 5 categories. The stagnant weather condition when wide-spread stable conditions controlled most part of
67 NCP resulted in the highest air pollution. The westerly and southerly wind caused both the regional transport and local build-
68 up of air pollutants.

69 Second, the pollutant concentration also depends on local mesoscale circulation coupled with a stable boundary layer and
70 synoptic-scale system (Miao et al., 2017), for example, valley wind, sea-land wind, heat island circulation, and mountain-
71 plain wind. Even under conditions associated with weaker synoptic circulations, these mesoscale systems largely determine
72 the peak concentration and spatial-temporal distribution of the pollutants (Miao et al., 2017; Li et al., 2019). Millan et
73 al.(1997), studied the mechanism of aerosol transport back and forth along the coast under the combined action of weather
74 system, sea-land winds and slope
75 wind. In coastal cities of West Africa, Adrien et al. (2019) simulated the transport and mixing processes of biomass combus-
76 tion aerosols in the boundary layer and at the top of the boundary layer under the action of dry convection and sea breeze fro-
77 nt. Tobias et al. (2017) studied pollution in coastal valley cities (Bergen, Norway), where the concentration of pollutants is
78 determined by both large-scale topography and small-scale sea-land winds, when there is a strong background wind, the sea-
79 land wind will submerge in the large-scale circulation, and the large-scale circulation and the local circulation in the
80 boundary layer will cancel each other, causing ground-level air to stagnate and pollution levels to rise. Zhai et al.(2019)
81 suggested that the easterly wind reached the strength of low-level jet streams and blew towards mountain in Beijing.
82 Aerosols below 2.0 km were lifted to the upper atmosphere and blown downstream by the strong south-westerly wind. Quan
83 et al. (2020) suggested that a combination of topography and planetary boundary layer (PBL) processes can drive the
84 regional atmospheric pollutant transport over NCP. A mountain-induced vertical vortex elevated ground pollutants to form
85 an elevated pollutant layer (EPL) which was transported to Beijing by southerly winds and downward to the surface through
86 PBL processes finally.

87 In summary, meteorological conditions can be divided into a large scale circulation type and local meteorological conditions
88 at different spatial scales. The circulation type governs local meteorological conditions and is effective in the identification
89 of haze pollution. Although, many studies have investigated the influence of the circulation type on the haze pollution (or air
90 quality) (Oanh et al., 2005; Zhang et al., 2016; Wu et al., 2017; He, et al., 2018). A comprehensive analysis combining
91 weather systems and the structure of the boundary layer with objective synoptic classification method, however, is still rare.
92 Liao et al. (2018) use the Self-Organizing Map method to classify the boundary layer in the Beijing area with radiosonde
93 data. A continuum of nine atmospheric boundary layer types was obtained from the near neutral to strong stable conditions,
94 which resulted in the dramatically increased of pollutants during all seasons except summer. For typical wintertime months,
95 they suggested that atmospheric boundary layer types are one of the primary drivers of day-to-day $PM_{2.5}$ variations in
96 Beijing. Miao et al. (2017) use the obliquely rotated principal component analysis in T-mode (T-PCA) approach to classify

97 summertime synoptic patterns over Beijing. Three types of synoptic patterns (67% of the total) favoring the occurrence of
98 heavy aerosol pollution were identified, which were characterized by southerly winds that favor the transport of pollutants to
99 Beijing. The clouds and cold/warm advection modulate the planetary boundary layer structure in Beijing in the afternoon.
100 Xu et al. (2019) also used T-PCA method to classify synoptic weather types during autumn and winter months in Shanghai.
101 Their study indicated that transport resulted from cold front had significant impact on PM_{2.5} levels in Shanghai, whereas
102 persistent server pollution events were more closely related to weak pressure before high. All these studies presented a good
103 view of air pollution formation influenced by weather system and planetary boundary layer structure with objective synoptic
104 classification method. But the classifications of weather system or boundary layer meteorology were carried out separately,
105 and the influences of these weather type or PBL type on air pollution were investigated for a long time average state.
106 Classification of haze pollution weather types accompanying with different PBL structure and their associations with haze
107 formation have seldom been reported in previous works, especially rare for the sever haze pollution events.
108 The Beijing area is located in the transition zone between the plain and mountainous areas, with mountains to the west, north,
109 and east. The southeastern region of Beijing is a flat plain that slopes toward the Bohai Sea. More than 20 million people live
110 in Beijing who are affected by both the weather system and local circulation in the boundary layer. To formulate optimized
111 emissions reduction strategies, we must master the main control factors that affect the haze pollution diffusion conditions in
112 Beijing under different weather and boundary layer conditions. In this study, based on the objective classification of
113 persistent pollution weather types, we examine the boundary layer structures of different weather types, revealing that the
114 thermal and dynamic mechanisms of the boundary layer structures influence the evolution of haze pollution. This study will
115 extend previous studies as it is an attempt to investigate the meteorological mechanism of haze pollution formation from the
116 perspective of interaction between weather system and boundary layer structure. In this paper, Sect. 2 provides descriptions
117 of methodology and data. In Sect. 3, the pollution weather types are classified, and 3-D conceptual model for the pollution
118 boundary layer is established for different weather types, and then their influences on spatial-temporal evolution of haze
119 pollution are investigated. The main findings are summarized in Sect. 4.

