**Abstract.** The Arctic Carbon Atmospheric Profiles (Arctic-CAP) project conducted six airborne  
surveys of Alaska and northwestern Canada between April and November 2017 to capture the spatial  
and temporal gradients of northern high-latitude carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>) and carbon  
monoxide (CO) as part of NASA's Arctic-Boreal Vulnerability Experiment (ABoVE). The Arctic-CAP  
20 sampling strategy involved acquiring vertical profiles of CO<sub>2</sub>, CH<sub>4</sub> and CO from the surface to 5 km  
altitude at 25 sites around the ABoVE domain on a 4- to 6-week time interval. We observed vertical  
gradients of CO<sub>2</sub>, CH<sub>4</sub> and CO that vary by eco-region and duration of the sampling period, which  
spanned the majority of the seasonal cycle. All Arctic-CAP measurements were compared to a global  
simulation using the Goddard Earth Observing System (GEOS) modeling system. Comparisons with  
25 GEOS simulations of atmospheric CO<sub>2</sub>, CH<sub>4</sub> and CO highlight the potential of these multi-species  
observations to inform improvements in surface flux estimates and the representation of atmospheric  
transport. GEOS simulations provide estimates of the near surface average CO<sub>2</sub> and CH<sub>4</sub> enhancements  
that are well correlated with aircraft observations (R=0.74 and R=0.60 respectively), suggesting that  
GEOS has reasonable fidelity over this complex and heterogeneous region. This model-data comparison  
30 over the ABoVE domain reveals that while current state-of-the-art models and flux estimates are able to  
capture broadscale spatial and temporal patterns in near-surface CO<sub>2</sub> and CH<sub>4</sub> concentrations, more  
work is needed to resolve fine-scale flux features that are observed. The study also provides a  
framework for benchmarking a global model at regional scales, which is needed to use climate models  
as tools to investigate high-latitude carbon-climate feedbacks.

## 1 Introduction

Accelerated Arctic system change (Hinzman et al., 2013), coupled with the vast quantities of carbon sequestered in the permafrost soils of the northern high latitudes (Hugelius et al., 2014), have led to concerns about the potential for significant carbon emissions due to changes in ecosystems, permafrost and large-scale disturbances like fires (Schuur et al., 2015; McGuire et al., 2018; Turetsky et al., 2020). Our understanding of the magnitude and behavior of the carbon system response to these changes is rudimentary (Koven et al., 2015). For instance, release of carbon from the permafrost pool could result in increased emissions of CH<sub>4</sub> from anaerobic degradation; increased emissions of CO<sub>2</sub> from aerobic degradation; increased uptake of carbon due to new availability of nutrients and above-ground ecosystem growth; or an increase in mobilization of carbon through runoff. Alternatively, increases in disturbances such as fires may significantly impact below-ground carbon storage, uptake of CO<sub>2</sub> and emissions of CH<sub>4</sub>, CO, and CO<sub>2</sub>. Limitations in our understanding of the accuracy of modeled fluxes of CO<sub>2</sub>, CO and CH<sub>4</sub> have increased uncertainties in predictions of the magnitude of Arctic carbon-climate feedbacks (e.g., Koven et al., 2011; Lawrence et al., 2015; Schaefer et al., 2014; Schneider von Deimling et al., 2012; Schuur et al., 2015).

The lack of observations represents a significant limitation that lead to both enhanced uncertainty and reduced fidelity in our model simulations. In general, land- and ocean-atmosphere fluxes from climate models are most commonly evaluated using flux measurements made with eddy covariance or flux chamber techniques. While flux measurements of these types are widely available over many ecosystem types, they represent the impact of limited spatial domains that are rarely more than a 1000 m radius around a given site (Gockede et al., 2005; Schmid, 2002) and may be significantly smaller depending on topography, wind direction and boundary layer stability. Land surface inhomogeneities within these small footprints (Baldocchi et al., 2005) and regional-scale (100-1000 km scales) variability of these ecosystems can lead to significant biases when eddy covariance measurements are scaled up to represent large areas. This is especially true in the Arctic where microtopography can result in fluxes varying by orders of magnitude on a scale of 1-100 meters (Johnston et al., 2014). While flux towers can be found in many ecosystem types, they do not necessarily represent landscape-scale heterogeneity within a broadly defined ecosystem such as the boreal forest, peatlands, or tundra regions of the Arctic. An alternative to the “bottom-up” evaluation approach is the “top-down” approach, which makes use of atmospheric measurements of species like CO<sub>2</sub>, CH<sub>4</sub> and CO and modeled atmospheric transport patterns to infer the surface fluxes needed to reproduce observed atmospheric concentrations. This inverse approach generally takes a forward-flux model, or a set of observations that are likely correlated with the flux, as a prior or first guess. The inverse approach then estimates the flux by scaling the prior. While the inverse approach results in a flux estimate that meets the constraint of the trace gas measurements and modeled transport, the variability in surface flux from these analyses cannot be directly attributed to mechanisms such as temperature changes, CO<sub>2</sub> fertilization and water stress. Also, inverse methods are influenced by errors in atmospheric transport and assumptions about error covariances, which are difficult to characterize (Gourdji et al., 2012; Lauvaux et al., 2012; Mueller et al., 2018; Chatterjee and Michalak, 2013).

In this study, we explore a hybrid approach using atmospheric trace gas mole fractions from aircraft profiles and an advanced global tracer transport model to evaluate the ability of current state-of-the-art

bottom-up land-surface flux models to capture complex carbon cycle dynamics over the northern high-latitudes. NASA's Goddard Earth Observing System (GEOS) general circulation model (GCM) is used with a unique combination of surface flux components for CO<sub>2</sub>, CH<sub>4</sub> and CO to create 4D atmospheric fields; these fields are subsequently evaluated using profiles collected during the Arctic Carbon Atmospheric Profiles (Arctic-CAP) airborne campaign.

