## 15 **Abstract**

16 Convective cloud systems in the maritime tropics play a critical role in global climate, but accurately representing  
17 aerosol interactions within these clouds persists as a major challenge for weather and climate modelling. We quantify  
18 the effect of ice-nucleating particles (INP) on the radiative properties of a complex Tropical Atlantic deep convective  
19 cloud field using a regional model with an advanced double-moment microphysics scheme. Our results show that the  
20 domain-mean daylight outgoing radiation varies by up to  $18 \text{ W m}^{-2}$  depending on the chosen INP parameterisation.  
21 The key distinction between different INP parameterisations is the temperature dependence of ice formation, which  
22 alters the vertical distribution of cloud microphysical processes. The controlling effect of the INP temperature  
23 dependence is substantial even in the presence of Hallett-Mossop secondary ice production, and the effects of  
24 secondary ice formation depend strongly on the chosen INP parameterisation. Our results have implications for  
25 climate model simulations of tropical clouds and radiation, which currently do not consider a link between INP particle  
26 type and ice water content. The results also provide a challenge to the INP measurement community, since we  
27 demonstrate that INP concentration measurements are required over the full mixed-phase temperature regime,  
28 which covers around 10 orders of magnitude.

# 1. Introduction

30 Deep convective clouds are important drivers of local, regional and global climate and weather (Arakawa, 2004;  
31 Lohmann et al., 2016). They produce substantial precipitation (Arakawa, 2004) and the associated phase changes  
32 release latent heat that helps to drive global atmospheric circulation (Fan et al., 2012). Convective clouds have a direct  
33 impact on climate through interactions with incoming shortwave and outgoing longwave radiation (Lohmann et al.,  
34 2016), for example by producing radiatively important long-lived cirrus clouds (Luo and Rossow, 2004). The clouds  
35 extend from the warmer lower levels of the atmosphere where only liquid exists to the top of the troposphere where  
36 only ice exists (Lohmann et al., 2016). Between these levels is the mixed-phase region where both liquid and ice  
37 coexist and interact (Seinfeld and Spyros, 2006). Within the mixed-phase region, primary ice particles can form  
38 heterogeneously through the freezing of cloud droplets by ice-nucleating particles (INP). The importance and relative  
39 contribution of heterogeneous freezing to ice crystal number concentrations (ICNC) and resultant cloud properties,  
40 such as cloud reflectivity, is very uncertain (Cantrell and Heymsfield, 2005; Kanji et al., 2017). This uncertainty stems  
41 from the difficulty of predicting INP number concentrations (Kanji et al., 2017; Lacher et al., 2018) as well as the  
42 difficulty of quantifying complex interactions between heterogeneous freezing and other ice production mechanisms  
43 (Crawford et al., 2012; Huang et al., 2017; Phillips et al., 2005).

44 Understanding the effects of INP on convective clouds presents substantial challenges. Measurements indicate that  
45 INP number concentrations can vary by as much as six orders of magnitude at any one temperature due to variations  
46 in, for example, aerosol source, chemical or biological composition, and surface morphology (DeMott et al., 2010;  
47 Kanji et al., 2017). Large variability exists even in measurements of individual regions or aerosol populations (Boose et  
48 al., 2016b; Kanji et al., 2017; Lacher et al., 2018). For example, there are four orders of magnitude variation in  
49 summertime measurements of INP number concentrations in the Saharan Air Layer at  $-33^{\circ}\text{C}$  (Boose et al., 2016b).

50 Even for particles of similar and known mineralogy, measurements of ice-nucleation efficiency can span several orders  
51 of magnitude: The spread in laboratory measurements of ice nucleation active site densities ( $n_s$ ) for different types of  
52 feldspar spans seven orders of magnitude at  $-15^{\circ}\text{C}$  (Atkinson et al., 2013; Harrison et al., 2016, 2019; Peckhaus et al.,  
53 2016). Our ability to understand and quantify such variability in INP concentrations has improved as more  
54 measurements have been made. Although INP concentrations do not simply correlate with meteorological variables  
55 such as pressure and temperature (Boose et al., 2016a; Lacher et al., 2018; Price et al., 2018), aerosol surface area  
56 (Lacher et al., 2018) and diameter (DeMott et al., 2015) provide some predictability and global models based on

57 known INP-active materials show reasonable skill in simulating global INP concentrations (Shi and Liu, 2019; Vergara-  
58 Temprado et al., 2017).

59 It is known from model simulations that changes in INP number concentration affect the microphysical properties and  
60 behaviour of deep convective clouds (Deng et al., 2018; Fan et al., 2010a, 2010b; Gibbons et al., 2018; Takeishi and  
61 Storelvmo, 2018). However, in these model studies perturbations to INP number concentrations have predominantly  
62 involved uniform increases in aerosol or INP concentrations with all simulations using the same INP parameterisation  
63 (Carrió et al., 2007; Connolly et al., 2006; Deng et al., 2018; Ekman et al., 2007; Fan et al., 2010a; Gibbons et al., 2018;  
64 van den Heever et al., 2006; Phillips et al., 2005), i.e. the temperature dependence of INP number concentrations was  
65 not altered. Where different INP parameterisations have been used (Eidhammer et al., 2009; Fan et al., 2010b; Liu et  
66 al., 2018; Takeishi and Storelvmo, 2018), the results have in most cases been interpreted in terms of the overall  
67 increase in INP number concentration (Fan et al., 2010b; Liu et al., 2018; Takeishi and Storelvmo, 2018). However,  
68 there are important structural differences between different INP parameterisations that have not yet been explored  
69 in detail. For example, currently available and regularly used parameterisations of INP vary substantially in the  
70 dependence of INP activity on temperature. We hypothesise that the difference between parameterisations will be  
71 particularly important for deep convective clouds because heterogeneous ice formation occurs over a very wide  
72 temperature range from just below 0 to around -38°C in the mixed-phase region of these clouds. For the same dust  
73 particle concentration, predicted INP concentrations can increase by up to three orders of magnitude from -15 to -  
74 20°C (corresponding to approximately 1 km altitude change) using an INP parameterisation with a steep temperature  
75 dependence (lower INP concentrations at high temperatures and higher INP concentrations at low temperatures)  
76 (Atkinson et al., 2013), but by less than one order of magnitude using an INP parameterisation with a shallower  
77 dependence (DeMott et al., 2010; Meyers et al., 1992). We hypothesise that such large differences in ice production  
78 rates between INP parameterisations are likely to affect cloud properties. In simulations of deep convective clouds  
79 over North America (Takeishi and Storelvmo, 2018) there were differences in the magnitude and altitude of droplet  
80 depletion depending on INP parameterisation choice (Bigg, 1953; DeMott et al., 2010, 2015).

81 Uncertainty in mixed-phase cloud properties is compounded further by a lack of quantification of the interaction of  
82 heterogeneous freezing with other ice production mechanisms. Ice crystals in the mixed-phase region can also be  
83 formed by secondary ice production (SIP) from existing hydrometeors (Field et al., 2017) and droplets can freeze  
84 homogeneously below around -33°C (Herbert et al., 2015). In observations of convective clouds with relatively warm  
85 cloud-top temperatures (Fridlind et al., 2007; Heymsfield and Willis, 2014; Ladino et al., 2017; Lasher-Trapp et al.,

86 2016; Lawson et al., 2015), ICNC has frequently exceeded INP number concentrations by several orders of magnitude,  
87 suggesting that secondary ice production is the dominant small-ice formation mechanism in mixed-phase regions  
88 (Ladino et al., 2017). The importance of heterogeneous ice production relative to secondary and homogeneous  
89 freezing has therefore been questioned (Ladino et al., 2017; Phillips et al., 2007) and it has been proposed that INP  
90 concentrations may only be relevant up to a threshold needed to initiate SIP (Ladino et al., 2017; Phillips et al., 2007),  
91 a value that may be as low as  $0.01 \text{ L}^{-1}$  (Crawford et al., 2012; Huang et al., 2017) for the Hallett-Mossop process  
92 (Hallett and Mossop, 1974). If this is the case, in clouds where SIP may also be initiated by the primary freezing of a  
93 few large ( $\sim 1 \text{ mm}$ ) droplets in a rising parcel (Field et al., 2017), INP number concentrations may be largely irrelevant  
94 to cloud ice properties. The effect of INP and INP parameterisation on convective cloud properties must therefore be  
95 examined with consideration for the presence of, and interactions with, SIP.

96 Here we explore how the choice of INP parameterisation affects the properties of a large and realistic cloud field  
97 containing clouds at all levels as well as deep convective systems in the eastern Tropical Atlantic with a focus on the  
98 top of atmosphere (TOA) outgoing radiation. The eastern Tropical Atlantic is an ideal location in which to examine the  
99 role of INP concentrations in convective cloud systems because, owing to its position at the interface between the  
100 Saharan Air Layer and the Inter Tropical Convergence Zone, it is subject to both high levels of convective activity and  
101 high loadings of desert dust, a relatively well-defined INP type (DeMott et al., 2003; Niemand et al., 2012; Price et al.,  
102 2018). First, we determine how the presence of INP alters the radiative properties of the cloud field. We then  
103 examine how the properties of the simulated cloud field, including cloud shortwave reflectivity, cloud fraction and  
104 anvil extent, depend on the choice of INP parameterisation. In particular, we examine the importance of the  
105 dependence of INP number concentration on temperature, referred to as INP parameterisation slope herein, as a  
106 major factor that determines cloud properties. We also examine the effect on cloud properties of the inclusion of SIP  
107 due to the Hallett-Mossop process.

108

## 109 **2. Methods**

### 110 **2.1. Model set-up**

#### 111 **2.1.1 Regional domain and initial conditions**

112 Simulations described in this article were performed using the Unified Model (UM) version 10.8 (GA6 configuration)  
113 (Walters et al., 2017). The UM is a numerical weather prediction model developed by the UK Met Office. We use a  
114 regional nest within the global model simulation (Fig. 1a), which has a grid spacing of 1 km (900\*700 grid points) and  
115 70 vertical levels. Meteorology of the driving global model is based on operational analysis data. Within the nested  
116 domain, the Cloud AeroSol Interacting Microphysics scheme (CASIM) is employed to handle cloud microphysical  
117 properties. A global model simulation (UM vn 8.5, GA6 configuration, N512 resolution (Walters et al., 2017)) is used to  
118 initialise the nested simulation at 00:00 on the 21st of August 2015 and is used throughout the simulation for the  
119 boundary conditions.

