#### Abstract

20 Surface ozone (O<sub>3</sub>) pollution during summer (June\_-August) over eastern China has become more severe in recent years, resulting in a co-occurrence of surface  $O_3$  and  $PM_{2.5}$  (particulate matter with aerodynamic diameter  $\leq 2.5 \ \mu m$  in the air) pollution-recently. However, the mechanisms regarding how the synoptic circulation pattern could might influence this compound pollution remains unclear. In This-this study, here-we applied the T-mode principal component analysis (T-25 PCA) method is used to objectively classify the occurrence of four synoptic weather patterns (SWPs) over eastern China, based on the geopotential heights at 500 hPa during summer (2015-2018). These Four four SWPs of over eastern China are were closely related to the western Pacific subtropical high (WPSH), exhibiting; significant intraseasonal and interannual variations. Based on the ground-level air quality and meteorological observations, remarkable spatial and temporal 30 disparities of surface O<sub>3</sub> and PM<sub>2.5</sub> pollution were also found under the impacts of the four SWPs. In Particularlyparticular, there were two SWPs that were sensitive to compound pollution (Type 1 and Type 2). Type 1 is was characterized by a stable WPSH ridge with its axis at about 22°N and the rain belt located in the south of the Yangtze River Delta (YRD)...); High temperature, moderate humidity and low precipitation occurred in the region from BTH to northern YRD (BTH -\_- NYRD), 35 resulting in a co-occurrence of O3 and PM2.5 pollution. Additionally, air pollutants can be transported by the prevailing southerly winds from southern plains and accumulated in the southern BTH, resulting in a worsen pollution. and Type 2 exhibits also exhibited a WPSH dominance (the ridge axis at  $\sim 25^{\circ}$ N), and <u>but with the rain belt</u> (over the YRD) in at a higher latitude compared with to Type 1. High temperature, medium-high humidity and low precipitation over the BTH were the 40 conducive factors related to the occurrence of the compound pollution events under Type 2. Furthermore, low boundary layer height (BLH) and high frequency of light-wind days (FLWD) could create favorable conditions for pollution maintenance. OverallIn general, synoptic weather patternsSWPs have played an important role as driving factors of surface O<sub>3</sub>-PM<sub>2.5</sub> compound pollution in a regional context. In addition to the impacts of local emissions, our results may provide 45 further insights regarding how regional environmental changes due to co-occurrence of high PM2.5 and high O3 level may be driven by the effects of meteorological factors. Overall, our findings demonstrate the important role played by synoptic weather patternsSWPs in driving regional surface

O<sub>3</sub>-PM<sub>2.5</sub> compound pollution, in addition to the large quantities of emissions, and may also provide insights into the regional co-occurring high <u>levels of both PM<sub>2.5</sub> and high O<sub>3</sub> level-via the effects of certain meteorological factors.</u>

al., 2019).

**Keywords:** <u>Synoptic synoptic</u> weather pattern, ozone, PM<sub>2.5</sub>, compound pollution, western Pacific subtropical high (WPSH)

#### 55 1. Introduction

In recent years, China has been experiencing serious air pollution problems <u>due-owing</u> to the <u>its</u> enormous emissions of polluting gases [e.g., sulfur dioxide, nitrogen dioxide (NO<sub>2</sub>), etc.] and aerosol particulates [e.g., particulate matter with aerodynamic diameter  $\leq 2.5$  (10) µm in the air PM<sub>2.5</sub> (PM<sub>10</sub>), etc.] associated with its rapid economic development, industrialization and urbanization, together with certain unfavorable meteorological conditions (Wang & and Chen, 2016; Zhang et al., 2014; Zhang et al., 2016). <u>In ParticularlyParticular</u>, atmospheric compound pollution has become serious (Li et al., 2019; Saikawa et al., 2017; Zhang et al., 2019a), especially for the economically developed and densely populated eastern urban agglomerations of China, such as the Beijing\_\_\_Tianjin\_\_\_Hebei (BTH), Yangtze River Delta (YRD) and Pearl River Delta (PRD) regions (Cai et al., 2017; Du et al., 2019; Ji et al., 2018; Li et al., 2020), exerting a severe threat in terms of public health, economy and society (Chen et al., 2019; Cohen et al., 2017; Day et al., 2017; Yim et

In general, a significant diurnal variation of PM<sub>2.5</sub> pollution <u>was has been</u> observed, possibly due to obvious the local emissions caused by industrial production and human activities for related to daily living (Amil et al., 2016; Liu et al., 2019a). <u>In Particularlyparticular</u>, the pollution level tends to be was higher during the morning and evening of a normal weekday, with a weakening weakened effect found in the afternoon, which may bepossibly caused by the co-effects of the boundary layer structure as well asand anthropogenic emissions. There was has also been a seasonal variation of PM<sub>2.5</sub> pollution <u>detected</u> across China, indicating a higher level of pollution in winter than summer (Ye et al., 2018; Zhang and Cao, 2015). The PM<sub>2.5</sub> level <u>of in</u> China showed a steady increase from 2004 to 2007, and has since stabilized (Ma et al., 2016); however, there are still frequent PM<sub>2.5</sub> pollution events in autumn and winter (Song et al., 2017; Yang et al., 2018; Ye et al., 2018; Zhang et al., 2014). In the past few years, the PM<sub>2.5</sub> concentration in China has decreased significantly as a result of measures introduced across the country that have reduced multi-pollutant emissions, adjusted the energy structure, and increased the supply of clean energy (Gui et al., 2019; Yang et al., 2020; Zhang et al., 2019b; Zhang et al., 2020). While PM<sub>2.5</sub> is still one of the dominant air pollutants across China, surface  $O_3$  pollution in summer has also gradually been risen to prominentprominence. Several studies have even indicated that O3 might have replace the role of  $PM_{2.5}$  as the primary air pollutant during summer (Li et al., 2019), which has caught the attention of researchers in recent years. For instance, Sun et al. (2016) showed that the observed summertime O<sub>3</sub> at Mt. Tai has increased significantly by 1.7 ppbv yr<sup>-1</sup> for the month of June and by 2.1 ppbv yr<sup>-1</sup> for the months of July-August during the period of 2003-to-2015. Furthermore, An-an increase of in the maximum daily 8-h average concentration of O<sub>3</sub> (MDA8 O<sub>3</sub>) at an annual-average rate of 4.6%, was reported by Fan et al. (2020), albeit with a decrease of <u>in</u> the frequency of PM<sub>2.5</sub> pollution.

90

80

85

The modulations of atmospheric circulation systems often lead to changes in meteorological elements, and to a large extent, thereby also affect the processes of pollutant formation, transmission and diffusion. Furthermore, And many studies have indicated that PM2.5 and O3 pollution are strongly correlated with local meteorological factors such as temperature, relative humidity (RH) and wind speed (WS) (Huang et al., 2016; Miao et al., 2015; Shu et al., 2019; Tai et al., 2010). Miao 95 et al. (2015) suggested that a low boundary layer height (BLH) and stable atmosphere would be an unfavorable condition for the dispersion of winter aerosol pollution over the BTH region. Zhang et al. (2017) found that the majority of  $O_3$  extremes occurred with daily maximum temperature (Tmax) of between 300 K and 320 K, minimum a RH (RHmin) of less than 40%, and a minimum WS of less than 3 m s<sup>-1</sup>, through the an analysis of extreme O<sub>3</sub> and PM<sub>2.5</sub> events from historical data (30 100 years for  $O_3$  and 10 years for  $PM_{2.5}$ ) in the United States. Furthermore, the number of annual extreme PM<sub>2.5</sub> days was highly positively correlated with the extreme RHmin/Tmax days, and the correlation coefficient between PM<sub>2.5</sub> and RHmin (Tmax) was highest in urban and suburban (rural) regions. Shi et al. (2020) studied the sensitivity of  $O_3$ -8h ( $O_3$  8-hour moving average) and  $PM_{2,5}$  associated with meteorological parameters. This Their study focused on the air pollution and meteorological 105 conditions between January and July, 2013, with a the results showing that temperature could have