Both the Arctic-CAP project and the GEOS model runs for the domain are part of NASA's Arctic Boreal Vulnerability Experiment (ABoVE, [www.above.nasa.gov](http://www.above.nasa.gov)), a decade-long research program focused on evaluating the vulnerability and resiliency of the Arctic tundra and boreal ecosystems in western North America (Miller et al., 2019). One of the primary objectives of the ABoVE program is to better understand the major processes driving observed trends in Arctic carbon cycle dynamics, in order to understand how the ecosystem is responding to environmental changes and to characterize the impact of climate feedbacks on greenhouse gas emissions. ABoVE has taken two approaches to better understand critical ecosystem processes vulnerable to change. The first is through ground-based surveys and monitoring sites in representative regions of the ABoVE domain. These multi-year studies provide a backbone for intensive investigations, such as airborne deployments. The Arctic-CAP campaign discussed here was one such airborne deployment that was conducted during the spring-summer-fall of 2017 (Section 2.1). The subsequent analysis described here illustrates how improvements in surface models develop through ground-based surveys, and monitoring sites can be evaluated and tested over larger spatial scales using such aircraft profiles (Section 3). This study uses Arctic-CAP aircraft profiles to directly evaluate both the transport model and the terrestrial surface flux models of CO<sub>2</sub>, CH<sub>4</sub> and CO. For the sake of demonstration, we rely on one transport model and one flux scenario for each tracer (i.e., CO<sub>2</sub>, CH<sub>4</sub> and CO) to show the utility of the three carbon species to diagnose and identify deficiencies in both flux and transport models. Ongoing and future studies build upon the results discussed here and further diagnose transport and flux patterns from multiple models based on additional aircraft and ground-based observations throughout the ABoVE domain.

## 2 Methods

### 2.1.1 Arctic-CAP Flight Planning and Sampling Strategy

Arctic-CAP was designed to measure vertical profiles of atmospheric CO<sub>2</sub>, CH<sub>4</sub> and CO mole fraction to capture the spatial and temporal variability of carbon cycle dynamics (Parazoo et al., 2016; Sweeney et al., 2015) across the ABoVE domain. Flights were conducted aboard a Scientific Aviation Mooney Ovation 3 (N617DH). Six campaigns were performed during 2017: late April – early May, June, July, August, September, and late-October – early November. Arctic-CAP flights surveyed the ABoVE Study Area and were organized around an Alaskan circuit and a Canadian circuit (Fig. 1). The Alaskan circuit covered a region where aircraft measurements were previously made during 2012–2015 by the Carbon in Arctic Reservoirs Vulnerability Experiment (CARVE; Miller et al., 2012), which included the Alaskan Boreal Interior, Brooks Range Tundra and the Alaskan Tundra ecoregions. The Arctic-CAP Alaska circuit was primarily west of Fairbanks, Alaska, and include Galena, Bethel, Unalakleet, Nome and Kotzebue. The northern section of the circuit overflowed Utqiagvik (formerly Barrow), Atkasuk, Deadhorse and the Toolik Lake Research Station – all North Slope tundra sites with long-term

measurements of atmospheric CO<sub>2</sub> and CH<sub>4</sub>. The Arctic-CAP Canadian circuit focused on flying over sites in and around the Inuvik and Yellowknife areas in the Canadian Arctic. In the Inuvik region, the aircraft overflew the Trail Valley Creek and Havipak Creek research sites, and the Daring Lake and Scotty Creek flux tower sites were overflown on the way to and from the Yellowknife area. The Canadian Circuit expands upon the ecoregions covered in the CARVE missions to include the Boreal Cordillera, Taiga Plain, Taiga Shield and the Southern Arctic Tundra ecoregions. Approximately 25 vertical profiles were acquired during each campaign (Fig 2). The majority of each flight day was spent in the well-mixed boundary layer with 2-4 vertical profiles up to altitudes of 5000 m above sea level (masl). Using missed approaches to get as near to the ground as possible, profiles diagnosed the temporal change in the boundary layer as well as the residual layers above where surface fluxes may have recently (< 3 days) influenced that atmospheric column. During the 2017 season, Arctic-CAP flights were complemented by additional vertical profiles collected by the ASCENDS (Active Sensing of CO<sub>2</sub> Emissions over Nights, Days, & Seasons, <https://www-air.larc.nasa.gov/cgi-bin/ArcView/ascends.2017?MERGE=1>), ATom (Atmospheric Tomography, Wofsy et al., 2018), and NOAA Carbon Cycle Aircraft Program ([www.esrl.noaa.gov/gmd/ccgg/aircraft/](http://www.esrl.noaa.gov/gmd/ccgg/aircraft/)) projects. The focus of this study will be on the CO<sub>2</sub>, CH<sub>4</sub> and CO data acquired during Arctic-CAP.

### 2.1.2 Aircraft and Payload

Arctic-CAP flights were performed in a Mooney Ovation 3 (N617DH, Scientific Aviation). The Mooney operated at a cruise speed of 170 kts and reached profile altitudes of 5 km (17,000 feet) on each flight, with most legs lasting 4-5 hours and covering an average distance of ~1350 km. The average ascent and descent rates were limited to ~100 m/min to minimize hysteresis in the temperature and relative humidity measurements. The basic research payload flown on all six research missions included continuous in-situ CO<sub>2</sub>, CH<sub>4</sub>, CO, H<sub>2</sub>O, temperature and horizontal winds. The in-situ measurements (Sweeney and McKain, 2019) followed the methodology described in Karion et al. [2013], and wind measurements followed the protocol outlined in Conley et al. [2013]. Programmable flask packages (PFPs; Sweeney et al., 2015) provided an independent check of the calibration scale of the continuous *in situ* CO<sub>2</sub>, CH<sub>4</sub> and CO measurements, as well as samples for more than 50 different species including N<sub>2</sub>O, SF<sub>6</sub>, and a variety of hydrocarbons, halocarbons and isotopes of carbon (Sweeney et al., 2020). Carbonyl sulfide measured in the flask samples can be used as a tracer of gross primary productivity (GPP) (Montzka et al., 2007), while ethane, propane and C-13 isotope of CH<sub>4</sub> provide another constraint on the source of the CH<sub>4</sub> emissions. Each flight sampled a single 12-flask package providing a total of ~84 flasks per research mission to better understand the factors controlling local fluxes of CO<sub>2</sub>, CH<sub>4</sub> and CO and the long-range transport of these species from low latitudes.