120

121 **2Data and methods**

122 **2.1 Meteorological data**

123 The weather classification data were derived from the ERA-Interim data from 2014–2017. ERA-Interim (0.125°×0.125°) is a
124 new reanalysis data from the ECMWF (European Centre for Medium-Range Weather Forecasts) after the ERA40, with 60
125 vertical layers and partially overlaps with the ERA40 in time. However, significant progress has been made in data
126 processing, for example, from the three-dimensional assimilation system(3-D VAR) to the four-dimensional assimilation
127 system(4-D VAR). There are 4 soil moisture layers with the depth of 7cm, 28cm, 100cm and 255cm respectively. The model

contains 20 vegetation types, and the land surface parameters change with the change of vegetation types (https://apps.ecmwf.int/datasets/). The 850hPa geopotential height field (30–50°N, 110–128°E) of the ERA-Interim was used to classify the weather system. The meteorological elements at 850hPa interact with the meteorological elements in the boundary layer. At the same time, the 850hPa is evidently influenced by the free atmosphere, especially in Beijing area, which can be regarded as the transition layer between local thermal circulation (valley wind, sea–land wind, and mountain–plain wind) and the free atmosphere. In addition, the hourly relative humidity, visibility, and wind speed observed at the Beijing Observatory (39.93°N, 116.28°E) were used in this study. A 12-channel (5water channels and 7oxygen channels) microwave radiometer (Radiometrics, Romeoville, IL, U.S.A.) was used to measure the hourly relative humidity and temperature profile in the atmosphere. The microwave radiometer was installed in the Beijing Observatory (39.93°N, 116.28°E) and was calibrated every three months. The wind profiles, including the wind speed and direction between 100 and 5,000m, are measured at the same station by a wind profiler. The wind profiler radar provides a set of profile data every 6min at a detection height of ~12–16km, and hourly data were used in this study. In data analysis, Beijing Local Time (BJT) was used.

2.2 Air quality monitoring data and haze pollution event definition

Hourly PM_{2.5} concentrations at 12 national stations and the daily air quality index (AQI) in Beijing are available from <http://zx.bjmemc.com.cn/?timestamp=1564483254009>. Surface PM_{2.5} mass concentrations were measured by the tapered element oscillating microbalance method. The measurements were calibrated and quality controlled according to the Chinese environmental protection standard (HJ 618-2011). As this study focuses on episodes of heavy haze pollution, we first defined the criteria. Haze is defined by the relative humidity and visibility. Considering that haze pollution mainly refers to reduced visibility caused by fine particulate matter, as well as taking into account the effects of the pollution levels and duration, the screening criteria for heavy haze pollution were still based on the AQI, PM_{2.5} concentration, and the duration of low visibility. The specific criteria of a haze pollution event can be defined as follows: the AQI reaches a moderate pollution level (AQI≥150) for more than or equal to 3 days in which at least 1 day reaches the heavy pollution level (AQI>200). The primary pollutant is PM_{2.5} in Beijing area. As defined by the AQI, the 24-h average concentration of PM_{2.5} must be above 115 µg m⁻³ for more than three consecutive days and above 150 µg m⁻³ for at least 1 day. At the same time, the accumulated time of horizontal visibility, that is, less than 5 km, has a duration of at least 12 h each day at the Beijing Observatory station. Based on these criteria, 32 events (125 days) were screened for heavy haze pollution in Beijing between 2014 and 2016. Eight events occurred in spring and summer while 24 events were concentrated in autumn and winter, 32 events accounting for 75% of the events that occurred during the study period (2014–2016). We collected ground-based routine meteorological observation data in North China, L-band radar second-order sounding data (including wind, temperature, and humidity), wind profile data, ceilometer data, and tower data during these events.

161 2.3 Attenuated backscattering coefficient measurements and boundary layer height calculation

162 2.3.1 Attenuated backscattering coefficient measurements

163 We used the CL31 and CL51 Vaisala-enhanced single-lens ceilometer instrument, which uses the pulse diode laser LIDAR
164 (laser detection and ranging) technology to measure the backscattering profile of atmospheric particles and the cloud height.
165 The main parameters of the CL31 and CL51 are respectively as follows: range of 7.6 and 13 km, reporting periods of 2–120
166 and 6–120s, reporting accuracy of 5 and 10m/33ft, peak power of 310w, and wavelength of 910nm. The geographic location
167 of the station is 39.974°N and 116.372°E, with an elevation of approximately 60 m (Tang et al.,2016).