120 The 21st of August 2015 was chosen for simulation to coincide with flight b933 of the Ice in Clouds Experiment – Dust  
121 (ICE-D) July-August 2015 field campaign that targeted convective clouds extending to and beyond the freezing level.  
122 The aerosol profile measured during flight b933 (Fig. 1b) was used to derive the aerosol profiles prescribed over the  
123 nested domain at the beginning of the simulation and are constantly applied at the boundaries. Model profiles were  
124 calculated as follows: The UM vn 10.3 was used to simulate a domain comprising the entire Tropical Atlantic and West  
125 Africa. This simulation was initiated on the 18<sup>th</sup> August 2015 with a grid spacing of 8 km using the UM operational one-  
126 moment microphysics (i.e. not CASIM) and the CLASSIC aerosol scheme with a 6-bin dust model (Johnson et al.,  
127 2015a). On the day of the b933 flight (21<sup>st</sup> August 2015), a dust layer was present between 2 and 3 km altitude.  
128 Comparison to MODIS AOD data indicates agreement between the model and observations (not shown). This UM vn  
129 10.3 simulation was used to calculate the average dust profile (mass and number concentration) over the CASIM  
130 domain on the 21<sup>st</sup> of August 2015 and these dust profiles are applied in the nested domain as the insoluble aerosol  
131 profiles (Fig. 1b). The approximate difference between the dust aerosol profile provided by the UM regional  
132 simulation and the observed aerosol profile measured during flight b933 (comprising both insoluble and soluble  
133 particles) is used as the soluble aerosol profile (Fig. 1b). The simulations are 24 hours in length.

#### 134 **2.1.2. CASIM microphysics**

135 CASIM is a multi-moment bulk scheme, which is configured to be two-moment in this work. Both number  
136 concentration and mass concentration for each of the five hydrometeor classes (cloud droplets, rain droplets, ice

137 crystals (or cloud ice), graupel, snow) are prognostic variables. The model set-up is very similar to that used in  
138 Miltenberger et al. (2018) including the parameter choices within CASIM. CASIM has been used and tested previously  
139 in simulations of coastal mixed-phase convective clouds (Miltenberger et al., 2018), South-East Pacific stratocumulus  
140 clouds (Grosvenor et al., 2017), Southern Ocean supercooled shallow cumulus (Vergara-Temprado et al., 2018),  
141 midlatitude cyclones (McCoy et al., 2018) and CCN-limited Arctic clouds (Stevens et al., 2018). The parameters used in  
142 the representation of the size distribution, density and terminal fall speed velocities of each of the five hydrometeor  
143 classes represented by CASIM are shown in Table 2 of Miltenberger et al. (2018).

144 Cloud droplet activation is parameterised according to (Abdul-Razzak and Ghan, 2000). The soluble accumulation  
145 mode aerosol profile shown in Fig. 1b is used for cloud droplet activation and a simplistic CCN activation  
146 parameterisation is included for the insoluble aerosol mode (Abdul-Razzak and Ghan, 2000) that assumes a 5% soluble  
147 fraction on dust. Scavenging of CCN or INP is not represented. Collision-coalescence, riming of ice crystals to graupel  
148 and aggregation of ice crystals to snow is represented. Rain drop freezing is described using the parameterisation of  
149 Bigg (1953). For reference, the modelled domain-mean out-of-cloud temperature and relative humidity are shown in  
150 Fig. 1c. The model time-step is 5 seconds.

151 Heterogeneous ice nucleation is represented using 5 different parameterisations: Cooper (1986) (C86), Meyers et al.  
152 (1992) (M92), DeMott et al. (2010b) (D10), Niemand et al. (2012) (N12) and Atkinson et al. (2013) (A13) (Fig. 2). C86  
153 and M92 calculate a freezing rate based on temperature and are independent of aerosol concentration. D10  
154 calculates an INP concentration from temperature and the concentration of insoluble dust aerosol with a diameter  
155 greater than 0.5  $\mu\text{m}$ . N12 and A13 calculate an INP concentration from the temperature dependent active surface site  
156 density and the surface area of insoluble dust aerosol ( $n_s$ ). For A13, a potassium-feldspar fraction of 0.25 is assumed.  
157 This is the upper recommended fraction (Atkinson et al., 2013) which was deemed appropriate because of the study  
158 region's exposure to Saharan dust outflow. M92 is described as a deposition and condensation freezing  
159 parameterisation (Meyers et al., 1992) and is often used alongside an immersion freezing parameterisation in  
160 modelling studies (Deng et al., 2018; Fan et al., 2010b, 2010a; Gibbons et al., 2018). However, the M92  
161 parameterisation is based on aircraft continuous flow diffusion chamber measurements and those measurements  
162 should capture all relevant nucleation mechanisms (see Vali et al., 2015). To represent nucleation at conditions  
163 relevant for clouds with liquid water present, we have set the saturation term in the M92 parameterisation to water  
164 saturation. One simulation is conducted with no active heterogeneous ice nucleation representation (NoINP). The INP  
165 parameterisations inspect the conditions (temperature, cloud droplet number, ICNC) and aerosol concentrations

166 within a gridbox and use that information to predict an ice production rate via heterogeneous freezing. The  
167 supercooled droplets are depleted by the freezing parameterisation, but scavenging of INPs is not represented.  
168 Homogeneous freezing of cloud droplets is parameterised according to Jeffery and Austin (1997).

169 The INP parameterisations tested in this study represent only immersion freezing. Heterogeneous ice nucleation by  
170 deposition and contact nucleation are not represented. Other mechanisms of heterogeneous ice formation should be  
171 tested and included in future studies but was beyond the scope of this work. However, immersion freezing is expected  
172 to be the dominant mechanism of heterogeneous ice formation in convective clouds (Ansmann et al., 2008; De Boer  
173 et al., 2011; Kanji et al., 2017) and therefore the simulations presented here should capture the majority of  
174 heterogeneous ice nucleation relevant for cloud properties. Immersion and homogeneous freezing of haze droplets  
175 are not represented, but it is unlikely that they contribute significantly to ice crystal number concentration in the main  
176 anvil cloud derived from mixed-phase cloud regions. However, the importance of these mechanisms on anvil cloud  
177 properties should be investigated in future work. Secondary ice production (SIP) is represented using an approximation  
178 of the Hallett-Mossop process which occurs between -2.5 and -7.5°C. The efficiency of the Hallett-Mossop process  
179 increases from -2.5 and -7.5°C to 100% at -5°C. The rate of splinter production per rimed mass is prescribed with 350  
180 new ice splinters produced per milligram of rime at -5°C. Splinters are produced from rime mass of snow and graupel.  
181 The ice splinters produced by the representation of the Hallett-Mossop process are the smallest allowable size of ice  
182 in the model (i.e.  $10^{-18}$  kg, volume radius  $\sim 0.11$   $\mu\text{m}$ ). The rate of splinter production by the Hallett-Mossop process is  
183 based on the best available estimate of the efficacy of the mechanism (Connolly et al., 2006; Hallett and Mossop,  
184 1974; Mossop, 1985). In-situ cloud observations have frequently observed ICNC that could be explained by the Hallett-  
185 Mossop process, but the mechanism underlying the Hallett-Mossop process as well as the ice particle production rate  
186 remain uncertain and not well quantified (Field et al., 2017). A maximum splinter production rate of 350 per milligram  
187 of rimed material has been measured in a number of laboratory studies (Hallett and Mossop, 1974; Mossop, 1985)  
188 and has been applied as the best estimate here and in previous modelling studies (Connolly et al., 2006), although  
189 other rates have also been measured (Heymsfield and Mossop, 1984; Saunders and Hosseini, 2001). Uncertainties  
190 regarding the rate of splinter production by Hallett-Mossop are an important consideration that will be investigated in  
191 future work; this study explores the structural uncertainty of the presence/absence of the Hallett-Mossop process as  
192 currently understood. Other mechanisms of SIP such as collision fragmentation, droplet shattering and sublimation  
193 fragmentation have been proposed (Field et al., 2017), but are not represented in these simulations, in part because  
194 they are very poorly defined and it is not clear how important they are. Other studies have attempted to model some

195 of these additional SIP processes (Phillips et al., 2018; Sullivan et al., 2018) but that was beyond the scope of this  
196 study.

### 197 **2.1.3. Cloud radiation**

198 The radiative processes are represented by the Suite of Community RAdiative Transfer codes based on Edwards and  
199 Slingo (SOCRATES) (Edwards and Slingo, 1996; Manners et al., 2017), which considers cloud droplet number and mass,  
200 as well as ice crystal and snow water paths for the calculation of cloud radiative properties. It does not explicitly  
201 consider changes in ice crystal or snow number concentration or size (though changes in number and size will affect  
202 mass concentrations which are considered), and does not consider any changes to rain or graupel species. The cloud  
203 droplet single scattering properties are calculated from the cloud droplet mass and effective radius in each gridbox  
204 using the equations detailed in Edwards and Slingo (1996). Snow and ice are combined to form one ice category for  
205 the purposes of the radiation calculations. The single scattering properties of this snow and ice category are calculated  
206 from their combined mass and the ambient temperature. The parameterisation of bulk optical properties of snow and  
207 ice used in the model is detailed in Baran et al. (2014).

208 The radiative properties (shortwave, longwave and total radiation) are calculated for daylight hours only, i.e. 10:00-  
209 17:00 UTC. For all other modelled properties presented, except when plotted against a corresponding radiative  
210 property, values are calculated for the last 14 hours of the simulation, i.e. from 10:00 - 24:00. The sensitivity of the  
211 outgoing longwave radiation and the cloud fraction to time period selection was tested and found to have little  
212 impact. The overall outgoing radiation (shortwave + longwave) will be sensitive to the time period selection owing to  
213 the absence of outgoing shortwave radiation at night-time. We focus on the radiation during daylight hours only  
214 because our simulation is only 24 hours in length owing to computational restrictions and therefore when the spin-up  
215 period is excluded from the analysis, less than 24 hours of simulation data remains with much of the night-time hours  
216 removed with the spin-up period.