### 2.1.3 GEOS Earth System Model & Atmospheric CO<sub>2</sub>, CO and CH<sub>4</sub> Modelling

The GEOS (Molod et al., 2015; Rienecker et al., 2011) model is a complex yet flexible modeling system that describes the behavior of the land and atmosphere on a variety of spatial (~12.5-100 km) and temporal (hourly to decadal) scales. GEOS includes both an atmospheric General Circulation Model (GCM) and data assimilation system that have been used to produce the widely-used Modern-

155 Era Retrospective Analysis for Research and Applications (MERRA) (Rienecker et al., 2011) and  
MERRA-2 (Bosilovich et al., 2015; Gelaro et al., 2017). The GEOS Forward Processing (GEOS FP)  
system produces atmospheric analyses and 10-day forecasts in near real-time, which are used to provide  
forecasting support to NASA field campaigns and satellite instrument teams (e.g. Strode et al., 2018).  
160 GEOS has also been used extensively to study atmospheric carbon species (e.g. Allen et al., 2012; Ott et  
al., 2015; Weir et al., 2020).  
The GEOS setup utilized in this work simulates CO<sub>2</sub>, CO and CH<sub>4</sub> simultaneously at nominal 0.5°  
horizontal resolution, 72 vertical layers (up to ~0.1 hPa) with trace gas output saved every 3-hours. For  
CO<sub>2</sub>, the surface fluxes consist of 5 different components from a Low-order Flux Inversion (LoFI)  
package (Weir et al., 2020): 1) net ecosystem exchange (NEE) from the Carnegie Ames Stanford  
165 Approach - Global Fire Emissions Database (CASA-GFED) mode with a parametric adjustment applied  
to match the atmospheric growth rate (Weir et al., 2020), 2) anthropogenic biofuel burning emissions,  
i.e., harvested wood product (Van Der Werf et al., 2003), 3) biomass burning emissions derived from  
the fire radiative power based Quick Fire Emissions Dataset (QFED; Darmenov and Da Silva, 2015) 4)  
170 fossil fuel emissions from the Open-source Data Inventory for Anthropogenic CO<sub>2</sub> (ODIAC; Oda and  
Maksyutov, 2011), and 5) ocean exchange fluxes based on *in situ* measurements of the partial pressure  
of CO<sub>2</sub> in sea-water from the Takahashi et al. (2009) dataset but adding back the inter-annual variability  
and applying a mean pCO<sub>2</sub><sup>sw</sup> growth rate of 1.5 μatm/yr at each point every year. For CO, the emissions  
include biomass burning emissions from QFED, and climatologies of fossil fuel and biofuel emissions  
and VOC fields (Duncan et al., 2007; Ott et al., 2010). Finally, the CH<sub>4</sub> flux collection consists of five  
175 components: 1) wetland emissions from the process-based ecosystem model LPJ-*ws/* (Lund-Potsdam-  
Jena model, WSL version - Poulter et al., 2011), 2) biomass burning emissions from the QFED, 3)  
industrial and fossil fuel emissions from the Emissions Database for Global Atmospheric Research  
(EDGAR v4.3.2, Janssens-Maenhout et al., 2017; Crippa et al., 2018), 4) agricultural emissions from  
EDGAR v4.3.2 and 5) anthropogenic biofuel burning emissions from EDGAR v4.3.2. Note that since  
180 the EDGAR v4.3.2 emissions record ends in 2012, the same set of values from 2012 were used for the  
year 2017. As shown later, this is not a bad assumption considering that for the majority of the ABoVE  
domain, the most critical CH<sub>4</sub> emissions are from the wetlands sector. On the other hand, care was taken  
to use a version of the LPJ-*ws/* model that includes a state-of-the-art hydrology subroutine  
(TOPMODEL) to determine wetland area and its inter- and intra-annual dynamics (Zhang et al., 2016),  
185 a permafrost and dynamic snow model (Wania et al., 2009) with explicit representation of the effects of  
snow and freeze/thaw cycles on soil temperature and moisture, and thus the CH<sub>4</sub> emissions. Table 1  
provides a summary of the flux components, their specifications and associated references.

190 **Table 1. Components of fluxes for simulation of atmospheric concentrations of CO<sub>2</sub>, CO and CH<sub>4</sub> in GEOS. Flux components that are the primary drivers of observed signals within our study domain are highlighted in bold italics.**

Flux type	Used in simulation of	Inventory / Process-based model name	Reference
Fossil fuel	CO <sub>2</sub>	ODIAC	Oda and Maksyutov, 2011
Biofuel	CO <sub>2</sub>	CASA-GFED3	Van Der Werf et al., 2003
<i>NEE</i>	CO <sub>2</sub>	LoFI CASA	Weir et al., 2020
Ocean	CO <sub>2</sub>	LoFI Takahashi	Weir et al., 2020
Biomass Burning / Fires	CO <sub>2</sub> , CO,	QFED	Darmenov and Da Silva, 2015
Fossil fuels & biofuels	CO	Climatology	Duncan et al., 2007
VOC	CO	GMI climatology	Duncan et al., 2007
<i>Wetlands</i>	CH <sub>4</sub>	LPJ- <i>wsl</i>	Poulter et al., 2011, Zhang et al.,
Agriculture and waste	CH <sub>4</sub>	EDGAR v4.3.2	Crippa et al., 2018
Biofuels	CH <sub>4</sub>	EDGAR v4.3.2	Crippa et al., 2018
Industrial and fossil fuel	CH <sub>4</sub>	EDGAR v4.3.2	Crippa et al., 2018

We have assessed global and pan-Arctic budgets (Tables 2 and 3) and compared against existing studies and estimates to establish the fidelity of the model fluxes for large-scale assessments.