<u>had</u> the greatest impact on the daily maximum O<sub>3</sub>-8h, while the PM<sub>2.5</sub> sensitivities <u>are-were</u> negatively (positively) correlated with temperature-,\_WS, and BLH (absolute humidity) in most regions of China. Miao et al. (2015) showed that RH <u>is-was</u> high when aerosol pollution occur<u>reds</u> in the BTH region. However, O<sub>3</sub> pollution in China is more frequent in summer, and the warm and

- 110 humid flow brought by the East Asian summer monsoon (EASM) induces a hot and humid condition over the summer. Zhao et al. (2019) investigated the RH of O<sub>3</sub> pollution in Shijiazhuang between 15 June and 14 July 2016, and found that the O<sub>3</sub> concentration was higher at moderate humidity (RH average during daytime from 10:00 to 17:00 LT was 40%–50%). Recently, Han et al. (2020) assessed the impacts of local and synoptic meteorological factors on the daily variability of surface
- O<sub>3</sub> over eastern China. This Their study revealed that the meteorological factors could explain ~46% of the daily variations of in summer surface O<sub>3</sub>, <u>In Particularlyparticular</u>, synoptic factors contributed to ~37% of the overall effects associated with the meteorological factors. Furthermore, six predominant synoptic weather patterns (SWPs) were identified by the self-organize organizing map, and related results indicated a weak eyelone cyclonic system and a southward prevailing wind
  inducing induced a the positive O<sub>3</sub> anomalies over the eastern China. The abovementioned studies indicates that the variations of meteorological factors play a non-negligible role in air pollution.

Therefore, classification of air pollution according to the-meteorological circulation has become particularly important, not least because of its worth when applied to air quality monitoring, forecasting and evaluation (Liu et al., 2019b; Ning et al., 2019; Yang et al., 2018; Zheng et al., 2015).

- 125 <u>Since 1990s, It-it</u> has become possible to objectively classify atmospheric circulation conditions using weather data such as <u>geopotential height (GH)</u>, sea level pressure, WS and temperature <u>since 1990s</u>, <u>so thatthus allowing</u> the <u>weather physical</u> mechanism of extreme weather <u>can-to</u> be better understood and analyzed. Compared with subjective weather classification, the objective approach has been widely used in air pollution research (Miao et al., 2017, 2019; Ning et
- 130 al., 2018). Miao et al. (2019), based on the daily 900 hPa GH fields during winter in Beijing, identified seven synoptic patterns using an objective approach, and found that the weak northwesterly prevailing winds and strong elevated thermal inversion layer, along with the local emissions of aerosols, play a decisive role in the formation of heavy pollution in Beijing; . The authors also noted also that the southerly prevailing winds can transport the pollutants emitted from

- 135 southern cities to Beijing. Zheng et al. (2015) studied the relationship between regional pollution and the patterns of large-scale atmospheric circulation over eastern China in October from 2001 to 2010 and identified six pollution types and three clean types. Specifically, weather patterns such as a uniform surface pressure field in eastern China or a steady straight westerly in the middle troposphere, particularly when at the rear of an anticyclone at 850 hPa, were found to be typically 140 responsible for heavy pollution events. Many studies have suggested a moderating modulating effect of the East Asian summer monsoon (EASM) and western Pacific subtropical high (WPSH) on air quality over China (Li et al., 2018; Yin et al., 2019; Zhao et al., 2010). In particular, Li et al. (2018) applied RegCM4-CHEM simulation to analyze the differences of in ozone between three strong and weak monsoon years, and found that the concentrations of O<sub>3</sub> over the central and eastern part of 145 China were higher in strong EASM years than that in weak EASM years. The anomalous highpressure system at 500 hPa, associated with downward dry, hot air and intense solar radiation can enhance the photochemical reactions to elevate the production of tropospheric O<sub>3</sub> (Gong and Liao, 2019; Yin et al., 2019). Furthermore, Zhao & Wang (2017) and Yin et al. (2019) noted that the positive GH anomalies at high latitudes tended to significantly weaken the cold-air advection from 150 the north-and resulting in locally high temperatures near the surface in northern China, while the WPSH can could transport sufficient water vapor to the YRD region and leading to a decrease in surface O<sub>3</sub>. In addition, different subregions can exhibit various distributions of pollutants, even with identical emission scenarios (Li et al., 2019; Saikawa et al., 2017; Zhang et al., 2019a). Also, it is still unclear how the distribution of pollution responds locally to large-scale atmospheric 155 circulation patterns. Due to a the variability of local meteorological conditions under the impacts of various synoptic weather types and the modulation of large-scale WPSH-movement of the WPSH (Li et al., 2018; Wang et al., 2019b; Zhao and Wang, 2017), the causes and consequences of meteorological factors for the formation of compound O<sub>3</sub>-PM<sub>2.5</sub> pollution could be complex. Overall, the mechanism by which the synoptic weather pattern (SWP) modulates the characteristics of  $O_3$ -PM<sub>2.5</sub> compound pollution has yet to be comprehensively described.
- 160

In this study, the SWPs corresponding to the co-occurrence of O<sub>3</sub>- and PM<sub>2.5</sub> pollution during summertime are-were analyzed, with a focusing on-the eastern China (104°-135°E, 17°-53°N). Then, the synoptic causes of O<sub>3</sub>—PM<sub>2.5</sub> compound pollution, as well as O<sub>3</sub>-only pollution, from the perspective of the objective classification of atmospheric circulation patterns, are-were revealed.

165 The findings are expected to provide a scientific reference for the monitoring, forecasting and evaluation of summertime air pollution in eastern China.

#### 2. Data and methods

The air quality data, including PM<sub>2.5</sub>, NO<sub>2</sub>, O<sub>3</sub>, and O<sub>3</sub>-8h, are from the national 24-h 170 continuous air quality observation published by the China Environmental Monitoring Station (http://www.cnemc.cn/). Summer hourly data (2015-2018) for 1174 stations- were retrieved form an observational network in eastern China (104°-135°E, 17°-53°N), which include the more prominent pollution areas in the eastern urban agglomeration, such as the BTH (113.5°-119.8°E, 36°-42.6°N), YRD (115.3°-122.6°E,27.2°-34.5°N), PRD (112.5°-113.7°E, 21.3°-23.1°N), 175 Guanzhong Plain [GZP (104.6°-112.2°E, 33.3°-36.8°N)], and Northeast Megalopolis [NEM (121.2°-131.0°E, 39.8°-47.3°N)] regions (the specific locations of stations and urban agglomerations are shown in Fig. 1a). Surface meteorological data, such as Tmax, precipitation, WS and RH from 611 meteorological observation stations, along with \_and radiosonde sounding data at 1400 Beijing time (BJT) from 63-64 stations and at 0800 BJT and 2000 BJT from 77 stations, in 180 eastern China, were obtained from the China National Meteorological Information Center of the China Meteorological Administration (http://data.cma.cn/site/index.html). The BLH was calculated according to the method given by Seidel et al. (2012) and Guo et al. (2016, 2019) (the detailed method can be seen in the supplementary materials), and the FLWD [frequency of light wind ( $\leq 2$ m s<sup>-1</sup>) days, which can be defined as the ratio between the number of the days with average daily 185 WS lower than 2 m s<sup>-1</sup> and the total days of each pattern], precipitation frequency (PF, which can be defined as the ratio of the number of the rainy days to the total days under each pattern), and MDA8 O<sub>3</sub> were also counted.

Additionally, for synoptic analysis of particulate matter and O<sub>3</sub> pollution in summer, we use the GH field at 500 hPa, wind, and specific humidity field at 850 hPa from the NCEP/NCAR (National Centers for Environmental Prediction/National Center for Atmospheric Research) daily reanalysis dataset on a 2.5° × 2.5° latitude/longitude grid during the study period. For further analysis of the modulation of the co-occurrence of O<sub>3</sub>-PM<sub>2.5</sub> pollution by the boundary layer structure in some local areas, we also used the BLH, uv-wind, vertical velocity, RH and temperature fields of the fifth generation European Centre for Medium-Range Weather Forecasts (ECMWF) reanalysis (ERA5), which has a high spatiotemporal resolution ( $0.25^{\circ} \times 0.25^{\circ}$ , hourly;

195 reanalysis (ERA5), which has a high spatiotemporal resolution (0.25° × 0.25°, 1 https://cds.climate.copernicus.eu/cdsapp#!/home).