217 Changes to outgoing radiation from cloudy regions and changes in cloud fraction both contribute to the total overall  
218 change in outgoing radiation between two simulations. The contributions from changes in outgoing radiation from  
219 cloudy regions and cloud fraction to the overall radiative differences between simulations were calculated separately  
220 as described below. The cloudy regions contribution, i.e. the difference in outgoing radiation between two cloudy  
221 regions due to changes in cloud albedo or thickness ignoring any changes in cloud fraction, ( $\Delta Rad_{REFL}$ ) to a

222 domain radiative difference between a sensitivity simulation (s) and a reference simulation (r) (s – r) is calculated  
 223 using Eq. (1).

$$224 \quad \Delta Rad_{REFL} = cf_r \times \Delta Rad_{cl} \quad (1)$$

225 where  $cf_r$  is the cloud fraction of simulation r and  $\Delta Rad_{cl}$  is the change in outgoing radiation from cloudy areas only  
 226 between simulations (s – r). The reference run (r) in Sections 3.1 – 3.4 refers to the NoINP simulation while the sensitivity  
 227 run (s) are simulations which include an INP parameterisation. In Section 3.5, the reference run (r) refers to a simulation  
 228 which has no representation of SIP and the sensitivity run (s) to a simulation which includes SIP due to the Hallett-  
 229 Mossop process. The contribution of cloud fraction changes, i.e. the change in radiation that can be attributed to an  
 230 area of clear sky in simulation s becoming cloudy in simulation r or vice versa, to the total change in domain outgoing  
 231 radiation ( $\Delta Rad_{CF}$ ) is calculated using Eq. (2).

$$232 \quad \Delta Rad_{CF} = (Rad_{r,cl} - Rad_{r,cs}) \times \Delta cf \quad (2)$$

233 Where  $Rad_{r,cl}$  is the mean outgoing radiation from cloudy regions in simulation r and  $Rad_{r,cs}$  is the mean outgoing  
 234 radiation from clear sky regions in simulation r and  $\Delta cf$  is the difference in domain cloud fraction between simulations  
 235 s and r (s-r). There is interaction between the outgoing radiation from cloudy regions and cloud fraction changes  
 236 ( $\Delta Rad_{INT}$ ) which is calculated in Eq. (3).

$$237 \quad \Delta Rad_{INT} = \Delta Rad_{cl} \times \Delta cf \quad (3)$$

238 The contribution of changes in the outgoing radiation from clear sky areas ( $\Delta Rad_{CSKY}$ ) can be calculated as shown in  
 239 Eq. (4).

$$240 \quad \Delta Rad_{CSKY} = \Delta Rad_{cs} \times (1 - cf_s) \quad (4)$$

241 Where  $\Delta Rad_{cs}$  is the change in mean outgoing radiation from clear sky areas between simulations s and r and  $cf_s$  is  
 242 the cloud fraction of simulation s.

243 The total outgoing radiation difference between simulations s and r ( $\Delta Rad_{s-r}$ ) is therefore as shown in Eq. (5).

$$244 \quad \Delta Rad_{s-r} = Rad_s - Rad_r = \Delta Rad_{REFL} + \Delta Rad_{CF} + \Delta Rad_{INT} + \Delta Rad_{CSKY} \quad (5)$$

245 The interaction term  $\Delta Rad_{INT}$  and the clear sky term ( $\Delta Rad_{CSKY}$ ) were found to be negligible and are therefore  
246 ignored for the purposes of this paper.

#### 247 **2.1.4. Model simulations**

248 The conducted simulations are as follows:

- 249 - Five simulations with different heterogeneous ice nucleation parameterisations (C86, M92, D10, N12 and  
250 A13) with a representation of the Hallett-Mossop process (SIP\_active).
- 251 - One simulation with no heterogeneous ice nucleation (NoINP), but with a representation of the Hallett-  
252 Mossop process (SIP\_active).
- 253 - Five simulations with different heterogeneous ice nucleation parameterisations (C86, M92, D10, N12 and  
254 A13) without a representation of the Hallett-Mossop process (SIP\_inactive).

255 The INP number concentration ([INP]) predicted by the five INP parameterisations (C86, M92, D10, N12, A13) are  
256 compared with the available measurements from the study region (Price et al., 2018; Welti et al., 2018) in Fig. 2,  
257 including those taken during the ICE-D field campaign (Price et al., 2018). All parameterisations are in reasonable  
258 agreement with the measurements (and with each other) at around  $-17^{\circ}\text{C}$ , but deviate strongly at higher and lower  
259 temperatures. It should be noted that all parameterisations tested in this work were developed between specific  
260 temperature ranges and extrapolation beyond these temperatures adds uncertainty. However, for the purposes of  
261 this paper and to allow a direct comparison between parameterisations, all parameterisations have been applied  
262 between 0 and  $-37^{\circ}\text{C}$ . Importantly, the INP parameterisation slopes of the chosen parameterisations span the range  
263 used within regional models (from a shallow  $d\log_{10}[\text{INP}]/dT = -0.07$  in M92 (Meyers et al., 1992) to a steep  
264  $d\log_{10}[\text{INP}]/dT = -0.45$  in A13 (Atkinson et al., 2013)).

265 When analysing the simulation output, cloudy grid boxes were classed as those containing more than  $10^{-5} \text{ kg kg}^{-1}$   
266 condensed water from cloud droplets, ice crystals, graupel and snow. Rain was not included to ensure analysis did not  
267 include areas below cloud base. Other cloud thresholds were tested and found to have no notable effect on the  
268 results. For cloud categorisation into low, mid and high clouds, model vertical columns containing cloudy grid boxes  
269 were categorised by cloud altitude. Low cloud occurs below 4km, mid cloud between 4 and 9 km and high cloud above  
270 9 km. Columns with cloudy grid boxes in two or more cloud categories were classified as mixed category columns  
271 according to the vertical placement of the cloudy grid boxes, e.g. low/high for columns containing cloud below 4 km

272 and above 9 km. 4 and 9 km were chosen as the low/mid and mid/high division points because they are just below  
273 two well-defined peaks in cloud base heights (not shown) and roughly correspond to the beginning of the  
274 heterogeneous and homogeneous freezing regions, respectively. For the correlation analysis where model outputs  
275 were plotted against parameterisation slope ( $d\log_{10}[\text{INP}]/dT$ ), a straight line was fitted to the D10 parameterisation  
276 between -3 and -37°C to obtain an approximate INP parameterisation slope. Other temperature ranges were tested  
277 and were found to have no notable effect on results.

## 278 **2.2. The observed case**

279 MODIS visible images of the 21<sup>st</sup> August 2015 are shown in Fig. 3 (a, b) alongside snapshots of the TOA outgoing  
280 longwave radiation in one of our simulations (c, d). The simulated cloud field has more cloud-free areas than the  
281 satellite images but in general produces clouds similar to those shown in the satellite image and in approximately the  
282 correct location. Overall the simulations produce a complex and realistic cloud field. Snapshots of the simulated model  
283 TOA outgoing shortwave radiation are shown in Fig. A1.

284 In-situ measurements of cloud and aerosol properties were made using the UK FAAM Bae-146 research aircraft, which  
285 was flown from Praia, Cape Verde Islands. An extensive suite of in-situ aerosol and cloud particle instruments were  
286 operated onboard the aircraft and are described in detail in Lloyd et al. (2019). The aircraft penetrated the growing  
287 convective clouds at a range of altitudes from just below the freezing level up to -20°C. In order to show that the  
288 model reproduces the observed conditions, the observational data were compared to the conditions in modelled  
289 clouds of similar size to those the aircraft flew in (10 – 150 km<sup>2</sup>) where a comparison was thought appropriate.  
290 Comparisons of a selection of simulated cloud properties with aircraft data are shown in Fig. A2. In-cloud  
291 measurements from the aircraft were selected using the same total water content threshold as for the model data  
292 ( $10^{-5}$  kg kg<sup>-1</sup>). Note that observational data only samples clouds along the 1D flight path, while model results include all  
293 grid points inside the selected clouds.

294 The vertical wind and cloud droplet and ice number concentrations are shown Fig. A2. The vertical wind speeds from  
295 the model and aircraft measurements agree well (Fig. A2a). The aircraft data exhibit less measurements of vertical  
296 wind speeds above 10 m s<sup>-1</sup> but that is expected since the aircraft was purposefully not flown in very high updraft  
297 speeds. The aircraft cloud droplet number concentration (CDNC), measured using a Droplet Measurement Technique  
298 (DMT) cloud droplet probe (which allows measurement of the cloud droplet size distribution for particles with  
299 diameters between 3 and 50 µm (Lloyd et al., 2020)), falls predominantly in the regions of parameter space most

300 highly populated by model data when plotted against vertical wind speed (Fig. A2b). Note that the simulated points in  
301 Figure A1b represent values of CDNC and updraft speed in all cloudy gridboxes, not just those at cloud base. The  
302 updraft speed is collocated with CDNC and therefore does not necessarily represent the updraft speed at which the  
303 cloud droplets were activated. The higher CDNC values exhibited in the model data may be due to the higher updraft  
304 speeds which were not measured by the aircraft. The observed ICNC was derived from measurements using the DMT  
305 Cloud Imaging Probes (CIP-15 and CIP-100, photodetector widths of 15 and 100  $\mu\text{m}$  respectively, both with 64  
306 detector elements) and the SPEC Stereoscopic optical array probe covering a size range from 10 to 6200  $\mu\text{m}$  using the  
307 SODA2 (System for OAP (optical array probe) Data Analysis) processing code (McFarquhar et al., 2017) to reconstruct  
308 ice particle images that are fully contained within the probe sample volume. Because of uncertainties in the optical  
309 array probe sample volume for very small images, only ice particle images greater than 100  $\mu\text{m}$  were included. The  
310 aircraft ICNC fall almost entirely within the range of the model values (Fig. A2c).