195 **Table 2. GEOS CO<sub>2</sub> Flux Estimates (PgC yr<sup>-1</sup>) for 2017. Flux emissions are specified for (a) the natural land sink component, which includes the sum of NEE and biomass burning, and (b) all anthropogenic source components, which include fossil fuel and biofuel burning.**

ABOVE Domain		pan-Arctic (>48 N)		Global	
Land Sink	Fuel Sources	Land Sink	Fuel Sources	Land Sink	Fuel Sources
-0.32	0.11	-1.84	1.37	-3.28	11.08

200 CO<sub>2</sub> flux estimates indicate that the ABOVE domain is a 0.32 PgC sink for our study year, 2017. This represents about 17% of the calculated pan-Arctic terrestrial carbon sink, which is consistent with the fraction of the land area > 48N represented by the ABOVE domain (~16%). Perhaps more significantly, the 1.84 PgC pan-Arctic sink represents 56% of the global sink for 2017. We attribute this large uptake to the vast boreal forests > 48 N, particularly in Siberia (Sasakawa et al., 2013), where the contemporary Arctic tundra is thought to be nearly carbon neutral with uncertainties allowing for a small to moderate sink or a small source (McGuire et al., 2016). These findings are also consistent with Wunch et al. (2013) who used GOSAT satellite data and TCCON ground-based column measurements to determine that interannual variability in Northern Hemisphere CO<sub>2</sub> uptake was dominated by changes in the boreal forest. More recent studies, such as Welp et al. (2016) and Commane et al. (2017) have also used atmospheric inversions to highlight that >90% of the carbon sink in the northern high latitudes reside in the boreal forests. Our simple forward model simulations and the Arctic-CAP data provide a unique opportunity to assess the validity of these previous findings over the ABOVE domain. Sub-regional flux estimates within the ABOVE domain are part of ongoing investigations and will be captured in future studies.

**Table 3. GEOS CH<sub>4</sub> Flux Estimates (TgCH<sub>4</sub> yr<sup>-1</sup>) for 2017. CH<sub>4</sub> flux emissions are specified for (a) the wetland component, and (b) all source components, which include wetlands, industrial and fossil fuel, agriculture and waste, biomass burning, biofuel burning and other natural emissions.**

ABoVE Domain		pan-Arctic (>48 N)		Global	
Wetland	All Sources	Wetland	All Sources	Wetland	All Sources
9.01	11.64	21.74	52.03	187.39	536.01

215 Examination of the specified CH<sub>4</sub> flux estimates for the ABoVE domain (Table 4) reveal a remarkable  
result: 78% of the emissions, 9.01 TgCH<sub>4</sub> yr<sup>-1</sup>, come from wetlands. Furthermore, ABoVE wetlands  
emissions account for 41% of pan-Arctic CH<sub>4</sub> wetland emissions. Both results suggest a  
disproportionately large contribution of North American wetlands to the regional CH<sub>4</sub> budget. Placing  
this in a larger context, the 52 TgCH<sub>4</sub> yr<sup>-1</sup> from all pan-Arctic emissions account for only about 10% of  
220 the global emissions. Our pan-Arctic CH<sub>4</sub> emissions estimate of 52 TgCH<sub>4</sub> yr<sup>-1</sup> is only 60% of the 82-84  
TgCH<sub>4</sub> yr<sup>-1</sup> determined by Thompson et al. (2017) for latitudes > 50N and the period 2005-2013. The  
reasons for this large discrepancy are unclear, particularly since the Thompson et al. (2017) study  
derived their estimate from an inversion of atmospheric CH<sub>4</sub> observations; previously, such top-down  
estimates have tended to be lower than most forward model emissions estimates. Subtracting the 11  
225 TgCH<sub>4</sub> yr<sup>-1</sup> we estimate for the ABoVE domain from our pan-Arctic value leaves 41 TgCH<sub>4</sub> yr<sup>-1</sup> for the  
remainder of the pan-Arctic. Future work with additional observations and model simulations will help  
us understand how specific sectors in the ABoVE domain can better capture the complexity of pan-  
Arctic CH<sub>4</sub> emissions. Our overall model value of 536 TgCH<sub>4</sub> yr<sup>-1</sup> for global CH<sub>4</sub> emissions in 2017  
falls just outside the range of annual emissions estimates for the decade 2008-2017 (Saunois et al.,  
230 2019). This discrepancy is primarily due to the fact that we are looking at different time periods and  
unlike Saunois et al. (2019), we do not extrapolate the EDGARv4.3.2 dataset using the extended FAO-  
CH<sub>4</sub> emissions and/or British Petroleum statistical review of fossil fuel production and consumption  
(see Equation 1 in Saunois et al., 2019); instead, we adopt a much more simplistic approach of repeating  
the EDGARv4.3.2 from 2012 for the year 2017. Contrary to the emissions from the coal, oil and gas  
235 sector, our wetland methane flux emissions are obtained from the LPJ-*ws/* model (Table 1). LPJ-*ws/*  
is one of the prognostic models that provide wetland emission estimates to the global methane budget  
(Table 2 in Saunois et al., 2019). It is not surprising then that our global wetland CH<sub>4</sub> emission  
estimates for 2017 is in line with both the bottom-up (100-183 TgCH<sub>4</sub> yr<sup>-1</sup>) and top-down (155-217 Tg  
CH<sub>4</sub> yr<sup>-1</sup>) estimates used in the global methane budget estimate.