<u>T-mode principal component analysis (The T-PCA)</u> is an objective mathematical computerbased method that can be used to classify the synoptic circulation patterns of regional gridded data in the troposphere at the lower level. Indeed, it is commonly regarded as the most promising weather

- 200 pattern classification method at present (Huth et al., 2008). Moreover, this approach has been widely used in the studies of aerosols and O<sub>3</sub> pollution-related atmospheric circulation in China (Miao et al., 2017, 2019; Ning et al., 2018, 2019). The T-PCA analysis module of the COST733 software (http://cost733.met.no/) developed by the European Scientific and Technical Research Cooperation, was used to classify the synoptic circulation pattern based on the 500 hPa GH field. The cost733class
- 205 program is a FORTRAN software package consists consisting of several modules for classification, evaluation and comparison of weather and circulation patterns. First, T-PCA classification of the cost733class performs the weather data are spatially standardization-standardized on weather data. Thenand split data into 10 subsets by T-PCA. Then and estimates the principal components (PCs) of weather information are estimated by applying based on singular value decomposition, and the PC
   210 score for each subset can be calculated after oblique rotation. Finally, the resultant subset with the
- <u>highest sum will be selected by</u>and compares <u>comparing</u> 10 subsets <u>based onaccording to</u> contingency tables, <u>and to select the subset with highest sum and return</u> its types <u>can be output as</u> well (Miao et al., 2017; Philipp et al., 2014)(<u>Miao et al. 2017</u>). To assess the performance of synoptic classification and determine the number of classes, the explained cluster variance (ECV)
   215 <u>is-was</u> selected in this study (Hoffmann & SchlüNzen, 2013; Ning et al., 2019; Philipp et al., 2014). The <u>dD</u>etailed information about the ECV <u>method</u> is provided in the supplementary <u>documentmaterial</u>.

Based on the Ambient Air Quality Standards (GB3095-2012) issued by the Ministry of Ecology and Environment of the People's Republic of China, O<sub>3</sub> (PM<sub>2.5</sub>) pollution occurs when the MDA8
 O<sub>3</sub> (PM<sub>2.5</sub> 24-h) concentration exceeds 160 (75) µg m<sup>-3</sup>. For a region, when haze occurs in-at more than 50% of the observed sites, the day can be defined as a haze day(Chen and Wang, 2015). In this

study, we characterized regional pollution days as occurring when the average values of more than 50% of sites in this region exceeded the aforementioned thresholds.used the average value of higher  $50\% O_3$ -and PM<sub>2.5</sub>-concentrations in each region as the regional values. The specific standard limits of each pollution level are according to their concentration limits based on the Technical Regulation on Ambient Air Quality Index (on trial) (HJ633-2012) issued by the Ministry of Ecology and Environment of the People's Republic of China (Table S1).

Finally, in order to make it clear in the analysis of different weather types of O3 and PM2.5 concentration change, we calculated the average distribution of O3 and PM2.5, as well as the 230 meteorological conditions for each type, and further calculated the anomalous distribution of these variables, (i.e., the average of  $O_3$  and  $PM_{2.5}$  and the average of the meteorological conditions under the respective patterns minus the average during summertime of  $2015-2018_{15}$  were given as well. The statistical significance was tested with a 0.05 confidence level via analysis of variance, which enabled us to distinguish the significant differences of spatial distribution characteristics between O<sub>3</sub> and PM<sub>2.5</sub> pollution under four SWPs.

235

#### 3. Results

250

225

#### 3.1 Spatial and temporal distribution of O<sub>3</sub> and PM<sub>2.5</sub> during summer 2015–2018

Figure 1 shows the summer averaged MDA8 O<sub>3</sub> and PM<sub>2.5</sub> concentrations at 1174 stations in 240 the eastern region of China for the period of 2015-2018. Among these stations, the MDA8 O3 concentration at most stations (795/1174) exceeds exceeded 100 µg m<sup>-3</sup>, of which 45 sites exceeded 160  $\mu$ g m<sup>-3</sup>. The highest O<sub>3</sub> pollution is was found in Zibo, Shandong, with a value of 181.5  $\mu$ g m<sup>-3</sup>. The averaged PM<sub>2.5</sub> at most sites (844/1174) wais below 35 µg m<sup>-3</sup>, while reaches it reached 62.6 µg m<sup>-3</sup> in Handan, Hebei Province. On the whole, the MDA8 O<sub>3</sub> and PM<sub>2.5</sub> in the BTH region and 245 its surrounding areas wais significantly higher than in other regions; and besides, the level of  $O_3$  in some urban clusters, such as the PRD, YRD, GZP and NEM regions, is was particularly higher than that of the surroundings, and thus, we focus on analyzing these key areas later in the paper.

Figures 2 and 3 respectively show the daily variations of in pollution levels of O<sub>3</sub> and PM<sub>2.5</sub>. In recent years, The the reduced visibility of haze days has weakens weakened the solar radiation reaching the ground and inhibits-inhibited photochemical reactions from generating  $O_3$  (Li et al.,

2019; Zhang et al., 2015), (Li et al., 2019; Zhang et al., 2015). as As a result, the concentration of O<sub>3</sub> has continues continued to increase with the mitigation of PM<sub>2.5</sub> pollution. During the study period, The the number of days of O<sub>3</sub> pollution in the BTH, YRD, PRD, GZP, and NEM regions were was 254, 133, 84, 165 and 96 days respectively, while the number of days of PM<sub>2.5</sub> pollution 255 were-was only 93, 8, 0, 2 and 1, of which compound pollution occurred on 76, 7, 0, 2, and 0 days according to Chinese standards (the asterisks in Fig. 3 indicate the co-occurred compound pollution events). China has implemented strict emission control policies and the effects were remarkable. China has implemented strict policies for emission control, and the effects of these policies were have been remarkable. However, despite a decrease in PM2.5 in the last five years, there was has also 260 been an increase in O<sub>3</sub>ozone pollution over China (Fan et al., 2020; Sun et al., 2016), although "double-high" pollution reported on the weather scale has been decreasedreduced. As the limit of PM2.5 concentration for pollution control is relatively loose in China, previous studies usually have tended to refer<del>red</del> to the interim target 1 (IT-1) of the World Health Organization (WHO) as the standard threshold. Our study pushed forward to the next stage, i.e., in which we used IT-2 of the 265 WHO's IT-2 threshold (24-h average concentration of PM<sub>2.5</sub> is of 35  $\mu$ g m<sup>-3</sup>) as our target limit to count the number of compound pollution days across each region. Based on this target, the number of pollution days for four SWPsthe five urban clusters were was 194, 52, 16, 47, and 20, respectively (Fig. 3). These results indicateed a severe situation of compound pollution that, despite PM<sub>2.5</sub> reductions, compound pollution events remain serious and deserve of is still deserved a public 270 attention. Thus, the situation of compound pollution is still serious and deserves attention. Overall, the O<sub>3</sub> and PM<sub>2.5</sub> concentrations in eastern China exhibits distinct intraseasonal and interannual variations, indicating that, aside from the changes in emission sources (because it is considered that inter-seasonal and short-term changes in emission sources are not significant), it-they may also be regulated by meteorological conditions, which is further analyzed below.

275

#### 3.2 Objective classification of large-scale synoptic circulation patterns in summer

To analyze the effect of meteorological conditions on the changes <u>of-in</u>  $O_3$  and  $PM_{2.5}$  concentrations, it is necessary to statistically analyze the large-scale weather circulation situation in summer. Existing studies have shown that the WPSH (500 hPa GH field with obvious anticyclonic

characteristics, and downward flow around the center) in summer prominently regulates the weather and climate of East Asia (Lu, 2002), owing to its various varying location, shape and intensity (Ding, 1994). A-ILow-level southerly monsoonal flow formed-forming at the periphery of the an anomalously enhanced WPSH, along with the ean transportation of warm and humid air from the ocean to East Asia, which might also be responsible for the asymmetric spatial distribution of ground-level O<sub>3</sub> in response to an enhanced WPSH for ground-level O<sub>3</sub>[,-i.e., a decrease in southern China but an increase over northern China (Zhao & Wang, 2017)].