311

## 312 **3. Results**

### 313 **3.1. Effect of INP and INP parameterisation on outgoing radiation**

314 We first examine the effect of INP parameterisation on the TOA outgoing daytime (10:00-17:00 UTC) radiation relative  
315 to the simulation where the only source of primary ice production was through homogeneous freezing (NoINP). Ice  
316 crystals formed via homogeneous freezing and sedimented to lower levels, can initiate ice production via the Hallett-  
317 Mossop process once converted to snow or graupel. When contrasting the effect of different INP parameterisations in  
318 Sect 3.1-3.4, the Hallett-Mossop process was always active including in the NoINP simulation. As stated in Sect. 2.1.3,  
319 the radiation code is represented by the Suite Of Community RAdiative Transfer codes based on Edwards and Slingo  
320 (SOCRATES) (Edwards and Slingo, 1996; Manners et al., 2017), and responds to changes in cloud droplet number and  
321 cloud droplet, ice crystal and snow mass. The results detailed below relate to either the domain-wide properties or all  
322 in-cloud regions within the domain. This means that the results describe the direct and indirect changes, for example  
323 changes to the Hallett-Mossop ice production, occurring due to the presence of INP across all cloud present in the  
324 domain, including low-level liquid clouds, mixed-phase clouds without a convective anvil and very deep convective  
325 clouds with an anvil. The effects of INP parameterisation and SIP on convective anvils are discussed in Sect. 3.4.  
326

327 Domain-mean TOA outgoing radiation (daylight hours, shortwave plus longwave) is enhanced by the inclusion of INP  
328 in all cases (Fig. 4a). The enhancement in outgoing radiation varies between  $2.6 \text{ W m}^{-2}$  for D10 and  $20.8 \text{ W m}^{-2}$  for A13  
329 relative to the NoINP simulation. There is a variation of up to  $18.2 \text{ W m}^{-2}$  depending on the chosen representation of  
330 heterogeneous ice nucleation, which shows that the INP parameterisation can affect outgoing radiation as much as  
331 excluding or including heterogeneous freezing altogether. The difference in radiation between the NoINP and the  
332 simulations where INP are present are caused mainly by changes to outgoing shortwave radiation. The inclusion of INP  
333 enhances outgoing shortwave radiation by between  $5.3 \text{ W m}^{-2}$  for D10 and  $26.6 \text{ W m}^{-2}$  for A13 (Fig. A3a). Differences  
334 in outgoing longwave radiation are comparatively small ( $-2.7 \text{ W m}^{-2}$  for D10 to  $-5.8 \text{ W m}^{-2}$  for A13; Fig. A3b) due to  
335 similar cloud top heights between simulations of these thermodynamically limited clouds. Bear in mind that SIP was  
336 active (SIP\_active) in the simulations summarised in Fig. 4a, including in the NoINP simulation in which the Hallett-  
337 Mossop process can be initiated by settling ice-phase hydrometeors (either by settling homogeneously frozen ice  
338 crystals subsequently converted to snow or graupel, or by settling snow or graupel formed from homogeneously  
339 frozen ice crystals at upper cloud levels), indicating that these cloud systems are sensitive to INP even in the presence  
340 of SIP. This is consistent with a comparatively small change in TOA radiation when SIP is active relative to when it is  
341 inactive (Fig. 4b and 3c) (we discuss the role of SIP in more detail in Sect. 3.5).

342 The slope of the INP parameterisation (i.e. the dependence of INP number concentration on temperature) is a key  
343 determinant of the outgoing radiation. There is a statistically significant correlation between INP parameterisation  
344 slope and total TOA outgoing radiation ( $r^2 = 0.75$ ,  $p < 0.01$ ,  $n = 10$ ) (Fig. 4c). Changes in outgoing radiation due to the  
345 presence of INP are caused by a combination of changes to the outgoing radiation from cloudy regions, caused by  
346 changes in cloud structure and microphysical properties, and changes to domain cloud fraction, whose contributions  
347 to the total radiative difference are shown in Fig. 4a (left and centre). In order to appreciate the reasons for these  
348 trends, we will now take a closer look at the effect of INP on outgoing radiation from cloudy regions only, domain  
349 cloud fraction and cloud type.

### 350 **3.2. Effect of INP and INP parameterisation on outgoing radiation from cloudy regions**

351 Here we discuss the changes in daytime outgoing radiation from cloudy regions only due to INP parameterisation  
352 choice. Daytime outgoing radiation from cloudy regions increases due to INP for all but one INP parameterisation (Fig.  
353 5a). The absolute change in outgoing radiation from cloudy regions is between  $-0.8$  (D10) and  $+28.1$  (A13)  $\text{W m}^{-2}$ , and  
354 the larger values are a result of large increases in reflected shortwave (up to  $+37.2 \text{ W m}^{-2}$ ) and relatively moderate  
355 decreases in outgoing longwave radiation (up to  $-11.1 \text{ W m}^{-2}$ ) from cloudy regions. The above absolute changes in

356 outgoing radiation from cloudy regions contribute between  $-0.7$  and  $+11.4 \text{ W m}^{-2}$  to the domain-mean change in  
357 outgoing radiation due to the presence of INP (Fig. 4a, cloudy regions contribution).

358 The enhancement of outgoing radiation from cloudy regions due to INP is caused primarily by increases in cloud  
359 condensate relative to the NoINP simulation (Fig. 5b). When INP are included in a simulation, snow and cloud droplet  
360 water path are enhanced, causing increases in total cloud condensate, despite decreases (in all except A13) in ice  
361 crystal water path due to a reduction in ice crystal number and mass concentrations caused by a reduction in the  
362 availability of cloud droplets for homogeneous freezing. Snow, cloud droplets and ice crystals are the hydrometeors  
363 that affect outgoing radiation in CASIM and the combined water path of these three species is significantly positively  
364 correlated with cloud shortwave reflectivity ( $r^2 = 0.62$ ,  $p < 0.01$ ,  $n = 11$ ) (Fig. 5c). The mechanism for this INP induced  
365 increase in cloud condensate and consequently cloud shortwave reflectivity is as follows: When heterogeneous ice  
366 nucleation is active, liquid is consumed in the warmer regions of mixed-phase clouds because of increased  
367 heterogeneous ice nucleation (Fig. 2) and SIP (Fig. A4a). The resultant additional ice crystals in mixed-phase regions  
368 facilitate riming causing increases in snow and graupel (Fig. A4c, d), increasing snow water path and reflectivity in  
369 mixed-phase and ice clouds. At the same time, the enhanced production of relatively heavy snow and graupel  
370 increases precipitation which on melting to form rain below the freezing level and subsequent evaporation below 4  
371 km, reduces out-of-cloud temperature and increases relative humidity (Fig. A5a, b). This leads to increases in water  
372 path in low-level liquid clouds and thus an enhancement in their shortwave reflectivity.

373 However, increases in total cloud condensate alone cannot account for the differences in outgoing radiation from  
374 cloudy regions between simulations using different INP parameterisations, which are caused by a combination of  
375 cloud microphysical responses. We find that outgoing radiation from cloudy regions is significantly negatively  
376 correlated with INP parameterisation slope ( $r^2 = 0.63$ ,  $p < 0.01$ ,  $n = 10$ ) (Fig. 6a), i.e. simulations using a steep INP  
377 parameterisation have a higher outgoing radiation from cloudy regions. This result makes sense when we consider the  
378 relationships between INP parameterisation slope and a multitude of cloud microphysical properties affecting cloud  
379 radiative properties. In particular, a steep INP parameterisation results in a mixed-phase cloud region characterised by  
380 a higher ice crystal water path aloft ( $r^2 = 0.80$ ,  $p < 0.01$ ,  $n = 10$ ; Fig. 6b) and higher cloud droplet number  
381 concentrations at the bottom of the mixed-phase region ( $r^2 = 0.89$ ,  $p < 0.01$ ,  $n = 10$ ; Fig. 6c) when compared to  
382 shallower parameterisations. A steeper INP parameterisation slope allows increased transport of liquid to upper cloud  
383 levels due to lower rates of heterogeneous freezing at the mid-bottom region of the mixed-phase cloud (lower  
384 supercooling, Fig. 2) and SIP at high temperatures (Fig. A4a). This, combined with higher INP concentrations at low

385 temperatures (Fig. 2), increases ICNC at upper mixed-phase altitudes, as well as enhancing the lifetime of liquid cloud  
386 droplets at lower altitudes in the mixed-phase region when compared to shallower INP parameterisations.

### 387 **3.3. Effect of INP and INP parameterisation on cloud fraction**

388 Overall cloud fraction is increased by INP for all INP parameterisations and these increases in cloud fraction contribute  
389 about as much to changes in domain-mean daytime radiation as the changes in outgoing radiation from cloudy  
390 regions (Fig. 4a, cloud fraction contribution). Increases in domain cloud fraction due to INP are driven by cloud cover  
391 increases in the warm and mixed-phase regions of the cloud (~ 4 -6 km), offset somewhat by decreases in the cloud  
392 fraction due to reduced homogeneous freezing in the ~ 10 - 14 km regime (Fig. 7a). Cloud fraction increases at mid-  
393 levels occur because heterogeneous ice nucleation induces an increase in precipitation-sized particles (snow and  
394 graupel) which sediment to lower levels and moisten the atmosphere by evaporation (Fig. A5a, b). This increases new  
395 cloud formation and may prolong the lifetime of existing cloud cells. Additionally, increased droplet freezing and  
396 riming in the mixed-phase cloud region releases latent heat and invigorates cloud development with increases in  
397 updraft speed just above 4 km (Fig. A5c). The increased cloud fraction at mid-levels due to INP are partially offset by a  
398 reduced cloud fraction above 10 km (Fig. 7a) which is caused by an INP induced enhancement in freezing and riming in  
399 the mixed-phase region reducing moisture transport to the homogeneous freezing regime. The ability of  
400 heterogeneous freezing to reduce the availability of moisture for homogeneous freezing has been previously observed  
401 (e.g. Gasparini et al., 2020; van den Heever et al., 2006; Kärcher and U. Lohmann, 2003; Lohmann and Gasparini, 2017;  
402 Phillips et al., 2005, 2007; Storelvmo et al., 2013).

403 The effects of INP on the altitude profile of cloud fraction are strongest for shallow INP parameterisation slopes, which  
404 have a freezing profile most different to that of the NoINP simulation (Fig. 7a). At 5 km, the shallowest  
405 parameterisation (M92) causes the largest increase in cloud fraction, while the steepest parameterisation (A13)  
406 causes the smallest ( $r^2 = 0.83$ ,  $p < 0.05$ ,  $n = 5$ ). At 12 km, the order is reversed, and steep parameterisations exhibit the  
407 highest cloud fraction ( $r^2 = 0.94$ ,  $p < 0.01$ ,  $n = 5$ ). The largest cloud fraction-induced increases in outgoing radiation  
408 relative to the NoINP simulation (Fig. 4a) are seen in simulations using steeper INP parameterisations because these  
409 simulations exhibit higher cloud fractions at high altitudes (~12 km), translating into the higher total cloud fraction.  
410 These slope dependent changes in cloud fraction are explained by a relationship between cloud fraction and several  
411 microphysical properties affecting cloud fraction. For example, steeper INP parameterisations produce higher ICNC at  
412 the top of the mixed-phase region (10 km) as well as higher ratios of ice crystal mass to snow and graupel mass within  
413 the homogeneous freezing region (12 km) (Fig. 7b, c). A higher number and mass of ice crystals relative to those of

414 larger precipitation-sized hydrometeors with the steepest parameterisations results in lower frozen hydrometeor  
415 sedimentation, a longer cloud lifetime and a higher cloud fraction.