240

### 3 Results

#### 3.1.1 Analysis of Profiles

Table 4. Arctic-CAP 2017 campaign summary

Campaign	Start (DOY)	End (DOY)
Apr/May	116	124
June	157	170
July	190	202
August	229	242
September	251	271
Oct/Nov	291	310

245 Vertical profiles of CO<sub>2</sub>, CH<sub>4</sub> and CO were acquired during 56 flights over the six Arctic-CAP  
campaigns from late April (day of year (DOY) 116) through early November (DOY 310) 2017 (Table  
4). Figure 4 presents the composite vertical profile data for each campaign. The monthly composite  
CO<sub>2</sub>, CH<sub>4</sub> and CO vertical profiles capture the expected variations in the seasonal cycle. The composite  
profiles also show more variability in the boundary layer (altitudes < 3000 masl) within each month and  
250 across months than in the free troposphere for CO<sub>2</sub> and CH<sub>4</sub> (altitudes > 3000 masl). Unlike CO<sub>2</sub> and  
CH<sub>4</sub>, CO variability in the free troposphere is significantly greater in July and October than the  
boundary layer showing either long-range transport of CO or CO injected high (>3000 masl) into the  
troposphere by local wildfires.

A clearer picture of the vertical gradients between the free troposphere and the boundary layer can be  
255 seen by subtracting free tropospheric means from measurements below 3000 masl. The CO<sub>2</sub> gradients  
between the measurements below 3000 masl and average daily free troposphere values show a  
drawdown in the boundary layer for most of the profiles starting in June and lasting until the end of the  
September campaign (Fig. 5). The drawdown signal in CO<sub>2</sub> over the Northern Alaska Tundra (often  
referred to as the “North Slope”) was most pronounced in mid-July and continued through the  
260 September campaign. The CO<sub>2</sub> drawdown in the more southerly regions of the Boreal Cordillera and  
Alaskan Boreal Interior peaked in August. By the October campaign many regions were showing  
significant enhancements in the boundary layer CO<sub>2</sub> mole fraction relative to the free troposphere. On  
the other hand, for both CH<sub>4</sub> and CO, significant enhancements were observed from June through early  
November. Methane enhancements over the Northern Alaska Tundra CH<sub>4</sub> enhancements were observed  
265 from July onward, consistent with patterns observed at the long-term surface monitoring station in  
Utqiagvik (Sweeney et al., 2016). Similarly, boundary layer CO<sub>2</sub> and CH<sub>4</sub> are both most enhanced in  
September and October on the North Alaska Tundra. Due to the high variability in CO above 3000 masl  
during July and October (Fig. 4), it is more difficult to use this approach to derive CO enhancements  
from surface fluxes. To avoid the impact of fire-based CO that has been injected into the free  
270 troposphere, the mean background value is taken from measurements above 4000 masl. This analysis

shows that Canadian Taiga and Alaskan Boreal Interior are the predominant sources of boundary layer CO emissions likely reflecting fires in these regions at that time. It should be noted that large enhancement values for CO<sub>2</sub>, CH<sub>4</sub> and CO were observed with the Alaskan Boreal Interior, which were the result of samples taken in the early morning (10:00 local time) before the boundary layer has fully developed (typically around 11:00-12:00 local time). This trapping of night-time emissions results in significant enhancements that quickly taper off with altitude. These measurements were typically taken during the first profile out of Fairbanks where the majority of the Arctic-CAP flights originated.

### 3.1.2 Model Data Comparisons

Aircraft profiles that measure the gradient from the boundary layer into the free troposphere are particularly useful for evaluating atmospheric models and for separating errors and uncertainties related to atmospheric transport and surface flux model simulations. This is demonstrated by comparing surface flux models for CO<sub>2</sub>, CH<sub>4</sub>, and CO using a single GCM to evaluate both the transport features and the flux model specifications. For the data-model comparison, the aircraft observations are aggregated to 10s averages and the model 4D fields (latitude, longitude, altitude and time) are sampled at the location and time of those 10s averages. Sampling with the 10s averages reduces the spatial representativeness error between the model grid cell and the aircraft observations.

### 3.1.3 Point by Point Comparison

In the GEOS model run used for these comparisons, an effort was made to match the global atmospheric burdens of CO<sub>2</sub>, CH<sub>4</sub> and CO; however, given the uncertainties in the sources and sinks of these trace gases and in the representation of long-range and local atmospheric transport, it is not uncommon to have mean offsets between the observed and the modeled mole fractions. To evaluate surface fluxes in the ABoVE domain, it is important to consider both the impact of regional-scale fluxes and long-range transport processes that control the mole fractions of CO<sub>2</sub>, CH<sub>4</sub> and CO throughout the ABoVE domain. A time series comparison of the modeled and the observed CO<sub>2</sub>, CH<sub>4</sub> and CO mole fractions (Fig. 6) suggests that gross features of the seasonal cycles are matched, although some significant differences require detailed analysis by considering different elements of each vertical profile.

### 3.1.4 Free Troposphere Comparisons

As demonstrated from the analysis of the boundary layer enhancements, it is useful to subtract the average free tropospheric mole fraction from each profile to better understand the local influences within a particular profile. Differences in the mean free tropospheric values, however, can be a valuable indicator of how large-scale biases in the model influence point-to-point comparisons.

In the case of CO<sub>2</sub>, the mean daily CO<sub>2</sub> mole fraction in the observed free troposphere is increasing faster than modeled values over the course of 6 research missions. The largest offset exceeds a mean value of ~2 ppm (observed – modeled) during the September campaign (Fig. 7). Based on the available model runs, it is difficult to diagnose what causes this offset, although a few hypotheses can be put forward. Given the decreasing latitudinal gradient for CO<sub>2</sub> in the free troposphere at this time of year,