Therefore, we used the T-PCA method to objectively classify the weather circulation of the 500-hPa GH field in the summers of 2015–2018, from which we ultimatelyand finally obtained four SWPs related to the movement and development of the WPSH. The location of western ridge point 290 and northern boundary of the WPSH at 500 hPa in Type 1 were is located at around 120°E and 30°N, respectively (Fig. 4a and Table S2). The southwestern flow of this WPSH could was able to transport water vapor to the YRD region, resulting in a southwestward prevailing wind across the YRD region and westward flow from the north of the WPSH forming a convergence area at 850 hPa. These conditions were also associated with high temperature and humidity during the summer with in the 295 Meiyu season, which Meiyu season is a climate phenomenon with characterized by continuous cloudy and rainy days that generally occurring occurs during June and July every year in across the middle and lower reaches of the Yangtze river, Taiwan of in China, central/southern Japan, and southern Korea. For Type 2, the westerly trough could was able to deepen as the WPSH shifts shifted northwards slightly from Type1 or retreated southeast from Type 3 (Fig. 4b). The 300 southwestsoutherly wind from the South China Seaocean could interact might have combined with the southerly wind in the northern eastern periphery of the WPSH. As a result, the sea land interaction could interact with southerly winds prevailed across the southeastern region across China, while northern China could bewas mainly controlled by the westerly trough. In compared comparison with to Type 2, Type 3 was characterized by presents the boundary of the WPSH being 305 at in-a higher latitude, with a westward extension (Fig. 4c), disintegrating a closed high-pressure monomer along the eastern coast of China, and the main body of the WPSH remains-remained over the ocean (Figs. 4c and S4). This has led to a condition that was completely controlled by the monomer of the WPSH over the YRD region, resulting ine hot and dry weather at the end the rainy season at the beginning of mid-summer. Figure. 4d indicated indicates that the location of the WPSH
 monomer was more to the western and northern compared with respect tounder the other SWPs,
 thus controlling the northern China for a long time; the western ridge point was located at around 95°E and the northern boundary was at around 40°N.

Figure 5 presents the daily and annual variations of the SWPs in the summers of 2015–2018. Usually, The the advancement of the WPSH in eastern China occurs in June and July, while its 315 gradual withdrawal of the WPSH occurs mainly in August, ; and in this respect, Type 1 and Type 2 represented normal WPSH characteristics during early and late summer. Type 3 and Type 4, however, eould reflected a split of the WPSH, which mainly occurs occurred in late summer. Consequently, there were 167, 117, 52 and 32 days for the Type 1, Type 2, Type 3 and Type 4 over the study period, respectively. Since the WPSH's movement is generally affected by the weather phenomenon 320 phenomena of its surrounding climatic systems (such as typhoons, the Tibetan high, etc.) (Ge et al., 2019; Liu and You, 2020; Shu et al., 2016; Wang et al., 2019), it could may have resulted in a shortterm southward retreat during the advancement of the WPSH (e.g., around 10 August 2018) and a short-term northward advancement during its process of retreat (e.g., 21 and 29 August 2016). For instance, tropical storm NEPARTAK generated at 0000 UTC (0800 BJT) 3 July 2016 over the 325 western North Pacific and upgraded to a super typhoon at 1200 UTC (2000 BJT) 5 July (Fig. S5; see also Su et al., 2017). Due to the rapid movement of NEPARTAK to the northwest, the WPSH quickly decomposed a monomer and moved north. With the strengthening and landing of the typhoon, the monomer gradually collapsed. The SWP also underwent a transition from Type 2 to Type 4, and then to Type 1 (Figs. 4 and S5). In general, the WPSH could is able to represent the 330 evidences of intra-seasonal and interannual changes over China, which will inevitably modulate the weather, as well as climatic and environmental changes in eastern China.

#### 3.3 O<sub>3</sub> and PM<sub>2.5</sub> pollution characteristics under <u>the</u> four SWPs

#### 3.3.1 Spatial characteristics

335

We calculated the averaged (Fig.  $\underline{S2S6}$ ) and anomalous (Fig. 6) spatial distributions of the MDA8 of O<sub>3</sub> and PM<sub>2.5</sub> under the four SWPs. The O<sub>3</sub> concentration is-was relatively high in the area north of the Yangtze River under Type 1, and the high values of the MDA8 O<sub>3</sub> are were mainly

concentrated in the North China Plain (NCP) region, with a total of 100 stations surpassing 160 μg m<sup>-3</sup>. Type 2 O<sub>3</sub> pollution is was slightly weaker than that for Type 1, and the MDA8 O<sub>3</sub> at the 72
sites exceeds exceeded 160 μg m<sup>-3</sup>. The O<sub>3</sub> high-value areas lie lay mainly in the NCP, GZP and YRD regions under Type 4, and there are were 37 stations with concentrations larger than 160 μg m<sup>-3</sup>. Of the four SWPs, the lowest overall MDA8 O<sub>3</sub> occurs occurred under Type 3, with only one site exceeding 160 μg m<sup>-3</sup> (Figs. S2aS6a-d). It is was also found that the regions that experiencing experienced significant positive deviations of the MDA8 O<sub>3</sub> from the summer mean are were as follows: the BTH, YRD and NEM regions under Type 1, the BTH and GZP regions under Type 2, the middle central of the YRD and PRD regions under Type 3, and the YRD, GZP and PRD regions under Type 4 (Figs. 6a\_d).

Analogously, Figs. 6e\_h shows the anomaly and significance of difference of in PM<sub>2.5</sub> under the four weather types, presented as positive anomalies in the south of the BTH and YRD regions under Type 1, in the BTH, GZP and PRD regions under Type 2, and in the GZP and PRD regions under Type 4. Due to the obvious seasonal variations of PM<sub>2.5</sub> concentration (higher in winter and lower in summer) (Liu et al., 2019a; Miao et al., 2015), no site exceeds exceeded 75 µg m<sup>-3</sup> for the averaged PM<sub>2.5</sub> concentration. Even so, the level of PM<sub>2.5</sub> in the BTH region is was still significantly higher under the four types than that for the other urban agglomerations (Figs. S2eS6e\_-h).

355

350

#### 3.3.2 Pollution pattern differences in key areas

Air pollution is principally found in dense urban areas such as the BTH and YRD regions (Gui et al., 2019; Han et al., 2019), so we took the BTH, PRD, YRD, GZP and NEM regions in the eastern region as key areas, counted the daily anomalies and average variation of O<sub>3</sub> and PM<sub>2.5</sub> in each key
region under the different weather patterns (Figs. 7 and S5S7), and calculated the over-limit ratio in those key regions via the 'stations × days' statistics (see Table 1). The diurnal variation of O<sub>3</sub> is was more obvious, peaking at about 15:00 (Beijing time)BJT, while contrasting diurnal variations of PM<sub>2.5</sub> are were given found for different regions. According to Figure Fig. 7 and Table 1, the following characteristics can could be identified for different urban clusters: (1) in the BTH region, the O<sub>3</sub> concentrations of Type 1 and Type 2 is were relatively high, with their over-standard-limit rates reaching 47.1% and 54.2%, and the PM<sub>2.5</sub> pollution rates of Type 2 and Type 1 reaching 18.8%

and 16.3%, respectively; (2) in the PRD region, the over-standard limit rates and concentrations of O<sub>3</sub> and PM<sub>2.5</sub> is-were similar under the four SWPs; (3) in the YRD region, the O<sub>3</sub> pollution overlimit ratio-rate presents as Type 1 > Type 4 > Type 2 > Type 3, PM<sub>2.5</sub> pollution largely appears appeared in-under Type 1, and both O<sub>3</sub> and PM<sub>2.5</sub> in-under Type 1 are-were higher than those in-for the other types; (4) in the GZP region, the O<sub>3</sub> pollution frequency is-was higher in-under Type 2 and Type 4, and PM<sub>2.5</sub> pollution occurs-occurred more frequently in-under Type 2; and (5) in the NEM region, O<sub>3</sub> pollution is-was always found in-under Type 1, Type 2 and Type 4, but the over-standard limit rate is-was no more than 15% and PM<sub>2.5</sub> pollution in-under Type 1 is-was more than in-under Type 2.