168 2.3.2 Boundary layer height calculation

169 As the lifetime of fine particles is long, that is, several days or weeks, the particles concentration in the boundary layer is
170 generally uniform, but is significantly different from that in the free atmosphere where particles concentration is much lower
171 (Lin et al.,2007;Kang et al.,2019). By analyzing the backscattering profile of the atmospheric particles, we located the abrupt
172 change in backscattering at the top of the boundary layer.

173 This study used the gradient method (Christoph et al., 2007; Zhang et al., 2013; Tang et al., 2015) to determine the boundary
174 layer heights. The maximum negative gradient in the aerosol backscattering coefficient profile occurs at the top of the
175 boundary layer, but is easily disturbed by data noise and the aerosol structure. Therefore, we must select a continuous region
176 of time or space for averaging to smooth the contour map vertically after averaging and adopt an improved gradient
177 (http://isars2010.uvsq.fr/images/stories/posterexabstracts/p_bls06_muenkel.pdf) method to manage severe weather (such as
178 precipitation and fog). Despite this, the gradient method still has certain defects, especially for neutral atmospheric
179 stratification, where the inverse calculation of the boundary layer height is not accurate.

180 2.4 Objective classification of pollution weather types

181 The 925 hPa geopotential height field is affected by both synoptic and local circulations, which can simultaneously reflect
182 the variation characteristics of weather system and boundary layer. Thus, the 925hPa geopotential heights of all pollution
183 events were analyzed in this study by using the 6h ERA-Interim reanalysis data. With 500 samples (4 times each day in 125
184 days), the rotated empirical orthogonal function (REOF) was used to determine which mode the pollution events belong to
185 according to the characteristic values of the different pollution events. (Paegle et al.,2002;Li et al.,2009). Since Lorenz (1956)
186 introduced empirical orthogonal function (EOF) analysis to atmospheric science, this simple and effective method has been
187 widely used in atmospheric, oceanic and climatic studies. The essence of EOF analysis is to identify and extract the
188 spatiotemporal modes that are ordered in terms of their representations of data variance (Lian et al.,2012). In the empirical
189 orthogonal function (EOF) analysis, the first few main components are the focus of the analysis element variance, such that
190 the EOF method can highlight the entire correlation structure of the analysis element. However, the local correlation
191 structure is not sufficient, which is a defect of the pollution weather classification based on the EOF. The spatial patterns

(EOFs) and the temporal coefficients of these modes are orthogonal. This orthogonality has the advantage of separating unrelated patterns, but it sometimes leads to the complexity of spatial structure and the difficulty of physical interpretation (Hannachi, 2007). Based on the EOF analysis, the REOF transforms the load characteristic vector field into a maximum rotation variance, as a result of which each point in the rotation space vector field is only highly correlated with one or a few rotation time coefficients. Previous studies have shown that REOF analysis can avoid non-physical dipolelike EOF analysis patterns, which often occur when known dominant patterns have the same symbols in the region (Dommenget et al., 2002). REOF analysis outperforms EOF analysis almost certainly in reconstructing spatially overlapped modes, and that this superiority is not sensitive to parameters such as the number of modes, the spatial scale of the signal, and the degree of rotation (Lian et al., 2012). Thus, the high load value areas are concentrated in smaller areas, while the remaining areas are relatively small and nearly 0, highlighting the pattern and characteristics of the abnormal distribution of elements (Paegle et al., 2002; Chen et al., 2003), the classification of heavy pollution weather types based on this method is more consistent with the requirements of this study. Pollution weather types were classified by the REOF method to analyze the differences in the structures of the pollution boundary layer.

3 Results and discussion

3.1 Pollution weather type classification and horizontal characteristic analysis

In this study, the 925hPa geopotential height was used to classify the pollution weather types into four categories with the REOF method, as shown in Fig. 1: (a) type1, that is, influenced by southerly winds at the rear of the high pressure system, (b) type2, that is, influenced by easterly winds at the bottom of the high pressure system, (c) type3, that is, a weak downdraft effect in the high pressure system, and (d) type4: no significant weather system. In this study, we observed 125 days of heavy polluted weather. Among these days, type1, type2, type3, and type4 had 67, 27, 21, and 10 days, respectively (Fig. 2), where the four weather types accounted for 53.6, 21.6, 16.8, and 8.0% of the total sampled weather event days, respectively. The total interpretation variance of the four types for all events was 97.8% while the independent interpretation variance was 43.69, 33.68, 16.51, and 3.92%, respectively (Fig. 2). This indicates that an objective weather classification can effectively obtain the main feature information of the pollution weather types.