the offset could be explained by sluggish meridional transport in the model. Alternatively, exaggerated biological uptake in the model in regions outside the study area could be pulling down the CO<sub>2</sub> in modeled free troposphere more rapidly than the drawdown observed over the ABoVE domain. Measured CH<sub>4</sub> increases faster than modeled CH<sub>4</sub> over the course of the campaign. Given the decreasing meridional gradient for CH<sub>4</sub> that exists during the summer months, sluggish transport could explain the difference between model and observations. Alternatively, modeled June-July-August emissions of CH<sub>4</sub> in areas surrounding the ABoVE domain could be underestimated, leading to slower increase in modeled free tropospheric CH<sub>4</sub>. Finally, the difference between modeled and observed mole fractions of CO in the free troposphere is mainly driven by inaccuracies in the modeled CO from fire plumes both within and outside the ABoVE domain. Figures 4, 6 and 7 show observations of large CO enhancements above 4000 masl during the July, August and October/November campaigns. Given the large excursions in the free tropospheric CO between different profiles, local fires were likely responsible for these enhancements. Accurately simulating the injection height of fire plumes is challenging (Freitas et al., 2007; Strode et al., 2018). The GEOS model distributes biomass burning emissions throughout the planetary boundary layer (PBL) to represent injection above the surface layer, but this method can result in underestimated local emissions for fire plumes detraining in the free troposphere. In regions remote to the ABoVE domain, emissions can be mixed and lofted by large-scale weather systems, which may explain why the model performs better in simulating long-range CO plume transport than it does in capturing the CO enhancements from local fires. The observation-model mismatch is likely compounded by the inability of the model to accurately simulate the subgrid-scale vertical mixing necessary for capturing vertical profiles for local sources.

### 3.1.5 Boundary Layer Comparisons

Accurately modeling boundary layer mole fractions of CO<sub>2</sub>, CH<sub>4</sub> and CO depends on an accurate representation of two key factors. First, there is a need to accurately model the local surface-atmosphere flux and second there is a need to correctly model the physical evolution of the PBL, as well as horizontal transport and vertical mixing out of the PBL into the free troposphere. GCMs have limited horizontal and vertical resolution and require parameterizations to predict both the rate of change and the absolute value of the PBL height over the course of the day. Errors in PBL mixing directly impact the tracer mole fraction estimate. Overestimation of the PBL height causes an artificial dilution of the impact of surface flux. Conversely, underestimation of the PBL height results in amplification of the impact of a surface flux on the simulated PBL mole fraction. Additionally, GCMs typically simulate large-scale horizontal gradients more accurately than PBL height unless there are large topographic changes that occur on horizontal scales less than the model resolution (for GEOS, 0.5 degree). This is because such large-scale patterns are generally well-constrained by the millions of in situ and satellite observations incorporated into meteorological analyses while PBL mixing is represented by highly simplified parameterizations. The three carbon species that we investigate in this study provide different diagnostic information about the model transport and flux specifications. In the case of a gas like CO that often comes from a specific point source in the Arctic, accurate placement of the emissions, both in the horizontal and the vertical,

and the modeled wind direction are critical factors. The ABoVE domain is made up of large expanses of forest and tundra in which CO<sub>2</sub> fluxes are more uniformly distributed, making the transport accuracy of individual plumes a less critical factor for simulating CO<sub>2</sub>. Accurately estimating CH<sub>4</sub> mole fractions may be more sensitive to horizontal transport in the PBL if CH<sub>4</sub> emissions are dominated by specific features such as lakes or wetlands, or anthropogenic point sources from oil and gas production such as those observed on the North Slope (Floerchinger et al., 2019). However, we observed consistent PBL CH<sub>4</sub> enhancements throughout each campaign (Fig. 5), suggesting a spatial homogeneity in CH<sub>4</sub> emissions rather than emissions from specific point sources.

### 3.1.6 The advantage of vertical trace gas gradients

While individual mole fraction measurements are challenging to reproduce given errors in both modeled surface fluxes and transport, the vertical profile provides a unique opportunity for removing significant uncertainties in transport in order to better assess the surface flux model of a specific long-lived tracer. Assuming that horizontal transport is a relatively small source of bias and the upper part of the free troposphere (>3000 masl) is largely unaffected by local processes, it is possible to use the information in the vertical profile to reduce the effects of vertical transport. This can be estimated by vertically integrating the net change in the PBL due to a surface flux from the surface to a specific altitude that is well above the boundary layer. For this study, almost all the enhancements for CO<sub>2</sub> and CH<sub>4</sub> were observed below 3000 masl. By subtracting the average free tropospheric (FT) values in both the model and the measurements and averaging the resulting enhancements or depletions for each profile mapped on equal altitude bins from surface to 3000 masl, we quantify a total enhancement resulting from the surface flux (Fig. 8). The resulting measured and modeled boundary layer enhancements show good matches for all three gases. The average measured enhancement in CO<sub>2</sub> and CH<sub>4</sub> below 3000 masl is correlated with the forward model such that more than 50% and 36%, respectively, of the variability observed is captured by the model (Fig. 8). The average CO enhancements in the lower 3000 masl is captured by the model with lesser accuracy – in fact, the model only captures 26% of the observed variability along with a significant bias throughout the growing season.

### 3.1.7 Average CO<sub>2</sub> enhancement

To understand the true value of the aircraft profile in evaluating the ability of the surface flux model to reproduce observed fluxes over large regional expanses, it is useful to rigorously compare the differences between modeled and observed near-surface enhancements. The enhancements of CO<sub>2</sub> below 3000 masl shown in Fig. 8 for both data and the GEOS model are well correlated. As expected, during April/May we see very little change in the average enhancements below 3000 masl, while June and July and August show significant drawdown, followed by enhancements in September and October/November (Fig. 6 and 8). The modeled enhancements in the lower 3000 masl reproduce the observations suggesting that the surface flux of CO<sub>2</sub> throughout most of the ABoVE domain is accurately modeled by GEOS. Despite the overall agreement indicated by aggregated statistics, a closer look shows significant differences in observed and modeled CO<sub>2</sub> enhancements for many individual flight days (Fig. 9).

Inspection of individual profiles (Fig. 10) reveal that in some cases the model is not capturing near-ground stratification. This is not surprising given that the observations have a much higher vertical resolution than the model's vertical resolution, which is  $\sim 100\text{m}$  in the PBL. Consequently, the observed mole fraction values are much higher than the model estimates because the model is not able to capture the stratification in the river valleys in the interior parts of the ABoVE domain. However, the overall modeled vertical gradients in  $\text{CO}_2$  match the observations suggesting that the large-scale vertical transport of emissions is accurately simulated above  $\sim 1000$  masl. As an example, the set of profiles from July 10 (Fig. 10) demonstrates that, although infrequent, high PBL heights and emissions from fires (as indicated by large ( $>400$  ppb) enhancements in CO) add some uncertainty to the average BL enhancement values. Both of these factors impact the mean free tropospheric correction and altitude of integration that we have chosen to accurately capture the total  $\text{CO}_2$  enhancement from the surface fluxes.