In summary, Type 1 is-was\_prone to the formation of compound pollution of O<sub>3</sub>-PM<sub>2.5</sub> compound pollution (that is, when the ground MDA8 O<sub>3</sub> concentration exceeds exceeded 160 μg m<sup>-3</sup>, the PM<sub>2.5</sub> concentration also exceeds exceeded 75 μg m<sup>-3</sup>) in the area from the BTH to northern YRD regions (Fig. S11S6), which can be denoted as "BTH—-NYRD O<sub>3</sub>-PM<sub>2.5</sub> compound pollution". In detail, Figure S128 shows the number and probability of occurrence of compound pollution days inat each site in summer during 2015-2018, indicating that a high occurrence probability (maximum values ean-approaching 46.7%) of compound pollution appeared inover the Northern China plainNCP (to the north of 32°N)r, and Aboutthat approximately 55.6% of compound pollution occurrence days at all sites occurred under Type 1. Similarly, Type 2 can also be denoted as "BTH O<sub>3</sub>--PM<sub>2.5</sub> compound pollution" with compound pollution occurrence days accounting for 33.8%, Type 3 as "BTH—YRD—PRD O<sub>3</sub>-only pollution", and Type 4 as "BTH—GZP—YRD— PRD O<sub>3</sub>-only pollution" (Fig.12).

#### 3.4 Analysis of potential meteorological factors

370

375

Therefore, t<u>T</u>o explore the meteorological causes of O<sub>3</sub> and PM<sub>2.5</sub> pollution, we analyzed the distribution of the average and anomalies for Tmax, RH, PF, BLH and FLWD under <u>the</u> four SWPs (Figs. <u>S6S9</u>, <u>S7S10</u>, 8 and 9). Under the influence of the EASM, over 80% of the stations experience high temperatures (Tmax > 27°C) in-under each SWP, although the anomaly of Tmax in-under Type 1 (early summer) presents-presented as negative (Fig. 8a). Type 1 is-was characterized by humid condition in the southern area and dry conditions in the northern region owing to an extensive

southwestern flow of the WPSH, resulting in a rain belt found in southeastern coastal area<u>s</u> such as <u>the</u> PRD and YRD regions. Type 2 <u>is-was</u> associated with meridional flow and dry and wet anomalies in northern China, resulting in a rain band <u>locating-located at-over</u> the central areas of between <u>the</u> BTH and YRD regions <u>due-owing</u> to the northern advancement of the WPSH compared with Type 1. Furthermore, there <u>is-was a greaterhigher</u> RH for most of the study sites under Type 3 and Type 4, possibly <u>a resultbecause</u> of the shifted rain belt in the BTH and NEM regions under Type 3 once the northern boundary of the WPSH <u>reaching-reachedat</u> 37.5°N, and an occurrence of heavy precipitation across the western PRD region as well as central areas <del>of</del> between <u>the</u> BTH and YRD regions under Type 4 (Fig. <u>\$6\$9</u>).

405 In terms of their anomalous spatial distributions, the positive anomalies of Tmax are-were located in the southern region of-under Type 3 and most of the eastern region of-under Type 4; and since Type 1 always appeareds in early summer, most areas are were negative (Figs. 8a-d). For RH, Types 2, 3 and 4 are-were negative for the south and positive for in the north, while the opposite was true under Type 1 is opposite (Figs. 8e-h). PF is-was characterized by positive anomalies in the area 410 south of the Yangtze River under Type 1, in the YRD region under Type 2, in the BTH and NEM regions under Type 3, and in the area between the BTH and YRD regions under Type 4 (Figs. 8i-l). As can be seen from Fig. 9, when the BLH at 14:00 (BJT) has had a positive anomaly, on the contrary FLWD has had a negative anomaly (e.g., BTH in Type 1), which indicates that the higher BLH, and the lower FLWD, the more conducive it was to the diffusion of pollutants, ; otherwise and conversely, 415 a lower BLH and higher FLWD (such as BTH in-under Type 2) do-did not support the diffusion of pollutants. After further inspection of Fig. <u>\$7\$10</u>, we found that the YRD region in-udner Type 1, the YRD in-under Type 2, the BTH and PRD regions in-under Type 3 and 4 have had shallow BLHs and high FLWDs, which is was detrimental to the transportation of pollution in these areas, thus corresponding to high levels of pollution under these weather patterns. But However, in some higher 420 BLH areas, there were was also more serious pollution in some higher BLH areas, such as in the

BTH region under Type 1, which we will discuss next.

#### 3.5 Potential implications of NO<sub>2</sub>

400

The Photochemical production of O<sub>3</sub> mainly involve emissions of volatile

425 organic compounds VOCs and NOx from anthropogenic, biogenic and biomass burning sources (Deng et al., 2019; Gvozdić et al., 2011; Sillman, 2002). The photochemical reaction of NO, NO<sub>2</sub>, and  $O_3$  in the troposphere forms a closed system (Yu et al., 2020), and this photochemical cycle of  $NO_x$  and  $O_3$  is the basis of photochemical processes in the troposphere. Oxidant (Ox,  $Ox = O_3 + O_3 +$ NO<sub>2</sub>), a conservative quantity over short time scales, is defined as a parameter to evaluate the 430 photochemical processes and, due to the unstable nature of NO, it can quickly react with the equivalent amount of O3 to generate NO2 (Kley et al., 1994). In order to compare the photochemical reaction efficiency of the five urban clusters under the different SWPs, Figure-Fig. 10 can presents the daily variations of NO<sub>2</sub> and Ox. These includeAs we can see, the daily variations of NO<sub>2</sub> showing showed two peaks during a day, including a first peak at-in the morning and an second peak 435 associated with traffic emissions in the evening (Xie et al., 2016; Yu et al., 2020). As we found the lowest point of NO<sub>2</sub> at 15:00 (BJT), and NO<sub>2</sub> can be photolyzed to produce O<sub>3</sub> during the day, this studywe assumed that this particular time was the peak time for O<sub>3</sub> formation ozone across the study areas. As NO<sub>2</sub> was is consumed through a photochemical reaction with the involvement of other precursors to produce a large amount of O<sub>3</sub>, Ox could can form a peak during in the afternoon. In 440 particular, abundant sunlight in summer is beneficial to the photochemical reaction process, but since most parts of eastern China are in-under a subtropical climate with the same period of rain and heat, the existence of the rainy season will inevitably inhibit the summertime photochemical process. Under the different SWPs, the photochemical reaction over each area has bore an obvious relationship with the rain belt. For example, the rainy season in the BTH and NEM areas mainly 445 occurs occurred in-under Type 3, and the Ox of Type 3 in this area is-was significantly lower than under the other SWPs.

#### 4. Discussion

In the last section, we have discussed how the SWPs and local meteorological factors modify 450 <u>modified the summertime</u> O<sub>3</sub> and PM<sub>2.5</sub> pollution. However, how <u>does\_did</u> the boundary layer structure interact with the co-occurrence <u>of</u> O<sub>3</sub>-<u>and</u> PM<sub>2.5</sub> pollution? In order tTo address this question, we conducted <u>a-some</u> further analysis <u>as follows</u>. As mentioned, <u>the</u> co-occurrence of O<sub>3</sub> and PM<sub>2.5</sub> pollution mainly <u>occurs-took place</u> in the BTH—NYRD <u>areas</u> under Type 1 and <u>in the</u> BTH area under Type 2. Lower WS and its negative anomalies at a lower boundary layer over the

- 455 BTH—NYRD under Type 1 and over <u>the BTH area</u> under Type 2, may not <u>have</u> enhanced the diffusion of air pollutants (Fig. <u>\$8\$11</u>). In contrast, <u>the moderate RH and its negative anomalies</u> might <u>have</u> favored the formation of compound pollution. Downward vertical motion and negative anomalies <u>could-might</u> also <u>have</u> stabilized the atmospheric characteristic of <u>the</u> boundary layer (Fig. <u>\$9\$12</u>). Furthermore, we summarized <u>the</u> boundary layer structure, precipitation, and ground-level
- wind flow across the BTH region. Based on the characteristics, we separately defined Type 1 and Type 2 into clean (both the concentrations of the both O<sub>3</sub> and PM<sub>2.5</sub> are were less than polluted level of pollution) and compound pollution periods (Figs. 11 and S10S13-S11S14). In Particularlyparticular, Type 1 has had a significantly warmer temperatures over the boundary layer during the compound pollution periods of the BTH region, than that of as compared with the clean periods. The daytime BLH under the compound pollution condition was also higher than that of under the clean condition. In addition, there were different directions of prevailing winds during the two periods, which The prevailing southerly winds during the compound pollution period were usually southward and could bemay have driven by the transportation of air pollutants transported from the southern plains, resulting in more serious pollution (Fig. 11; see also Miao et al., 2019b, 2020). Miao et al. (2020) also proposed another mechanism—that is, the synoptic southerly warm advections at the top of PBL, can strengthen the elevated thermal inversion layer and suppress the
- development of the PBL, causing worse pollution. Co-influencing influenced by the topographical effect of the northern mountainous areas and the boundary layer structure, air pollutants could be trapped in the BTH region. In comparison, although there was a southward southerly prevailing wind prevailing in the BTH region (Figs. 11 and S11S14), the rain belt also being located in the southern area of the BTH might lend-have led to the potential removal of PM<sub>2.5</sub> (Fig. 9j). Therefore, compound pollution across the BTH region might mainly have been due to local emissions of air pollutants.