### 416 **3.4. Effect of INP and INP parameterisation on cirrus anvils**

417 Our results show that the INP parameterisation affects the properties and spatial extent of cirrus anvils. We define  
418 cirrus anvils to be regions where cloud is present above 9 km only (further details available in Sect. 2.1.4). 2D aerial  
419 images of cloud categorisation (Fig. 8a-f) show well-defined regions of anvil cloud (light blue - H) surrounding a large  
420 convective system containing clouds at a range of altitudes from <4 km to >9 km. There are clearly differences in the  
421 extent and position of cloud categories between simulations (Fig. 8a -f).

422 The presence of INP reduces convective anvil extent by between 2.1 and 4.1% of the domain area depending on the  
423 choice of INP parameterisation (Fig. 8 g), corresponding to a decrease in anvil cloud of between 22 and 53% relative to  
424 the NoINP simulation (not shown). The reduction in anvil extent in the presence of INP is caused by increased liquid  
425 consumption at all mixed-phase levels, due to heterogeneous freezing, enhanced SIP and increased graupel and snow  
426 production, reducing the availability of cloud droplets for homogeneous freezing (Fig. A4b), reducing ICNC at cloud-  
427 top, and reducing cloud anvil extent (Fig. 8g), in agreement with previous studies (e.g. Gasparini et al., 2020; van den  
428 Heever et al., 2006; Kärcher and U. Lohmann, 2003; Lohmann and Gasparini, 2017; Phillips et al., 2005, 2007;  
429 Storelvmo et al., 2013).

430 Reductions in anvil extent caused by INP are somewhat offset by the overall increases in cloud fraction across the  
431 domain (Fig. 8g). However, it is possible that the effect of INP and INP parameterisation choice on anvil cloud fraction,  
432 and the contribution of anvil cloud to overall cloud fraction and radiative changes, would become larger with a longer  
433 analysis period. This is because detrained convective anvils can persist longer in the atmosphere than the convective  
434 core that creates them (Luo and Rossow, 2004; Mace et al., 2006), but this is beyond the scope of the current study.

### 435 **3.5. Importance of secondary ice production**

436 It has been argued that the observed (or derived) primary ice particle production rate is unimportant for convective  
437 cloud properties when secondary ice production (SIP) is active (Fridlind et al., 2007; Heymsfield and Willis, 2014;  
438 Ladino et al., 2017; Lawson et al., 2015) because primary ice crystal concentrations are often overwhelmed by ice  
439 crystals formed via SIP (Field et al., 2017). However, the results shown in Fig. 4a (in which the simulations included  
440 SIP) do not support this argument. We find that the microphysical and radiative properties of the cloud field depend  
441 strongly on the properties of the INP even when SIP due to the Hallett-Mossop process occurs. Furthermore, the

442 effect of including SIP on daylight domain-mean outgoing radiation varies between  $-2.0 \text{ W m}^{-2}$  and  $+6.6 \text{ W m}^{-2}$  (Fig.  
443 4b), showing that the presence of the Hallett-Mossop process has a smaller effect than the INP parameterisation and  
444 that the sign and magnitude of this effect depends on the INP parameterisation. The mean effect on daylight domain-  
445 mean outgoing radiation of including INP is  $+9.8 \text{ W m}^{-2}$  whereas the mean effect of including SIP via the Hallett-  
446 Mossop process is  $+2.9 \text{ W m}^{-2}$ . Therefore, rather than primary ice being simply overwhelmed by SIP, it actually  
447 determines how SIP affects cloud microphysics. Other mechanisms of SIP have been proposed (Field et al., 2017;  
448 Korolev and Leisner, 2020; Lauber et al., 2018) and the impact of INP on cloud properties in the presence of these  
449 mechanisms, particularly those present at temperatures below  $10^\circ\text{C}$  such as droplet shattering (Lauber et al., 2018),  
450 should be tested in future but this was beyond the scope of the present study.

451 The effect of SIP on the radiative properties of the cloud field is dependent on INP parameterisation choice, both in  
452 magnitude and sign of change (Fig. 4b). SIP makes the clouds more reflective independent of the chosen  
453 parameterisation (Fig. 4b, cloudy regions contribution) due to increases in snow and cloud droplet water path. N12  
454 and A13 have the largest overall radiative response to SIP because changes to the radiative forcing from cloudy  
455 regions and cloud fraction contributions act to increase outgoing radiation (Fig. 4b). However, the cloud fraction  
456 response to SIP is opposite for C86, M92 and D10 meaning the cloudy regions and cloud fraction contributions act in  
457 opposite directions, reducing the total radiative forcing.

458 The different response of the domain cloud fraction to the presence of SIP is caused by substantial variation between  
459 simulations in the anvil cloud extent (Fig. 8h), from an increase of 10% ( $+0.9\%$  of the domain area) in N12 to a  
460 decrease of 40% ( $-3.6\%$  of the domain area) in M92 (Fig. 8h). These non-uniform changes in cloud fraction and  
461 outgoing radiation can be explained by differences in the response of cloud freezing profiles to SIP due to variations in  
462 INP parameterisation slope. For all INP parameterisations, SIP reduces the availability of liquid at higher altitudes. For  
463 shallower parameterisations such as M92 this causes a reduction in the amount of cloud droplets reaching the  
464 homogeneous freezing regime and thereby reduces ICNC and cloud anvil spatial extent. However, in simulations using  
465 a steep parameterisation, almost all available droplets are frozen heterogeneously before they reach the  
466 homogeneous regime (see reduced homogeneous ice production rates in N12 and A13 in Fig. A4b). Therefore, in  
467 simulations using a steeper parameterisation, such as N12, a reduction in liquid availability due to SIP occurs at the  
468 top of the heterogeneous freezing regime, reducing the availability of liquid for riming, causing a reduction in frozen  
469 hydrometeor size at high altitudes, a reduction in hydrometeor sedimentation and an increase in anvil extent. The  
470 effects of INP parameterisation slope and the Hallett-Mossop process on the simulated cloud field properties are

471 summarised in Fig. 9. Overall, our simulations show that INP parameterisation choice and slope is an important  
472 determinant of cloud field micro- and macrophysical properties, even when SIP is active, and that choice of INP  
473 parameterisation affects the cloud field response to SIP.

474

## 475 **4. Limitations of this modelling study**

476 The lack of consideration of ice and snow particle number by the SOCRATES radiation scheme is an important  
477 limitation of the results presented here. Changes to ICNC, without a co-occurring change in ice crystal mass  
478 concentrations, will not be reflected in modelled radiative fluxes. However, our results are still very relevant for  
479 climate model simulations as climate models do not typically account for ICNC in their radiation calculations and have  
480 frequently been shown to poorly represent ice crystal mass concentrations (Baran et al., 2014; Waliser et al., 2009).  
481 The SOCRATES representation of radiation with a dependence on ice mass is a more accurate and realistic  
482 representation of radiation than is seen in many climate models which often derive bulk optical properties using  
483 empirically derived deterministic relationships between ice particle size and environmental temperature and/or ice  
484 water content (Baran et al., 2014; Edwards et al., 2007; Fu et al., 1999; Gu et al., 2011). However, the effect of INP  
485 parameterisation on deep convective clouds radiative properties using a radiation code that considers ice particle  
486 number should be explored in future studies. The sensitivity of the cloud field to the chosen INP parameterisation and  
487 SIP indicates the importance of accurately representing ice water content in climate models and linking this ice water  
488 content to ice-nucleating particle type.

489 Another limitation of the SOCRATES radiation code is its lack of consideration of rain and graupel particles. The effects  
490 of these hydrometeors are expected to be less than that of ice, snow and cloud droplets as they precipitate faster and  
491 therefore have a shorter lifetime. Furthermore, the effect of graupel on the tropical longwave radiative effect has  
492 been found to be negligible and dwarfed by that of snow (Chen et al., 2018). The global radiative effect of rain has also  
493 been found to be small in the vast majority of cases even at high temporal and spatial resolution (Hill et al., 2018). The  
494 effect of the incorporation of these hydrometeors into radiative transfer parameterisations should however be tested  
495 in future studies.

496 The use of both aerosol-dependent (D10, N12, A13) and solely-temperature dependent (C86, M92) parameterisations  
497 in this study means that we have examined the radiative sensitivity of a complex cloud field to a larger variety of INP

498 parameterisations used in weather and climate models than if we had exclusively used parameterisations that  
499 consider aerosol concentration. However, this experimental design has limitations. For example, due to the lack of  
500 aerosol dependence of the C86 and M92 schemes a 'presumed' dust concentration is implicitly present in these two  
501 cases and remains uniform throughout the simulation period. The effect of INP parameterisation choice on convective  
502 cloud field properties should also be examined with the inclusion of aerosol scavenging but this was beyond the scope  
503 of this study. Aerosol scavenging would allow the aerosol number concentration to be reduced by cloud droplet  
504 activation and the number of dust particles within cloud droplets to be tracked and depleted when frozen  
505 heterogeneously. In the simulations presented here, the heterogeneous freezing rate is calculated using the  
506 interstitial aerosol number concentration and the ICNC of the gridbox in question meaning that ice crystals advected  
507 into the gridbox will reduce the heterogeneous nucleation rate even if they were frozen elsewhere in the domain.