### 3.1.8 Average $\text{CH}_4$ enhancement

Although the correlation between the observed and modeled average enhancements of  $\text{CH}_4$  is significant, there are some key deviations that should be noted. In particular, we see some clear biases in the seasonality where the enhancements in the early part of the season are underestimated by the model while the enhancements in the later part of the season are overestimated. This is demonstrated both by the comparisons of average enhancements (Fig. 8) and of mole fraction enhancements below 3000 masl (Fig. 9) where the mean difference (observed – modeled) switches from positive to negative over the course of the study period. The Arctic-CAP profile observations provide a critical point of comparison to which future surface flux models of  $\text{CH}_4$  can be compared, helping to identify areas where process improvements are needed.

### 3.1.9 Average CO enhancement

The comparison of observed and modeled average enhancements of CO is less useful because some of the critical assumptions we make for this comparison are designed to shed light on surface processes affecting  $\text{CO}_2$  and  $\text{CH}_4$ . The biggest limitation in the CO simulation for interpreting vertical profile observations appears to be in the accuracy of the vertical distribution of CO emissions. While the model shows an increase in mole fractions during the July and October/November campaigns, the extreme mole fractions in the observations are twice that of the model (Fig. 6). A good example of how the model and the observed mole fractions are different can be seen on July 10, 2017 (Fig. 10) during a flight up the Mackenzie River in the Northwest Territories of Canada. Here, large enhancements of CO ( $>400$  ppb) are observed at altitudes between 3000 and 5000 masl while  $\text{CH}_4$  and  $\text{CO}_2$  boundary layer enhancements are observed below 3000 masl in most of the profiles measured that day. The  $\sim 100$  ppb CO/ppm  $\text{CO}_2$  ratio and the large CO enhancement not only support the idea that a fire is the source but that the fire is nearby ( $<100$  km). Both the magnitude and altitude of the CO enhancement point to a few critical limitations in the model that was less important for  $\text{CO}_2$  and  $\text{CH}_4$ . First, most GCMs, including GEOS, do not take into account the massive heat source that fires provide to correctly model the injection of fire emissions above the boundary layer. Second, the fire radiative power observations used to estimate emissions can be obscured by thick clouds or aerosols resulting in the emissions

estimates missing some fire hotspots. Third, the heterogenous nature of fires as a surface source of CO means that any inaccuracies in horizontal transport or location of the fire will play a large role in the ability of the model to accurately reproduce the observations. Fourth, the lack of diurnal cycle in biomass burning emissions from the emission database (QFED; Table 1) may result in ‘temporal aggregation errors’, whereby the model simulations may miss the high emission values that coincide with the daytime aircraft observations.

### 3.1.10 Model-data mismatch over ecoregions

It is also helpful to break the model-data mismatch into regional domains (Fig. 11) to obtain more insight into where the observed and modeled concentrations diverge, and whether the difference can be attributed to the underlying fluxes or deficiencies in the model’s atmospheric transport. For most regions and times of year, the difference in average CO<sub>2</sub> enhancements is not statistically significant; however, there are certain regions such as the Northern Tundra of Alaska, where the modeled average CO<sub>2</sub> enhancements are significantly different and amplify a pattern that is observed over other regions. In early spring, the model slightly overestimates observed boundary layer enhancements but a month later the model underestimates drawdown. Figures 6 and 11 suggest that the model drawdown in CO<sub>2</sub> preceding the observed early-summer CO<sub>2</sub> drawdown. The difference between observed and modeled enhancements change sign again during the July flight in Northern Tundra Alaska with an underestimation of the drawdown. Similar patterns can be observed in the Canadian Boreal Cordillera, suggesting that the timing of the summertime drawdown is too early in the model in this region. Over the same period, however, comparisons over the Western Alaska Tundra depict opposite patterns (although far more subtle). While the offsets in the fall months are smaller, there is the suggestion that the enhancements in the Southern Arctic and Canadian Taiga ecoregions are both underestimated in the model. For CH<sub>4</sub>, the seasonal bias (underestimation in the spring and overestimation between July-September) in the integrated enhancements between observations and models stands out as the most significant feature. The notable exceptions are again the Northern Tundra of Alaska and Canadian Boreal Cordillera, where CH<sub>4</sub> enhancements in July and at the end of October are significantly underestimated. For reasons explained earlier, the CO comparison is less informative. However, if one were to analyze data from the month of September, which had no significant influence from fires in the free troposphere, it would suggest that the model continues to underestimate the impact of CO emissions across all regions.

### 3.1.11 Separating local, region and global vertical gradients

By extracting enhancements below 3000 masl from the observations and the model we have largely separated two major sources of biases and uncertainty in a model-data comparison – vertical transport and offsets in background mole fraction. However, it should be acknowledged that gradients between the boundary layer and free troposphere are not controlled exclusively by local fluxes and that in the Arctic, in particular, vertical gradients can be controlled by non-local influences. To explore the impact of long-range transport Parazoo et al. (2016) performed three simulations to better understand the drivers of the vertical gradient over Alaska and found that 48% of the amplitude (April/May-July/August) in the seasonal vertical gradient was driven by local fluxes from Alaska while the rest was

465 driven by fluxes from the rest of the Arctic (11%) and low latitude (<60N, 41%). For CO<sub>2</sub>, the impact of  
long-range transport to the vertical gradient is complicated by the difference in timing of the initial  
drawdown in the spring and the uptick in the fall at low latitudes versus that of high latitudes. The  
earlier drawdown of CO<sub>2</sub> at low latitudes and the transport of that air via the free troposphere to Arctic  
significantly reduces the negative vertical gradient in the Arctic. At the same time, the early uptick of  
470 CO<sub>2</sub> mole fraction in the Arctic relative to the low latitudes enhances the positive vertical gradient in the  
early fall (Parazoo et al., 2016).