480

In summary, the different SWPs  $\frac{\text{can}}{\text{modulated}}$  the regional variability of summertime O<sub>3</sub> and PM<sub>2.5</sub> and their causes in summer via changes to the local meteorological conditions as follows:

(1) Type 1: The area to the north of the YRD under Type 1 is controlled by the westerly zone in the north of the WPSH at 500 hPa. In Figure S12, we counted the number and probability of <u>occurrence of compound pollution days in each site in summer during 2015-2018, indicating that</u> <u>high-occurrence\_probability\_(maximum\_values\_can\_approach\_46.7%) of compound\_pollution</u> <u>appeared in the Northern China plain (to the north of 32°N). About 55.6% of compound pollution</u> <u>occurrence days at all sites occurred under Type 1.</u>Under the conditions of high temperatures (Tmax > 27°C), moderate humidity (RH ~60%), and low PF, photochemical reactions are largelywere greatly promoted to cause severe O<sub>3</sub> pollution. Meanwhile, <u>the BTH</u>—NYRD <u>areas is-were</u> located in front of the westerly trough, under the influence of the warm and humid air of the WPSH, and so the

hygroscopic growth of fine particulates will-potentially\_caused a certain amount of PM<sub>2.5</sub> pollution (Li et al., 2017b; Zhang et al., 2016b), becoming O<sub>3</sub>-PM<sub>2.5</sub> compound pollution (Fig. 12). ParticularlyIn addition, the prevailing southerly winds in the boundary layer ean-were able to transport the pollutants emitted from southern cities to the BTH, atmospheric stratification is-was stable when the air mass is-was\_sinking\_(Miao et al., 2019b; Figs. 11 and S12), and compound pollution may have been especially severe. Although a relatively higher BLH occurred in the BTH region, the prevailing southerly winds in the boundary layer has-served to further increased the pollution more. In Figure S12, we counted the number and probability of occurrence of compound pollution days in each site in summer during 2015-2018, indicating that high occurrence probability (maximum values can approach 46.7%) of compound pollution appeared in the Northern China plain (to the north of 32°N). About 55.6% of compound pollution occurrence days at all sites occurred under Type 1.

(2) Type 2: As the northern advance of WPSH from Type 1 or the retreat from Type 3 or Type 4, and the northern region is still controlled by the westerly zone. O<sub>3</sub>Ozone pollution is was severe under the meteorological conditions of high temperatures, moderate humidity, and few-weak precipitations. The PM<sub>2.5</sub> in the BTH region, which is was located in front of the westerly trough, is was high since the shallow boundary layer and low wind frequency are-were unfavorable for pollutant the diffusion of pollutants. Therefore, O<sub>3</sub>-PM<sub>2.5</sub> compound pollution can-was also be rather frequent (Fig. 12). About 33.8% of compound pollution occurrence days at all sites occurred under Type 2 in summer during 2015-2018.

510

(3) Type 3: High temperatures, low humidity, and few-weak precipitations over the YRD region tended to generate a large amount of  $O_3$ , while the positive BLH and negative FLWD

anomalies are were unfavorable to  $O_3$  accumulation. On the other hand, summer typhoon activities might <u>have</u> weakened the WPSH intensity over the YRD region, leading to the eastward retreat and northward shift of the WPSH. As a result, <u>the</u> high WS across coastal areas <u>could-was able to</u> ease the ground-level  $O_3$  pollution (Shu et al., 2016). For the BTH and PRD regions, <u>the</u> high PF tends <u>tended</u> to suppress the  $O_3$ -production <u>of  $O_3$ . Only 6.8% of the compound pollution occurrence days</u> at all sites occurred under Type 3, in accordant with light  $O_3$ -only pollution over the areas of the <u>BTH, YRD and PRD (Fig. 12)</u>.

515

(4) Type 4: High temperatures, medium-high humidity and few-weak\_precipitations in the
520 GZP and PRD regions <u>can-were able to</u> cause O<sub>3</sub>-PM<sub>2.5</sub> compound pollution, but <u>the</u>PM<sub>2.5</sub> pollution in both regions <u>are-was</u> not heavy, which is possibly in relation to local lower pollutant emissions <u>of pollutants</u>. The probability of compound pollution occurrence under Type 4 is about <u>5.1%</u>. Under the control of the WPSH, there <u>are-were</u> strong photochemical reactions at high temperatures and little rainfall in some eastern regions (such as the northern BTH, YRD), which is <u>was</u> also conducive to O<sub>3</sub> generation (Fig. 12). Meanwhile, relative to Type 1, O<sub>3</sub> pollution is-was lighter in the BTH, due to the differences of RH, BLH and FLWD.

It is important to note that our work contains a few limitations and uncertainties. Although T-PCA, an objective classification method, was chosen in this study, there were still some subjective decisions made, e.g., the number of SWPs (Huth et al., 2008). In the present work, we selected four 530 SWPs based on both the larger ECV and greater  $\Delta$ ECV to furthest reduce the subjective impact. Nevertheless, at a large scale, the present four SWPs were closely associated with intraseasonal movements of the WPSH, because the WPSH is one of the most important components of the present large-scale SWPs in summertime (Zhao and Wang, 2017). In addition, note that short-term disturbances induced by typhoons with specific pattern were not excluded. The quick passage of a 535 typhoon in summer could lead to various atmospheric processes (e.g., precipitation, large-scale subsidence) and pollution levels (Deng et al., 2019), which should be explored in future work. Besides, although this study emphasizes the important impacts of large-scale synoptic drivers of cooccurring summertime O<sub>3</sub> and PM<sub>2.5</sub> pollution in eastern China, the presences of PM<sub>2.5</sub> may play a role in radiation forcing to reduce O<sub>3</sub>. Indeed, the interaction between O<sub>3</sub> and PM<sub>2.5</sub> deserving of 540 further exploration in future work to better comprehend the mechanism of O<sub>3</sub>-PM<sub>2.5</sub> compound

#### pollution.

#### 5 Conclusions

In this study, T-PCA, an objective classification method, was applied to classify the 500-hPa 545 weather circulation pattern <u>as-into</u> four SWPs in the summers of 2015–2018. It was found that these four SWPs <u>are-were</u> closely related to the development of the WPSH. The spatial and temporal distribution characteristics of O<sub>3</sub> and PM<sub>2.5</sub> pollution in eastern China under <u>the</u> four SWPs were analyzed to regulate and differentiate O<sub>3</sub> and PM<sub>2.5</sub> pollution in key areas. We <u>find-found\_two</u> synoptic patterns <del>are were</del> prone to leading to <u>the</u> co-occurrence of O<sub>3</sub> and PM<sub>2.5</sub> pollution: in BTH– 550 NYRD <u>areas</u> under Type 1<sub>2</sub> and <u>the</u> BTH <u>area</u> under Type 2 <del>are were</del> associated with the double high levels of O<sub>3</sub> and PM<sub>2.5</sub>. The probabilities of compound pollution at all sites under Type 1, 2, 3, and 4 <u>are-were</u> 54.3%, 33.8%, 6.8%, and 5.1% respectively.