508 Furthermore, while many cloud macro- and microphysical were correlated with INP parameterisation slope, the slope  
509 of the parameterisation at low temperatures for the A13 and N12 parameterisations can be flat because the  
510 parameterisations plateau once they reach the number concentration of dust represented in the model gridbox in  
511 question. This means that at high dust concentrations, the slope of the INP parameterisation correlates with the INP  
512 concentration at temperatures between -25 and -35°C (Figure 2). This means that the absolute number concentration  
513 of aerosols capable of nucleating ice is not decoupled from the INP parameterisation slope in some INP  
514 parameterisations and that some cloud responses attributed to changes in the INP parameterisation slope may have  
515 in fact been caused by the absolute INP number concentration at cold temperatures. The relative importance of the  
516 INP parameterisation slope and the absolute number concentration of aerosols capable of nucleating ice will be  
517 investigated in future work. However, whether the INP number concentration plateaus at cold temperatures is  
518 determined in part by the INP parameterisation slope, and correlations with INP parameterisation slope are evident at  
519 both warm and cold cloud altitudes indicating the importance of the INP parameterisation slope.

520 This study utilised our best estimate of ice production by the Hallett-Mossop process (Connolly et al., 2006; Hallett  
521 and Mossop, 1974; Mossop, 1985), the most well-studied SIP mechanism, to try and understand the effect of the  
522 process, as currently understood, on deep convective cloud properties. The work indicates that INP concentrations at  
523 all mixed phase temperatures can be important for cloud properties even in the presence of the Hallett-Mossop  
524 process, and that the impact of the Hallett-Mossop process depends on INP number concentrations. The dependence  
525 of the rate of ice production by the Hallett-Mossop process on INP number concentrations (Figure A5a) in particular  
526 highlights that the role of SIP in clouds may be dependent on INP. However, the rate of ice production by the Hallett-

527 Mossop process is very uncertain and other mechanisms of SIP have also been proposed (Field et al., 2017). We  
528 recommend that similar studies examining the effect of INP should be conducted with the inclusion of other proposed  
529 SIP mechanisms, particularly those that may be present at temperatures below  $-10^{\circ}\text{C}$ , such as droplet shattering  
530 (Lauber et al., 2018). However, this was beyond the scope of the present study due in part to the lack of quantification  
531 and parameterisations for these other mechanisms (Field et al., 2017). Future work will attempt to overcome the  
532 above caveats by using statistical emulation (Johnson et al., 2015b) to examine the interacting effects of dust number  
533 concentration, INP parameterisation slope and SIP in an idealised deep convective cloud.

534

## 535 **5. Conclusions**

536 We quantified the effect of INP parameterisation choice on the radiative properties of a deep convective cloud field  
537 using a regional model with advanced double-moment capabilities. The simulated domain exceeds  $600,000\text{ km}^2$  and  
538 therefore captures the effects of INP and INP parameterisation on a typical large, complex and heterogeneous  
539 convective cloud field. The presence of INP increases domain-mean daylight TOA outgoing radiation by between 2.6  
540 and  $20.8\text{ W m}^{-2}$  and the choice of INP parameterisation can have as large an effect on cloud field properties as the  
541 inclusion or exclusion of INP. These effects are evident even in the presence of SIP due to the Hallett-Mossop process,  
542 refuting the hypothesis that INP is irrelevant beyond a minimum concentration needed to initiate the Hallett-Mossop  
543 process (Crawford et al., 2012; Ladino et al., 2017; Phillips et al., 2007). An important caveat of this result is that other  
544 SIP mechanisms, such as droplet shattering (Ladino et al., 2017; Lauber et al., 2018), are not represented in our model  
545 simulations. Furthermore, the effects of SIP on the cloud field properties are strongly dependent on INP  
546 parameterisation choice. Both the magnitude and direction of change in cloud fraction and total outgoing radiation  
547 due to SIP varies according to INP parameterisation choice. Microphysical alterations to cloud properties are  
548 important contributors to radiative differences between simulations, in agreement with previous studies documenting  
549 the effect of aerosol-cloud interactions to the radiative forcing by deep convective clouds (Fan et al., 2013). For  
550 example, increasing cloud condensation nuclei concentrations, with no perturbations to INP, was shown to increase  
551 cloud albedo and cloud fraction, deepen clouds and increase TOA outgoing radiation by  $2\text{-}4\text{ W m}^{-2}$  (Fan et al., 2013).  
552 Here we find that even for the same aerosol and CCN concentrations, just altering the relationship between aerosol  
553 concentration and ice-nucleating ability can cause changes in daylight TOA outgoing radiation of up to  $18.2\text{ W m}^{-2}$  in  
554 our domain.

555 Our results indicate that the slope of the INP parameterisation with respect to temperature ( $d\log[\text{INP}]/dT$ ) is  
556 particularly important: Outgoing total radiation, along with many cloud field and microphysical properties affecting  
557 radiation, were significantly correlated with INP parameterisation slope. Best practise for accurately representing INP  
558 number concentrations based on current knowledge is to utilise parameterisations that link aerosol number and  
559 particle size to INP number concentration (e.g. D10, N12, A13) but that is not enough without also using a  
560 parameterisation in which the temperature dependence of the INP number concentrations matches reality; the  
561 largest differences in domain outgoing radiation existed in this study between simulations using aerosol dependent  
562 parameterisations (D10 and A13). These large variations in outgoing radiation between simulations using different  
563 aerosol dependent INP parameterisations justifies investment in observational campaigns to more effectively  
564 constrain the range of expected INP concentrations and parameterisation slopes in the Saharan dust outflow region,  
565 and other regions dominated by maritime deep convective activity.

566 The significance of the slope of the INP parameterisation indicates the potential importance of accounting for  
567 differences in aerosol composition in modelling studies. For example, INP derived from marine organics (Wilson et al.,  
568 2015) have a shallower slope than mineral dust INP (Atkinson et al., 2013; Niemand et al., 2012). Furthermore, real-  
569 world INP concentrations are known to have complex temperature dependencies with biological INP, such as soil  
570 borne fungus and plant related bacteria, making significant contributions at the warmest temperatures and mineral  
571 components being more important at lower temperatures (O'Sullivan et al., 2018). The work here suggests that the  
572 presence of biological INP might be to reduce liquid water transport to the upper levels of the cloud, reducing cirrus  
573 anvil extent, but also to increase low cloud fraction. Nevertheless, measurements in the eastern tropical Atlantic  
574 indicate that biological INP in the Saharan dust plumes is at most a minor contribution and that the parameterisations  
575 with shallow slope in Fig. 2 produce too much glaciation at warm temperatures.

576 The results presented here also present a new framework for understanding the effect of SIP by identifying a potential  
577 relationship between the effect of the Hallett-Mossop process and INP parameterisation slope. The significance of INP  
578 parameterisation slope also highlights the importance of characterising the INP concentration across the entirety of  
579 the mixed-phase temperature range rather than just at one temperature, or in a narrow temperature range, as is  
580 common in many field campaigns. For example, in the ICE-D field campaign, INP concentrations at temperatures  
581 above -7 and below -27°C were not measurable due to experimental and sampling constraints (Price et al., 2018).  
582 Measuring INP over the entire mixed-phase temperature range, throughout which deep convective clouds extend,  
583 conceivably covering around 10 orders of magnitude in INP number concentration, represents a major experimental

584 challenge. This issue is compounded by the fact that INP spectra cannot reliably be extrapolated to higher or lower  
585 temperatures since our underpinning physical understanding of what makes an effective nucleation site is lacking  
586 (Coluzza et al., 2017; Holden et al., 2019; Kanji et al., 2017). This work demonstrates the importance of solving these  
587 problems and measuring INP number concentrations across the entirety of the mixed-phase temperature spectrum,  
588 as has been demonstrated in previous work (e.g. Liu et al., 2018; Takeishi and Storelvmo, 2018).

#### 589 **Data Availability**

590 The datasets generated and analysed in this study are available from the corresponding author on reasonable request.

#### 591 **Author Contributions**

592 REH, AKM, KSC, PRF and BJM contributed to the design, development and direction of the study. REH and AKM set up  
593 and ran the UM-CASIM simulations presented in the paper. REH processed and analysed the UM-CASIM datasets.  
594 JMW, AAH and BJS built and maintained the Met-Office CASIM model used to run the simulations. ZC and RJC  
595 provided processed aircraft data from the ICE-D b933 flight and helped with the comparison of model data with  
596 aircraft measurements. REH, AKM, JMW, AAH, ZC, RJC, KSC, PRF and BJM edited the manuscript.

#### 597 **Competing interests**

598 The authors declare no competing interests.

#### 599 **Acknowledgements**

600 This work has been funded by European Research Council (ERC, grant 648661 MarineIce) and the Natural Environment  
601 Research Council (NERC, grant NE/M00340X/1). We acknowledge the use of Monsoon, a collaborative High  
602 Performance Computing facility funded by the Met Office and NERC. We acknowledge the use of JASMIN, the UK  
603 collaborative data analysis facility. We obtained moderate resolution imaging spectroradiometer (MODIS) Corrected  
604 Reflectance images from the NASA Worldview website (<https://worldview.earthdata.nasa.gov/>). Airborne  
605 measurements were obtained from the ICE-D field campaign and specifically the b933 flight on the 21<sup>st</sup> August 2015.  
606 The ICE-D campaign used the BAe-146-301 Atmospheric Research Aircraft which is operated by Directflight Ltd (now  
607 Airtask) and managed by the Facility for Airborne Atmospheric Measurements (FAAM). At the time of the  
608 measurements FAAM was a joint entity of NERC and the UK Met Office. We thank all the people involved in the ICE-D  
609 campaign.