As shown in Fig. 1, the Beijing area is located toward west of the high-pressure system that has its center located in the sea. The low pressure system is located in the northern Hebei province for type1, where southerly winds control the 925hPa, which is favorable for the regional transportation of pollutants. Type1 is similar to the results of pattern2 and pattern4 by Zhang et al. (2016) accompanied by regional transmission characteristics. Type1 is also similar to the results of type 1 by Miao et al. (2017) with southerly winds throughout the layer. When type2 appears, the Beijing area is located at the bottom of the high pressure system in Northeast or North China. In the plain area, the sea level pressure in the eastern part of Beijing is higher than that in the central Beijing area, such that there is an evident pressure gradient. Due to pressure-gradient forcing, the boundary layer appears within the easterly wind component while the easterly wind speed is smaller, which leads to

224 pollutant convergence into the plains along the Taihang Mountains, When type3 appears, the high pressure center is located
225 in the middle of Mongolia, where Beijing is in the front of the weak high pressure system, with a northwest current at
226 925hPa. However, the wind speed is lower than that affected by strong cold air, because of which it is difficult to penetrate
227 the lower layer of the boundary layer and the wind can only exist in the upper atmosphere of the boundary layer. When type4
228 appears, western Mongolia is a high pressure region and Southern Hebei province is a low pressure area, where there is only
229 a low pressure system with a smaller spatial and temporal scale. The synoptic-scale low pressure system is already located
230 over the sea in the eastern Jianghuai region, showing that the high and low pressures corresponding to the synoptic-scale
231 system are far from the Beijing area, which results in a weak synoptic-scale pressure gradient in Beijing and the surrounding
232 areas (Fig. 1d). Most areas in North China do not have strong weather systems and the average wind speed in the boundary
233 layer is smaller, which is favorable to the formation and maintenance of the local circulation considering the topography in
234 the Beijing area (Fig. 1i). The wind speed of type4 in the lower boundary layer is more difficult to regulate via the evolution
235 of the wind field based on the effect of descending momentum. Therefore, the dynamic pollutant process in the boundary
236 layer in type4 is more related to the local circulation.

237 3.2 Vertical thermal and dynamic structure characteristics under four weather types

238 The vertical structure of the atmosphere is very important for the formation and evolution of extreme haze events. The
239 vertical thermal and dynamic structures of four weather types are investigated in three-dimensional view. Figure 3 to Figure
240 6 presented the vertical distribution of temperature, wind and RH, respectively. The temperature in Fig. 3 and vertical speed
241 profiles in Fig.5 are averaged for each weather type by using the 6h ERA-Interim reanalysis data, respectively. The hourly
242 mean wind profiles in Fig.4 are observed at the Beijing Observatory, and the hourly mean relative humidity in Fig.6 is
243 measured with a microwave radiometer at the same site. According to the classification of weather type, the spatial-temporal
244 average analysis of the observed data is carried out. To classify the pollutant regimes according to the various meteorological
245 features, we summarized relevant thermodynamic and dynamic parameters in Table S1.

246 Figure 3 shows that the strong inversion is located at 800–900hPa for type1. In type2, easterly winds with low temperatures
247 influence the temperatures below 800hPa, where a cooling layer appears at 900 hPa, with the height of inversion between
248 700 and 800hPa. The inversion height for type3 is the lowest among the four types due to the sinking motion, where the
249 inversion is mainly below 900hPa, which causes a rapid decline in the atmospheric capacity. The atmospheric structure is
250 also relatively stable in type4, whose inversion structure is similar to type2. However, the inversion intensity (0.4°C) in type4
251 are weaker than that in type2 (0.7°C), and the wind speed is also small in type4.

252 As shown in Fig. 4, the basic flow is the southerly wind below 2,000m in type1, where a southwest wind appears from 500–
253 2,000m. The south wind is below 500m between 04:00 BJT and 20:00 BJT, and the easterly wind appears at other times. The
254 south wind speed below 500m is $4\text{--}6\text{ m s}^{-1}$ which is higher than the easterly wind ($2\text{--}4\text{ m s}^{-1}$). In type2, the basic flow above
255 1,000m is westerly wind, where the layer between 500 and 1,000m is a weak wind layer. We note that the wind velocity in
256 this layer is the smallest when there is an increase in the easterly component below 500m. This indicates that the weak wind