- The Type 1 weather pattern appears appeared frequently in early summer, with a stable WPSH ridge axis at about 22°N, and the warm and humid air brought by the WPSH reaches-reached the area south of the Yangtze River, where a high temperature and high humidity hot and humid Meiyu season is was formed, with the high humidity would suppressing the photochemical reaction of O<sub>3</sub> generation. Meanwhile, the north of China is was controlled by a low-pressure trough at 500 hPa with high temperatures and little rain. The hygroscopic growth of PM<sub>2.5</sub> occurs occurred in the corresponding area in front of the trough with a small amount of water vapor transported by the WPSH, causing compound pollution of O<sub>3</sub> and PM<sub>2.5</sub> in the BTH—NYRD regions. In addition, the prevailing southerly winds in the boundary layer ean-were able to transport the pollutants emitted from southern cities to the BTH region, and the atmospheric stratification is was stable when the air mass is was sinking. Thus, the compound pollution ean bewas potentially severe. In general, the synoptic circulation in the boundary layer might be responsible for the concentration of pollutants
- 565 under this SWP<del>s</del>.

Under Type 2, the WPSH <u>shifts shifted</u> northwards from Type 1 or <u>retreats retreated</u> southwards from Type 3 or Type 4, to 32.5°N, with the meridional deepening of the East Asian major trough at 500 hPa, and thus warm and humid airstreams <u>are were</u> brought to the <u>Northern northern</u> China (e.g., the BTH region), gradually elevating temperatures and humidity. Although <u>the</u> positive RH anomaly

- promotes promoted the hygroscopic growth of the PM<sub>2.5</sub>, water vapor absorbs absorbed solar radiation leading by contrast to reduced O<sub>3</sub> formation by contrast. As a result, the probability of double high levels of O<sub>3</sub> and PM<sub>2.5</sub> under Type 2 is was less than under Type 1, and the extent of compound pollution in under Type 2 is was also narrowed, which was mainly located in the BTH area. On the other hand, weak precipitation, shallow boundary layer and low wind speedWS in the BTH area tended to create favorable conditions for pollution the maintenance of pollution. In spite of the southerly winds over the BTH area, the precipitation in southern cities has reduced pollutants concentrations and reduced horizontal transportation. The mMeteorological factors might have been responsible for the accumulation of compound pollution.
- In general, the location of the WPSH is was found to be tightly associated with O<sub>3</sub> pollution in eastern China, and the changes of in meteorological conditions in different regions affected by the WPSH ean-induced significant regional differences in O<sub>3</sub> and PM<sub>2.5</sub> pollution. On the one hand, the appropriate warm and moist flow brought by the WPSH ean-promoted hygroscopic growth of the fine particulate matter in some local areas (i.e., the BTH\_-NYRD areas under Type 1 and the BTH area under Type 2), resulting in the increased of PM<sub>2.5</sub> concentrations; On-whilst on the other hand, transboundary O<sub>3</sub> and PM<sub>2.5</sub> was were simultaneously transported to these local areas at the same time, which may have contributed to the formation of the co-occurring surface O<sub>3</sub> and PM<sub>2.5</sub> pollution. More importantly, the effects of various large-scale weather circulation patterns on the O<sub>3</sub>\_-PM<sub>2.5</sub> compound pollution and their corresponding physical and chemical processes, have been clarified, which has important scientific reference value in terms of summer air-quality forecasts, as 590 well as assessment and policy-making services.
  - Besides, although this study emphasized the important impacts of large-scale synoptic drivers of co-occurring summertime O<sub>3</sub> and PM<sub>2.5</sub>-pollution in eastern China, the presences of PM<sub>2.5</sub>-may play a role in radiation forcing to reduce O<sub>3</sub>, the interaction between O<sub>3</sub> and PM<sub>2.5</sub> which deserves further exploration to better comprehend the mechanism of O<sub>3</sub>-PM<sub>2.5</sub> compound pollution in the future work.

#### Data availability

595

Hourly PM2.5, NO2, O3, and O3-8h data is-are published by the China Environmental Monitoring

Station (http://www.cnemc.cn/). Surface meteorological data, such as Tmax, precipitation, WS and RH, and radiosonde data can be obtained from the China National Meteorological Information Center of the China Meteorological Administration (http://data.cma.cn/site/index.html). The NCEP/NCAR daily reanalysis dataset can be download from https://psl.noaa.gov/data/gridded/data.ncep.reanalysis.html. The ERA5 hourly reanalysis dataset can be derived from https://cds.climate.copernicus.eu/cdsapp#!/home.

Table 1. Over-limit ratio and concentration of MDA8 O<sub>3</sub> and PM<sub>2.5</sub> calculated via 'stations × days' statistics in key urban clusters under four SWPs

Notes: stas  $\times$  days, stations  $\times$  days; OLR, Over-limit ratio; Con, Concentration (µg m<sup>-3</sup>).

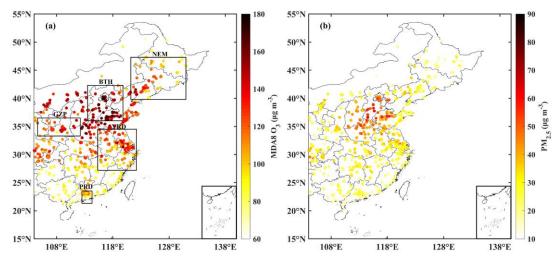

Fig. 1. Average concentration of MDA8 O<sub>3</sub> (a) and PM<sub>2.5</sub> (b) in eastern China during <u>the</u> summers of 2015–2018. Stations and key urban clusters (black box<u>es</u>) are shown in (a).

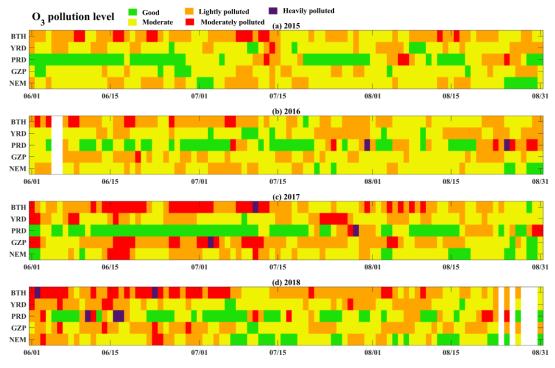

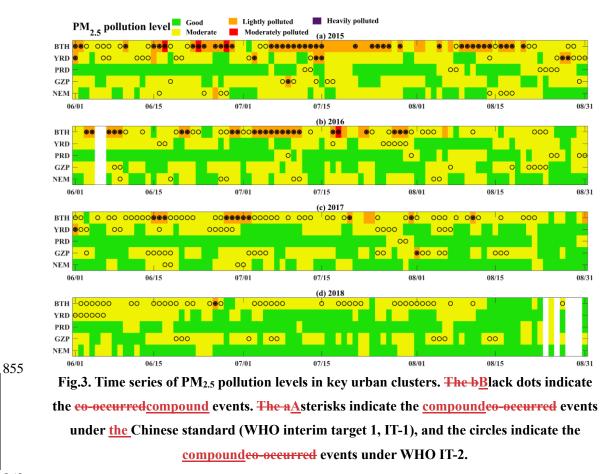

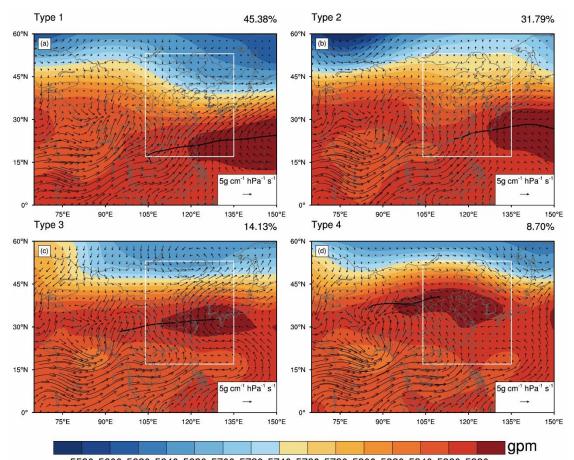

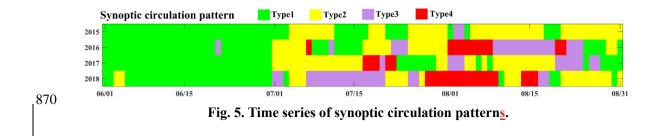

Fig. 2. Time series of MDA8 O<sub>3</sub> pollution levels in key urban clusters.