893

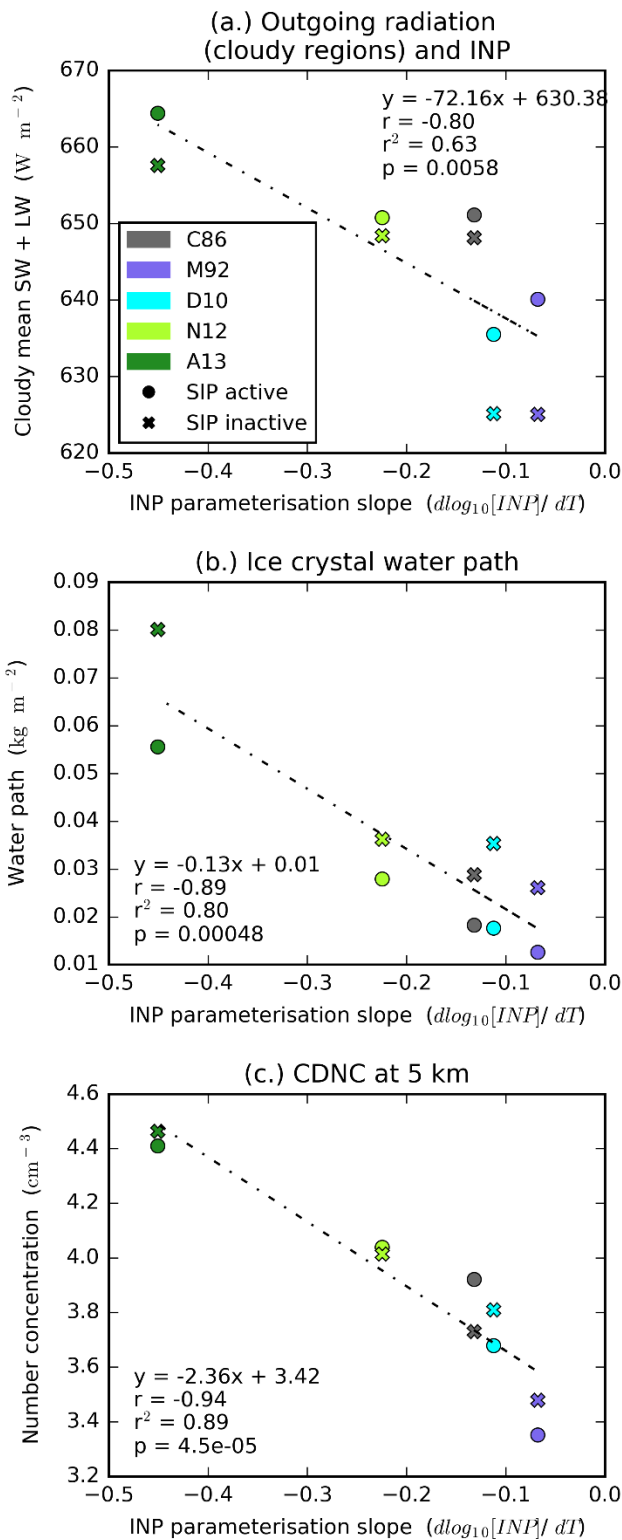

894 **Figure 4.** Effect of INP and secondary production on top of atmosphere (TOA) daytime (10:00-17:00 UTC) outgoing  
 895 radiation. Effect of INP parameterisation (a) and SIP (a representation of the Hallett-Mossop process) (b) on domain-  
 896 mean daytime TOA outgoing radiation and total domain-mean daytime TOA outgoing radiation plotted against INP  
 897 parameterisation slope (c). In (a), the change from the NoINP simulation is shown (INP - NoINP) with SIP active. In (b), the  
 898 change from SIP\_active to SIP\_inactive is shown (SIP\_active – SIP\_inactive). A positive value indicates more outgoing  
 899 radiation when INP or SIP are active. In (a) and (b), the relative contributions of changes in outgoing radiation from cloudy  
 900 regions (left) (i.e.  $\Delta Rad_{REFL}$  from Eq. (1)) and cloud fraction (middle) (i.e.  $\Delta Rad_{CF}$  from Eq. (2)) to the total radiative  
 901 forcing (right) (i.e.  $\Delta Rad_{s-r}$  from Eq. (5)) with simulation *s* referring to simulations with INP active in (a) and to the  
 902 SIP\_active simulations in (b) and simulation *r* referring to the NoINP simulation in (a) and to the SIP\_inactive simulations

903 in (b) are shown (calculation described in Sect. 2.1.3). In addition to the simulated values, a regression line (n=10) is  
 904 shown in (c) along with its associated statistical descriptors.

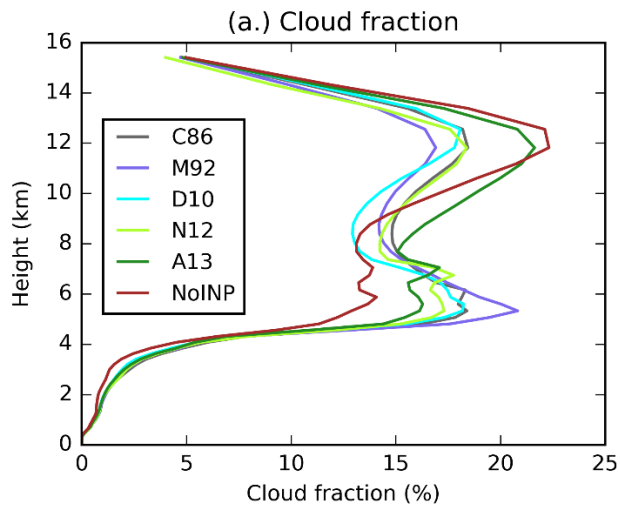

905  
 906 **Figure 5.** INP and TOA outgoing daytime (10:00-17:00 UTC) radiation from cloudy regions. Absolute change in outgoing  
 907 shortwave, longwave and total radiation from cloudy regions relative to the NoINP simulation (i.e.  $\Delta Rad_{cl}$  used in Eq.  
 908 (1)) (a), the percentage change in water path (WP) associated with snow (S), ice crystals (IC) and cloud droplets (CD)  
 909 relative to the NoINP simulation (b), and mean daytime outgoing shortwave from cloudy regions plotted against the sum

910 of S, IC and CD water paths (c). Note different scale for CD water path in (b). In addition to the simulated values, a  
 911 regression line (n=11) is shown in (c) along with its associated statistical descriptors.

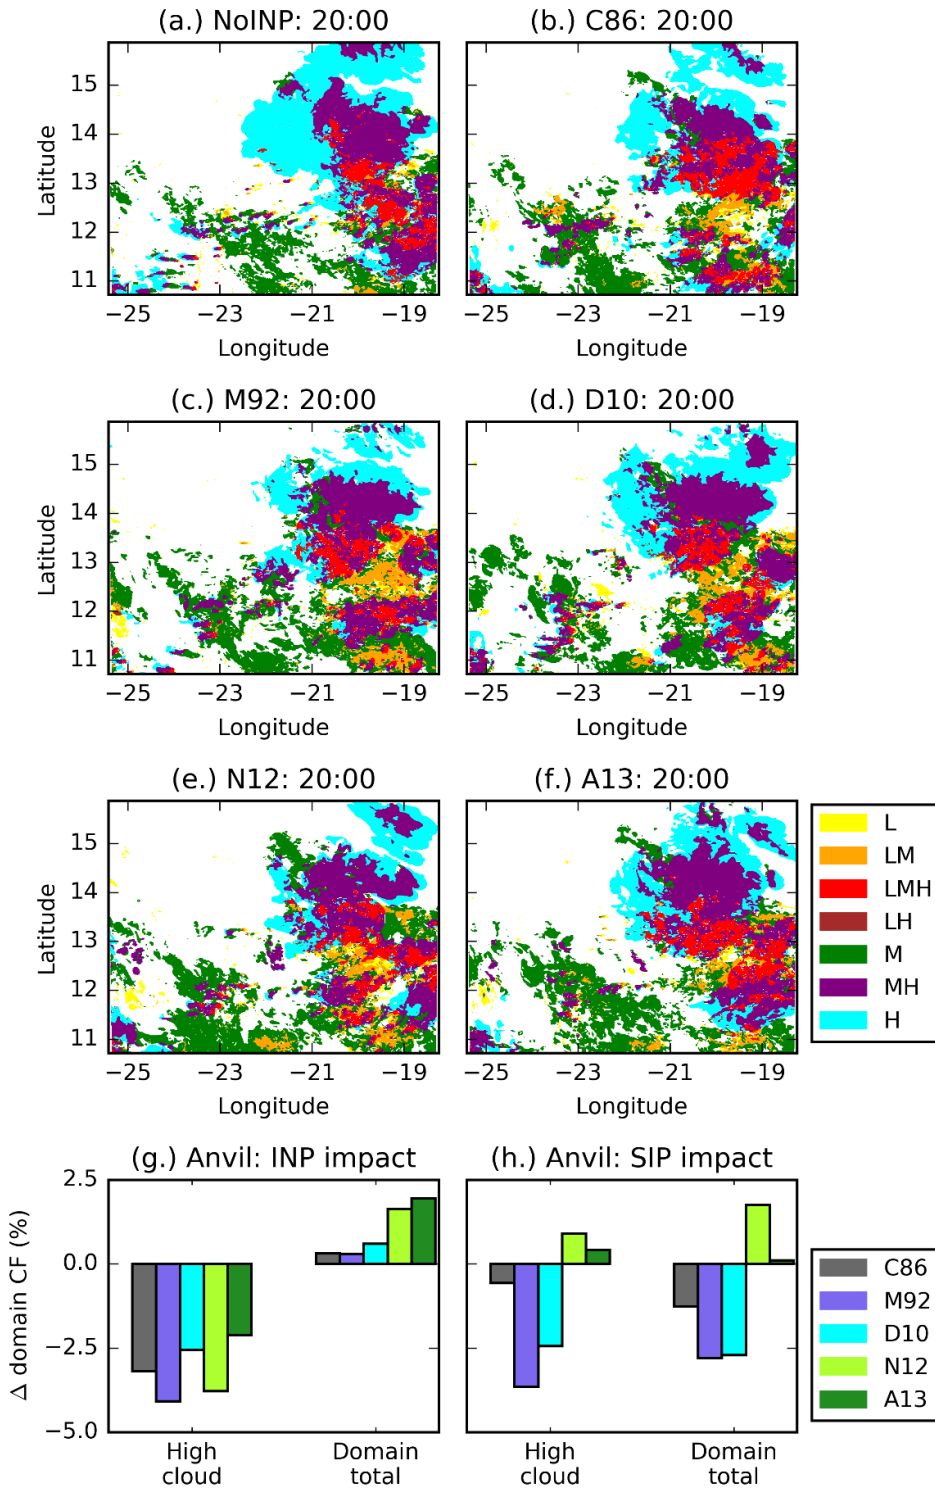

912  
 913 **Figure 6. Outgoing daytime (10:00-17:00 UTC) radiation from cloudy regions and INP parameterisation slope. Scatter plots**  
 914 **of INP parameterisation slope and total daytime outgoing radiation from cloudy regions (a), in-cloud mean ice crystal**  
 915 **(cloud ice only) water path (b), and in-cloud cloud droplet number concentrations at the start of the mixed-phase region**  
 916 **(5 km) (c). Also shown are the respective regression lines (n=10) and associated statistical descriptors.**