layer is the wind shear transition layer between the westerly wind above 500m and the easterly wind below 500m. The easterly and westerly winds cancel each other at this height and form a small wind velocity layer. From 04:00 BJT to 20:00 BJT, southerly winds appear below 500m while we observe the appearance of easterly winds at other times. The space-time structure of the wind field below 500 m was similar to that of type1, but the southerly wind speed was lower than in case of type1. In type3, the wind above 500m originates from the northwest from 04:00 BJT to 14:00 BJT. At altitudes below 500 m, the wind is southerly during these hours and northerly at other times. Whether it is southerly or northerly, the wind speed is smaller. Mountain–plain wind in the Beijing area causes this diurnal and nocturnal circulation of the wind field. In type3, the wind velocity below 500m is less than that of type1 and type2, because the basic flow is northerly, where northerly wind superposes onto the plain wind (southerly), which may weaken the southerly wind speed. The observed data are the superposition results of two scale wind fields (i.e. local circulation and synoptic airflow). Westerly or weak northerly winds above 1,000m in type4 control the atmosphere, where the wind velocity below 1,000m is significantly weak. For the majority of the time, the wind velocity is less than 4 m s^{-1} , but the mountain–plain diurnal cycle wind can still be observed from the diurnal variation in the wind direction. From 08:00 BJT to 18:00 BJT, the wind is southerly while mainly northerly at night. Weak wind speeds last for a long period in the boundary layer of type4, because of which the local thermal and dynamic conditions can become the main factors that affect the spatial-temporal distribution of haze pollutants in Beijing. Figure 5 shows that, above 700hPa, type1, type2, and type4 are ascending movements. The maximum of the synoptic scale ascending movement appears in 900–950hPa. With an increase in the height, the intensity of the ascending movement gradually weakens, whereas in type3, below 750hPa can be characterized as a sinking movement. The intensity of the sinking movement increases gradually with decreasing pressure, where the maximum of the sinking movement appears at 900–950hPa. The intensity of the subsidence movement from this layer at 900–950hPa to the ground decreases a second time. Therefore, the sinking movement affects the inversion layer of type3, where the height of the inversion layer is the lowest of all types, resulting in type3 characterized by the smallest atmospheric capacity among the four types. Based on Figure 6, the relative humidity profiles for the four weather types have both similarities and differences in their space-time structures. The similarities in the four types are the increased and decreased relative humidity below 1,000m during the night and day, respectively, with a reverse in the relative humidity appearing at an altitude about 500 m during the day. The relative humidity of the surface layer decreases daily from 10:00 BJT to 20:00 BJT with an increase in the solar radiation. The thickness of the dry layer in the surface layer increases continuously, reaching its maximum height at ca. 14:00 BJT or 15:00 BJT every day, but the maximum height of the dry layer does not exceed 500m. The top of the dry layer is the reverse of the relative humidity layer. Above 1,000m, the relative humidity of the other three types, except type2, decreases significantly during the day. However, the relative humidity increased evidently in type4 above 2,000m. As mentioned in section 3.1, in type4, Beijing is located between a high pressure and a low pressure and in the front of the weak frontal zone. Stratus cloud with high stability is located in the front of the weak frontal zone above 2,000m, so relative humidity above 2,000m is higher.

290 The difference in the relative humidity field among the four types can be summarized as follows. The average relative
291 humidity below 1,000m is higher than that above 1,000m. The inverse relative humidity structure appears below 500m in
292 type2 and type3 from 00:00 BJT to 05:00 BJT, with a maximum relative humidity center of more than 90%. Above 500m,
293 the relative humidity also increases from 05:00 BJT to 12:00 BJT. The relative humidity structures of type1, type2, and
294 type3 all contain a baroclinic structure from lower to higher levels, where the baroclinic structure in type2 is more evident
295 because the basic flow in type2 is westerly, which reflects the baroclinic characteristics of the atmosphere in the mid-high
296 latitudes of East Asia. The basic flow is generally westerly in this area, where type1 and type3 are more typical of the
297 disturbances in the northerly and southerly wind in the westerlies, which is the fluctuation feature of the basic flow (Fig. 6).
298 The relative humidity profile in the pollution boundary layer formed under the condition of wave-current interaction in the
299 atmosphere.

300 Type2 has strong westerly characteristics below 3,000m (Fig. 4), which reflects more baroclinic characteristics in the
301 atmospheric vertical structure for the westerlies. Based on the analysis of the wind field, type4 is characterized by an average
302 wind speed that is the weakest among the four types. Three important factors determine the baroclinicity, that is, the density
303 gradient, pressure gradient, intersection angle between the density surface and pressure surface. This may be an important
304 factor why relative humidity field has more barotropic characteristics. From the analysis of the baroclinic and barotropic
305 characteristics, we can observe that the weather systems of type1, type2, and type 3 have a significant influence on the
306 accumulation and transport of pollutants in the Beijing area. The mountain–plain wind in type4 can occur due to weakening
307 in the weather system (Fig. 4).

308 3.3Construction of 3-D conceptual model for the pollution boundary layer

309 Based on the characteristics of the circulation field and the vertical thermodynamic structure for the four weather types, we
310 established conceptual models of the boundary layer structure under the influence of the four pollution weather types.
311 Because the vertical axes are different for the wind profile and temperature profile, we chose the pressure axis, which is
312 widely used in meteorology, to make conceptual model. In Beijing area, 700hPa,850hPa and 925hPa are generally located at
313 a height of about 3,000m,1,500m and 800m, The four types are: (a) type1: southerly transport; (b) type2: easterly
314 convergence; (c) type3: sinking compression; (d) type4: local accumulation (Fig. 7). When type 1 appears, the Beijing area is
315 located at the rear of the high-pressure system, consistent with southerly winds throughout the atmosphere (Fig.1e and Fig.4),
316 and multilayer inversion occurs in the boundary layer (Fig. 3). Under the influence of a southerly wind, haze pollutants
317 accumulate in front of the Yan and Taihang Mountains. The air pollutants in the Hebei region have evident regional transport
318 features (Fig. 1). When type2 appears, the Beijing area is located at the bottom of the high-pressure system, where the air
319 above 850hPa (about 1500m in Beijing) is a westerly wind, with easterly winds below 850hPa. Under the influence of
320 easterly winds below 850hPa, haze pollutants tend to accumulate in front of the Taihang Mountains. The cross-mountain air
321 mass flows from west to east, preventing the further dispersion of air pollutants in front of the Taihang Mountains. When
322 type3 appears, a weak high-pressure system controls the Beijing area. A weak subsidence northwest flow influences the