5580 5600 5620 5640 5680 5700 5720 5740 5760 5780 5800 5820 5840 5860 5880 Fig. 4. 850-hPa 850 hPa water vapor flux (WVF = V \* q/g, where q is specific humidity, g is gravitational acceleration, V is horizonal wind; vectors; see scale arrow at-in\_the bottom right in units of 5 g cm<sup>-1</sup>hPa<sup>-1</sup>s<sup>-1</sup>) and 500-hPa GH (contours; see scale bar at bottom in units of gpm) patterns based on objective classification (see text for details). White The white boxframed area is for the area of eastern China, the number at-in\_the upper-upper-right corner of each panel indicates the frequency of the occurrence of each pattern type, and the black line of-in\_each panel presents the ridge axis of the WPSH.

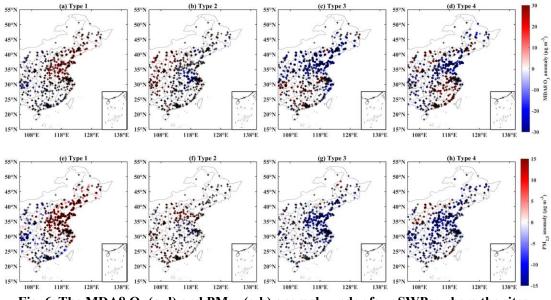

Fig. 6. The MDA8 O<sub>3</sub> (a-d) and PM<sub>2.5</sub> (e-h) anomaly under four SWPs, where the sites

875 marked with a '+' indicates the Analysis of Variance passes the significance level of 0.05.

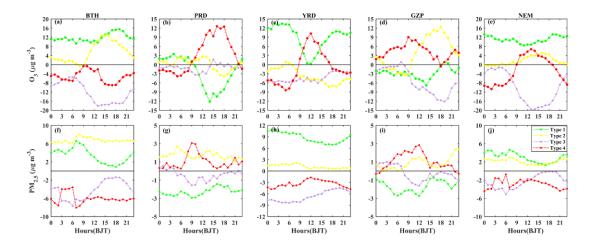

Fig. 7. Daily variations of O<sub>3</sub> and PM<sub>2.5</sub> anomalies under four SWPs in key urban clusters.

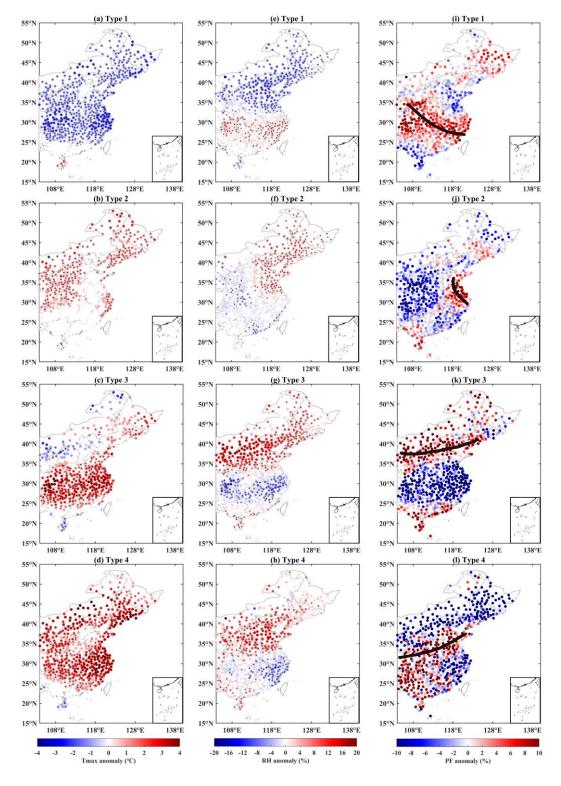

Fig. 8. <u>Same aAs in</u> Fig. 6 but for Tmax (a–d), RH (e–h), and PF (i–l). The black solid line presents the rain belt of each SWP.

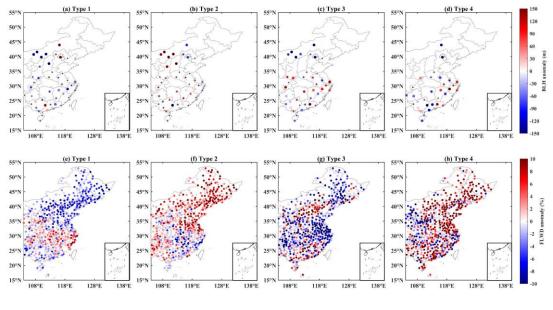

Fig. 9. Same aAs Fig. 6 but for the BLH at 14:00 BJT (a-d) and FLWD (e-h).

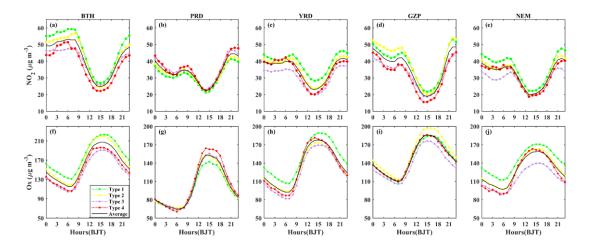

Fig. 10. Daily variations of NO<sub>2</sub> (a\_-e) and Ox (f\_j) under four SWPs in key urban clusters.

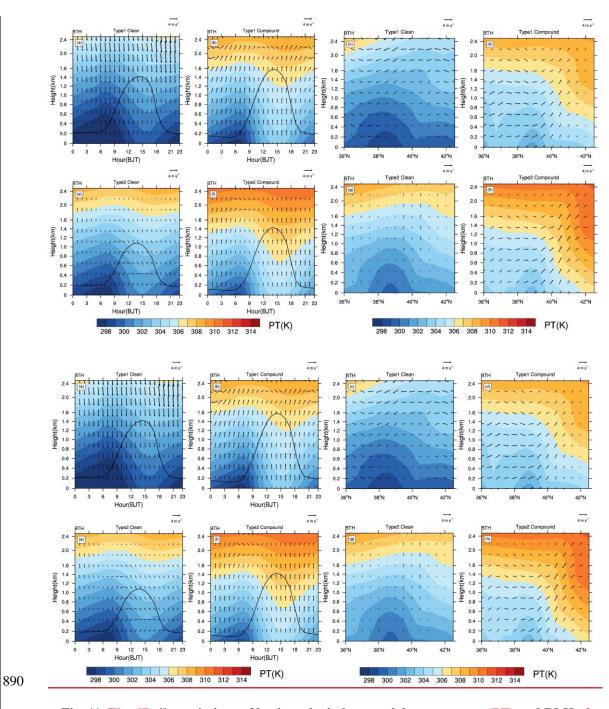

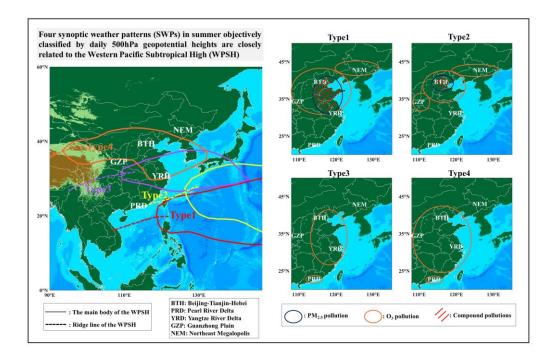

Fig. 11. The dDaily variations of horizonal wind, potential temperature (PT) and BLH of boundary layer in the BTH area under during clean and compound pollution periods of under Type 1 and Type 2 (a, b, e, f). The vertical cross-section of u-wind, w-wind and potential temperature PT for the same situation of in the BTH region (c, d, g, h). The w-wind is multiplied by 100 when used. The data has been derived are from the ERA5 reanalysis-

<del>data</del>.

900 Fig. 12. Schematic diagrams describing the relationships between the WPSH, four SWPs and summertime O<sub>3</sub> and PM<sub>2.5</sub> pollution in various regions.