917

918 **Figure 7. Cloud fraction and INP parameterisation slope. Domain-mean cloud fraction profile (a), INP parameterisation**  
 919 **slope plotted against ice crystal number concentration at 10 km (b) and mass ratio of ice crystals to snow plus graupel at**  
 920 **12 km (c). Also shown in (b) and (c) are the respective regression lines (n=10) and associated statistical descriptors.**

921

922

923 **Figure 8. Vertical composition of cloud. 2D distribution of cloud type at 20:00 for all six SIP\_active simulations (a-f), as**  
 924 **well as anvil and domain cloud fraction change (10:00-24:00 UTC) due to INP (g) and due to SIP (h). Clouds are categorised**  
 925 **according to their altitude into low (L, <4 km), mid (M, 4-9 km) and high (H, >9 km) levels and mixed category columns if**  
 926 **cloud (containing more than  $10^{-5}$  kg kg $^{-1}$  condensed water from cloud droplets, ice crystals, snow and graupel) was present**  
 927 **in more than one of these levels (a more detailed description can be found in Sect. 2.1.4). A positive value in (g) or (h)**  
 928 **indicates higher values when INP (g) or SIP (h) are active.**

929

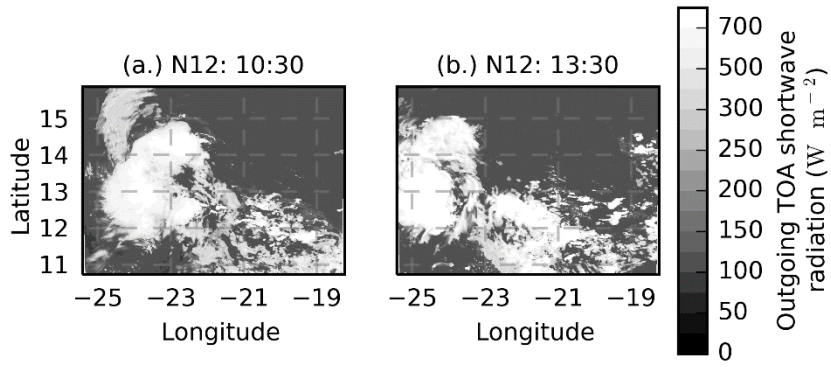

931

932 **Figure 9. Schematic of the main effects of INP parameterisation slope (i.e. a steep (a) or shallow (b) temperature**  
 933 **dependence of INP number concentrations).**

937

938 **Figure A1. The cloud field. Simulated top of atmosphere outgoing shortwave radiation for the N12 simulation at 10:30 (a)**

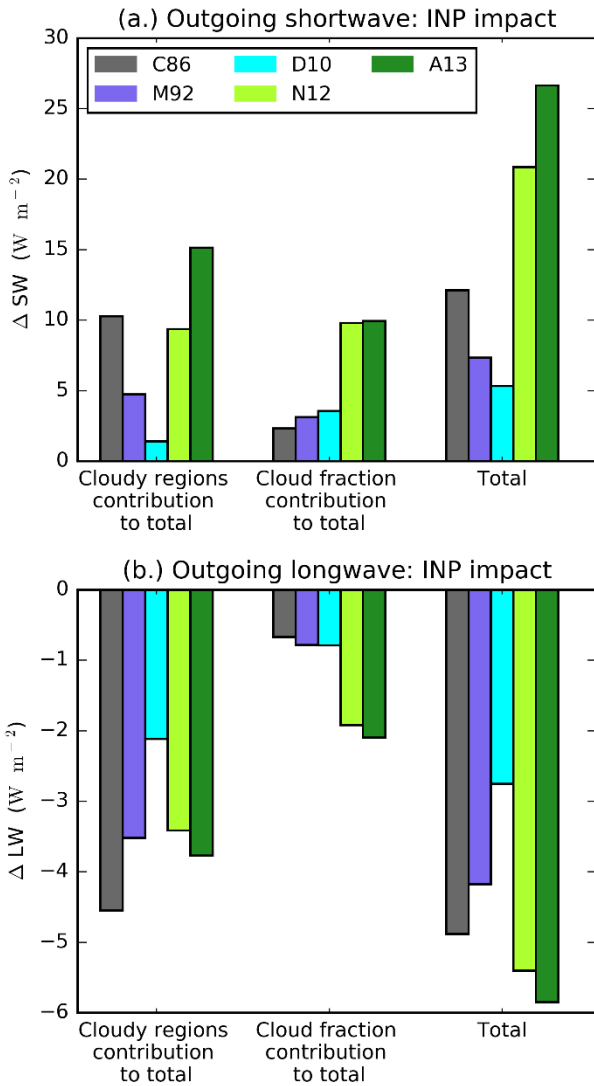

939 **and 13:30 (b).**

940

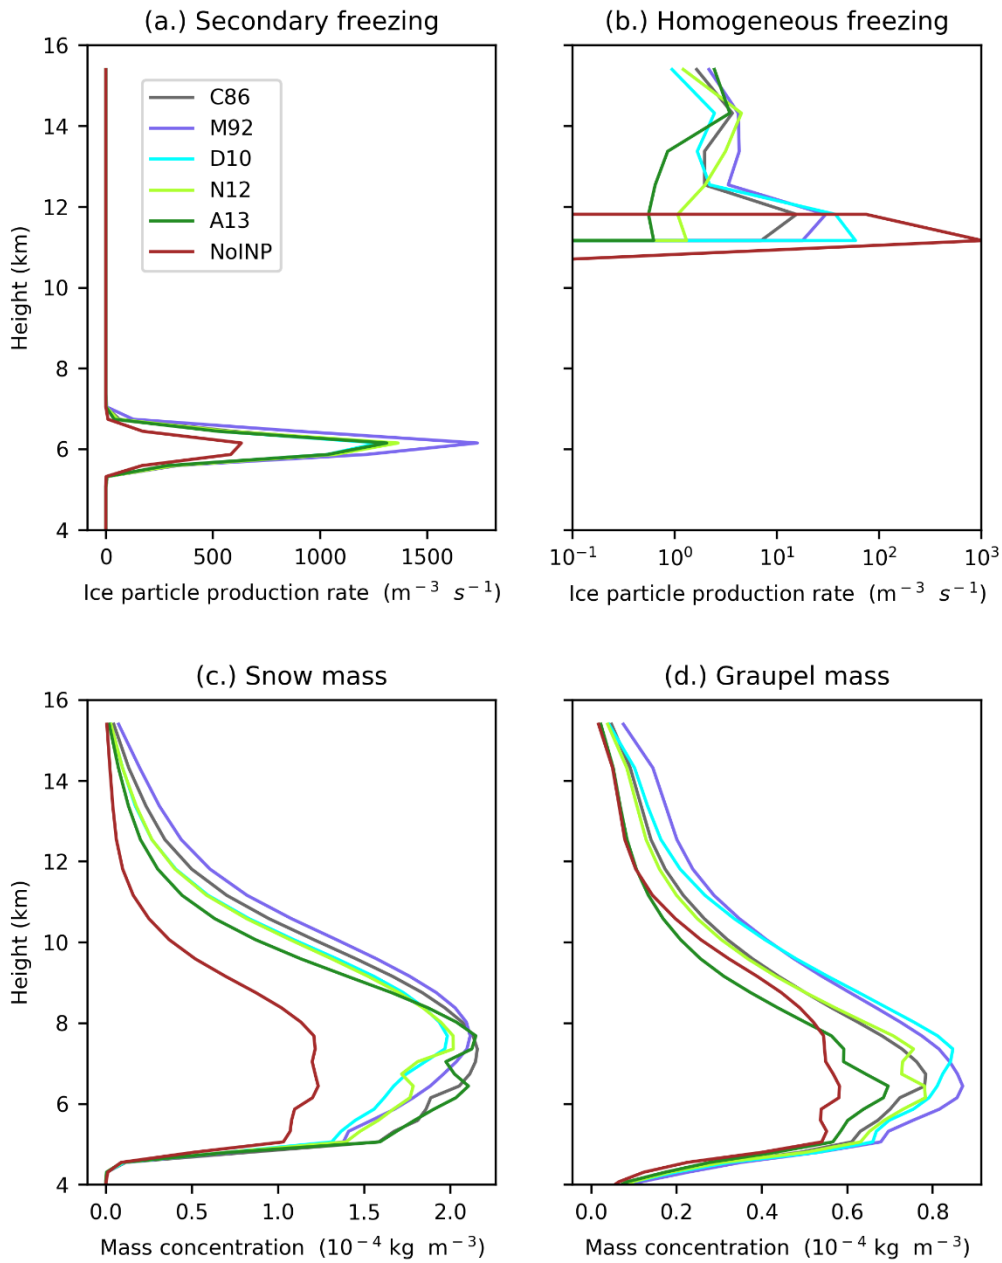

941 **Figure A2.** Comparison of observed conditions from the b933 ICED field campaign flight on the 21st August 2015 and the  
 942 modelled conditions. Vertical wind speed from the model and aircraft data (a), a 2D histogram of modelled vertical wind  
 943 against cloud droplet number concentration (CDNC) (b) and altitude plotted against ice crystal number concentration  
 944 (ICNC) (c) with the aircraft data overlaid. Modelled values are selected from clouds between 10 and 150  $\text{km}^2$  in size from  
 945 the N12 simulation.

947

948 **Figure A3. Effect of INP on domain-mean TOA outgoing daytime (10:00-17:00 UTC) shortwave and longwave radiation.**  
 949 **The change from the NoINP simulation is shown (INP - NoINP). A positive value indicates more outgoing radiation when**  
 950 **INP are present. The contributions of changes in outgoing radiation from cloudy regions (left) (i.e.  $\Delta Rad_{REFL}$  from Eq. (1))**  
 951 **and cloud fraction (middle) (i.e.  $\Delta Rad_{CF}$  from Eq. (2)) to the total radiative forcing (right) (i.e.  $\Delta Rad_{s-r}$  from Eq. (5)**  
 952 **with simulation s referring to the simulations with INP active and simulation r referring to the NoINP simulation) are also**  
 953 **shown (calculation described in Sect. 2.1.3).**

954

955

956 **Figure A4. Profiles of some microphysical properties of the simulated clouds. Mean in-cloud ice particle production rates**  
 957 **from secondary (b) and homogeneous (c) freezing, snow mass concentration (c) and graupel mass concentration (d).**