atmosphere above 850hPa, which further compresses the capacity of the atmosphere to absorb pollutants in the boundary layer. The southerly wind at 850hPa is favorable for pollutant transportation in the region and accumulation in front of the Yan and Taihang Mountains. The atmospheric vertical structure in the high-level northwest wind and low-level southward wind provides excellent conditions for the stability of atmospheric stratification with respect to dynamic conditions and a thermal structure. The 850hPa southerly winds favor regional pollutant transport and their accumulation in the area along the Yan and Taihang Mountains. The atmospheric vertical structure of the high-level northwest wind and low-level southerly wind provides excellent conditions for stratification stability in terms of dynamic-thermal structures because southerly wind at 850hPa is warm advection, where advection inversion can form in the boundary layer, while weak subsidence above 850hPa can cause subsidence inversion. These two inversion mechanisms are coupled at the interface between the northwest wind and southerly wind, resulting in stable atmospheric stratification. When type4 appears, there is often no evident synoptic-scale system surrounding Beijing, with a weak pressure gradient above 850hPa. Therefore, the average wind speed is weak. The most important local circulation in Beijing, that is, the mountain–plain wind, begins to form in the boundary layer and plays an important role in the spatial and temporal distribution of atmospheric pollutants, with the wind direction continuously shifting from the south to the north. The air pollutants accumulate near the terrain convergence line formed by the mountain–plain wind. The terrain convergence line also swings from north to south, such that air pollution in the Beijing area often appears as a “different sky” relative to a clean sky in the north and a polluted sky in the south.

3.4 Effects of the four pollution weather types

3.4.1 Statistical analysis: effects of the four weather types on haze pollution

Figure 8 shows the statistical characteristics of the $PM_{2.5}$ concentrations and meteorological elements in terms of the four polluted weather types. The daily average $PM_{2.5}$ concentration in type3 is the highest at $245 \mu g m^{-3}$ and type4 is the lowest at $181 \mu g m^{-3}$ (Fig. 4). The daily average relative humidity values of the four pollution weather types are $>60\%$, with a maximum relative humidity of 72.3% in type3 and a minimum relative humidity of 63.5% in type4 (Fig. 8b). Under the influence of a high relative humidity and high $PM_{2.5}$ concentration, the daily average visibility for the four heavy pollution weather types is less than 4,000m, with a minimum daily average visibility of 2,193m in type1. The maximum daily average visibility is 3,624m in type4 (Fig. 8c). The mean 24h wind speeds for the four pollution weather types are all less than $2.0 m s^{-1}$.

The mean daily wind speeds of type1 and type3 are both smaller, that is, 1.38 and $1.49 m s^{-1}$, respectively. The mean daily wind speeds of type2 and type4 are relatively higher, that is, 1.70 and $1.76 m s^{-1}$, respectively (Fig. 8d). There is a significant negative correlation between the boundary layer height and $PM_{2.5}$ concentration. The lowest boundary layer height was 386.5 m for type3, followed by type1, whereas type4 had the highest boundary layer height.

In this study, we calculated the distribution of the weather types from the first to last day of the persistent haze pollution events (Fig. 9). The daily synoptic types from the first to eighth day of persistent haze pollution events were calculated. As

356 the number of pollution events that lasted more than five days is relatively small, the classification results were combined
 357 with the statistics for the events defined as greater than or equal to five days. The results show that the cumulative proportion
 358 of type1 and type2 occurrences on the first and second pollution day are more than 80%, indicating that regional transport
 359 plays a more prominent role in the initial stage of haze pollution formation, which is consistent with previous analyses
 360 (Zhong et al.,2018). On the third day and thereafter, the proportion of type1 began to decrease, but still exceeded 30%.
 361 Type2, type3, and type4 began to alternately affect the Beijing area. This indicates that, after the first and second days, the
 362 center of high pressure over East China in type1 began to move eastward away from the mainland. Beijing is located at the
 363 rear of the high-pressure system, where the $PM_{2.5}$ concentration corresponding to type1 increases throughout most of the day.
 364 The timing of the initial rise in the $PM_{2.5}$ concentration is the earliest among the four types (Fig. 10a), which indicates the
 365 role of the rear within the high-pressure system in the transmission of pollutants (Fig. 11). When the upstream weather
 366 system begins to affect the Beijing area, it is occasionally located at the bottom of the high-pressure system (type2). The
 367 diurnal variation in the $PM_{2.5}$ concentration in type2 was similar to the mean annual variation in the $PM_{2.5}$ concentration in
 368 the Beijing area. The first peak was at 10:00 and the second was at 20:00(Zhao et al., 2009) (Fig. 10a). Easterly or
 369 southeasterly winds appear near the ground and the concentration of $PM_{2.5}$ in Tianjin drops (Fig. 11). The weak high-pressure
 370 system in type3 can directly affect the haze pollution diffusion conditions in the Beijing area, but the intensity of the cold air
 371 behind the upper trough is weak. The $PM_{2.5}$ concentration in type3 is higher at night and lower during the day, with the
 372 highest average $PM_{2.5}$ concentration among the four types. Based on this analysis, we can observe that, in type3, the height of
 373 the inversion layer is the lowest and the atmospheric capacity to contain pollutants is also the lowest under the influence of a
 374 weak downdraft (Fig. 10a). This has resulted in very small wind speed near the ground and large areas of air pollution in the
 375 north of China(Fig. 11). In type4, there is no evident weather system that affects the Beijing area. An increase in the thermal
 376 difference between the mountain and plain affects local circulation development. A shear line of wind field formed by local
 377 circulation can be seen in the North China Plain (Fig. 11). The average $PM_{2.5}$ concentration in type4 is the lowest among the
 378 four types. The diurnal variation in the $PM_{2.5}$ concentration shows a typical "v" pattern. After sunrise, the $PM_{2.5}$
 379 concentration begins to decrease while, after sunset, the $PM_{2.5}$ concentration increases significantly, which was due to the
 380 fluctuation of aerosols under local meteorological conditions (Fig. 10a). Based on Fig. 10b, the boundary layer height of
 381 type3 is the lowest among all types for most part of a day, which is mainly related to the suppression of the weak synoptic-
 382 scale downdraft. The change in the trend of the boundary layer height is similar between type 2 and type 4 for most of the
 383 day. However, the boundary layer height is less developed when the thermal conditions are strongest between 12:00 and
 384 18:00, which is similar to type3. The boundary layer heights of type2 and type4 are relatively high, and the corresponding
 385 $PM_{2.5}$ concentrations are the lowest out of the four pollution types (Fig. 10b).
 386 The above analysis shows that in one persistent multi-day pollution event, the weather patterns that affect the Beijing area
 387 change daily, that is, they also change according to the basic principles of synoptic dynamics, which is the natural
 388 development and evolution of rossby waves in the mid-high latitude westerly belt. This also indicates that it is not
 389 appropriate to classify a multi-day pollution event as a defined type (such as the low-pressure or high-pressure type). We

cannot rule out the possibility that a pollution event may occur for several consecutive days under the influence of a low-pressure system, which is a rare event. Even then, this may also be a combination of different low-pressure systems. In addition, we note that, in one persistent multi-day heavy pollution event, different types of pollution weather types are linked together in a permutation that affects the structure of the boundary layer and thus the change in the $PM_{2.5}$ concentration (Fig. 9). As different types of weather systems form different haze pollution events, we discuss the type of boundary layer structure formed by certain weather systems in the Beijing area and how this boundary layer structure influences the evolution of haze pollution formation in the next section.

3.4.2 Effects of four weather types on the 3-D spatial-temporal evolution of haze pollution

An example of a five-day haze process (December 22 to 26, 2015) is adopted to investigate the effects of four weather types including the boundary layer structure on the three-dimensional structure of the haze pollution process. December 22 is type1, the whole layer is southerly wind (Fig. 13) and the ground is the convergence zone (Fig. 12), which facilitates regional pollutant transport (Fig. 14). The vertical wind speed is weak upward movement (Fig. 13) and the temperature inversion is maintained throughout the day (Fig. 15), which is favorable for the accumulation of pollutants. Under the influence of southerly winds, the sensitive source areas related to the Beijing area are generally the plain areas along the Taihang Mountains in Hebei province (Wang et al., 2017). According to the dynamics, the positive vorticity advection in the direction of Beijing forms in the plain area. The positive vorticity advection in this boundary layer has two functions. First, the positive vorticity airflow is affected by the friction, coriolis effect, and pressure-gradient force. Second, the positive vorticity advection continuously transports the converging space field to the Beijing area and, at the same time, also transfers a large amount of external pollutants.

Type3 is on December 23. The ground is controlled by high pressure (Fig. 12), the atmosphere is prevailing northwest wind below 3,000m (Fig. 13), and the boundary layer height further decreases (Fig. 15). There are few relevant studies on type3. Because in the past, when the northerly wind appears, it indicates the arrival of cold air and the diffusion conditions will improve, but sometimes this is not the case. We found that the research results of Wu et al. (2017) put emphasis on the importance of subsidence motion on haze formation mechanism in the conceptual model, which is consistent with the key role of weak subsidence motion in type3. The thickness of haze layer formed by regional transmission and local accumulation is less than 300 m (Fig. 14).

Type4 is on December 24th, and the ground is the convergence zone (Fig. 12). The aerosol concentration and relative humidity in Beijing area drops rapidly and then rises rapidly, and the boundary layer rises to more than 1500m during the period when the aerosol concentration drops (Fig. 14 and Fig. 16). Under the action of weather system and local circulation, the pollution zone in the boundary layer swings southward and northward. There are some research achievements on aerosol of local circulation, which are generally carried out from the aspects of mountain topography and land-sea distribution with local characteristics (Li et al., 2018; 2020). These studies require observations with high spatial and temporal resolution to identify boundary layer structures.

423 Type3 occurs on December 25 once again, when the northwest wind appears again in the upper atmosphere, the vertical
424 movement is a continuous weak sinking movement (Fig. 13) and the boundary layer height continues to maintain below
425 300m(Fig. 14). The temperature inversion is maintained throughout the day(Fig. 15). December 26 is type2. Beijing area is
426 located at the bottom of high pressure(Fig. 12), and easterly winds prevail in the lower layer of the boundary layer(Fig. 13).
427 The diffusion conditions of air pollution here can be divided into two stages. In the first stage, the easterly wind is below
428 1,000m, and the northerly wind is above 1,000m, so the aerosol can not spread to the upper atmosphere(Fig. 13). In the
429 second stage, the high pressure continued to move eastward and lost its influence on the Beijing area. When the northerly
430 wind over 1,000m changed to the westerly or southwesterly wind, the upper and lower atmosphere were connected, and the
431 upward movement of $m s^{-1}$ magnitude was stimulated in the boundary layer(Fig. 13), the haze process ends when the aerosol
432 is lifted into the upper atmosphere(Fig. 14).

433 4 Conclusion

434 In this study, we objectively classified pollution weather events based on the REOF method using integrated observation
435 data from meteorology and the environment, combined with the ERA-Interim reanalysis data($0.125^{\circ} \times 0.125^{\circ}$). We then
436 synthesized the thermodynamic and dynamic structures of the boundary layer under the different pollution weather types to
437 construct the corresponding boundary layer conceptual models. The results show that four weather types mainly affect the
438 pollution events in Beijing: (a) type1: southerly transport, (b) type2: easterly convergence, (c) type3: sinking compression,
439 and (d) type4: local accumulation. The explained variance in the four pollution weather types were 43.69(type1), 33.68
440 (type2), 16.51(type3), and 3.92% (type4), respectively.

441 In persistent pollution events, the proportion of type1 and type2 occurrences were more than 80% on the first and second
442 days, with subsequent alternations to the other types. The atmospheric structures of type1, type2, and type3 have typical
443 baroclinic characteristics in the mid-high latitudes, indicating that synoptic-scale systems, together with local circulation,
444 affect the accumulation and transport of pollutants in the boundary layer. On the other hand, the atmospheric structures of
445 type4 have typical barotropic characteristics, which indicates that local circulation plays a major role in pollutant
446 accumulation and transport. This is the first time that the baroclinic and barotropic characteristics of the atmosphere have
447 been introduced into the discussion of pollution boundary layer.

448 Among the four types, southerly winds, with certain thicknesses and intensities, appeared in the boundary layer of type1,
449 which was favorable for the transportation of pollutants to Beijing, accumulating more in areas along the Yan and Taihang
450 Mountains. On the other hand, the pollution level in the central plain area of Hebei was relatively small. For type2, the
451 pollutants mainly concentrated along the Taihang Mountains due to the influence of the interaction between weak easterly
452 winds and topography. The vertical structure of the atmosphere was unfavorable for pollutants to ascend into the mountains.
453 Type 3 had the lowest inversion height, boundary layer height, and the highest surface relative surface humidity, which are
454 favorable for $PM_{2.5}$ hygroscopic growth. Correspondingly, type3 had the highest $PM_{2.5}$ concentration. Type4 had the highest

boundary layer height and lowest surface relative humidity among the four pollution types, whose PM_{2.5} concentration was relatively low when exposed to local mountain–plain winds. Pollutant accumulation is related to dynamic oscillation along the convergence line of the mountain terrain. The results of this study allow us to understand the formation mechanism of different heavy pollution boundary layers from synoptic scale and boundary layer perspectives, as well as to provide scientific support for scientific emissions reduction and air quality prediction. The different heavy pollution weather types and heavy pollution boundary layers not only reflect the interaction between the atmospheric mean flow and fluctuation, but also reflect the process of heavy pollution weather types shaping the boundary layer. In addition, through the analysis of 1–4 types pollution processes(December 22 to 26,2015), we further illustrate the influence of different weather systems on the shaping of the pollution boundary layer in the continuous pollution process.

Although we attempted to collect data on all types of atmospheric pollution boundary layer structures in the Beijing area, there are still certain data samples that were not collected. These data can also explain the pollution characteristics associated with the four heavy pollution boundary layers from other factors, such as PM_{2.5} composition data. We also speculate that there is feedback between aerosols and the boundary layer, which was not examined in this study. Although there have been numerous studies on atmospheric pollutant transport, there are few studies on 3-Dpollutant transportation, which will be the focus of our future investigations.