To account for the background vertical gradient in CH<sub>4</sub> entering the contiguous US, Baier et al. (2020)  
and Lan et al. (2019) subtracted 12-15 ppt from the vertical gradient to account for a preexisting  
gradient in CH<sub>4</sub> coming onto the continent. Analysis of the background gradient suggests that this  
475 preexisting vertical gradient is a combination of upstream emissions and wind shear which separates the  
origin of the boundary layer air from that of the free troposphere. Large meridional gradients in CH<sub>4</sub>,  
such as those observed in the mid latitudes, will drive depletion of the free troposphere relative to that  
of the boundary layer over the Arctic. Similarly, CO vertical gradients will also be affected by non-local  
fluxes and wind shear between the boundary layer and the free troposphere. In the case of CO and CH<sub>4</sub>  
480 there is also likely to be a vertical gradient that is influenced by the oxidation of these molecules.  
However, given the relatively long residence time of these molecules and the low sampling altitude in  
the free troposphere (between 3000 and 5000 masl) of this experiment, this effect is small.  
From this perspective, the preexisting vertical gradient outside the domain of interest illustrates the  
importance of the model accuracy in non-local fluxes and the importance of long-range transport in the  
485 analysis. One approach ensuring a better boundary conditions is to use a global inversion (e.g.  
CarbonTracker (Peters et al., 2007)) to initialize the local region where the prognostic flux model is  
then run to simulate local fields as is done to initialize regional Lagrangian inversion models (e.g. Hu et  
al., 2019).

## 490 4 Conclusions

The Arctic-CAP campaign was composed of 6 different research missions from April to November  
2017. It sampled CO<sub>2</sub>, CH<sub>4</sub> and CO vertical profiles from the surface to 5000 masl across the ABoVE  
domain in Alaska and Northwestern Canada, covering 6 major Arctic ecoregions. Arctic-CAP airborne  
surveys included large Tundra and Boreal ecosystems that are the likely sources of large changes in the  
495 seasonal cycle of CO<sub>2</sub> and have been the subject of great speculation about future emissions of CH<sub>4</sub>.  
Arctic-CAP's CO<sub>2</sub>, CH<sub>4</sub> and CO profiles provide an excellent basis for evaluating the surface flux  
models used within state-of-the-art atmospheric transport models, and thus, are an important tool for  
understanding carbon cycle feedbacks. Comparisons of Arctic-CAP CO<sub>2</sub>, CH<sub>4</sub> and CO observations  
against GEOS model results show that: (a) for CO<sub>2</sub>, the flux model (land and ocean biosphere and fossil  
500 fuel) reproduces seasonal and regional depletions and enhancements observed by aircraft profiles after  
adjusting for small systematic offsets; (b) for CH<sub>4</sub>, the model simulations agree reasonably well with the  
observed vertical profiles, but the model underestimates CH<sub>4</sub> in the spring and overestimates it in the  
fall. Modeled North Slope CH<sub>4</sub> is underestimated throughout the measurement period pointing to

505 deficiencies in the wetland flux specifications over this ecoregion; and (c) for CO, the comparison  
between modeled and observed values were confounded by large biomass burning enhancements in the  
free troposphere that were not captured in the model. Despite these minor shortcomings, the forward  
model estimates for CO<sub>2</sub> and CH<sub>4</sub> represent a marked improvement in model-data differences compared  
to those done previously for CARVE (Chang et al., 2014; Commane et al., 2017). Results and the flux  
budgets demonstrate that model representation of CO<sub>2</sub> and CH<sub>4</sub> for northern high-latitude ecosystems  
510 have advanced significantly since the state-of-the-science survey by Fisher et al. (2014). Inversions of  
the Arctic-CAP data using these fluxes as the prior estimate should further refine the flux estimates and  
the budget for the ABoVE domain. We note that our comparisons used only GEOS forward model  
values and slightly different model-data mismatches may be obtained by using a different transport  
model.

515 Finally, this study highlights the value of collocated airborne CO<sub>2</sub>, CH<sub>4</sub> and CO vertical profiles for  
quantifying model strengths and weaknesses. This feedback is essential to improve model  
characterization of both surface-atmosphere fluxes and atmospheric transport and to improve our  
confidence in the accuracy of projections of future conditions. We strongly recommend regular,  
systematic CO<sub>2</sub>, CH<sub>4</sub> and CO vertical profile observations across the Arctic as an important and cost-  
520 effective method to monitor the Arctic system and abrupt transformations or potential tipping points in  
the permafrost carbon feedback.

## 5 Data Availability

Aircraft data can be found at <https://doi.org/10.3334/ORNLDAAAC/1658>

## 10 Author contributions

CS, KM, CM, AC did experimental design. CS, TN, SW, KM carried out experiment. CS, AC, CM, RB, SW, LS, LH helped with manuscript.

## 535 11 Competing interests

The authors declare that they have no conflict of interest.

## 14 Acknowledgements

This research was supported by the NASA Terrestrial Ecology Program award #NNX17AC61A, “Airborne Seasonal Survey of CO<sub>2</sub> and CH<sub>4</sub> Across ABOVE Domain”, as part of the Arctic-Boreal Vulnerability Experiment (ABOVE). A portion of the research presented in this paper was performed at  
545 the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. GEOS model runs and the work of AC was supported by funding from the NASA ROSES-2016 Grant/Cooperative Agreement NNX17AD69A.

755

Figure. 1. The Arctic-CAP surveys were designed to sample the Arctic boreal ecosystems of the ABoVE domain. Black text labels represent the six ecoregions covered by this study and white text denote cities and states / provinces. Gray dots depict the locations on which the Arctic-CAP vertical profiles were centered (© Google Earth).

760

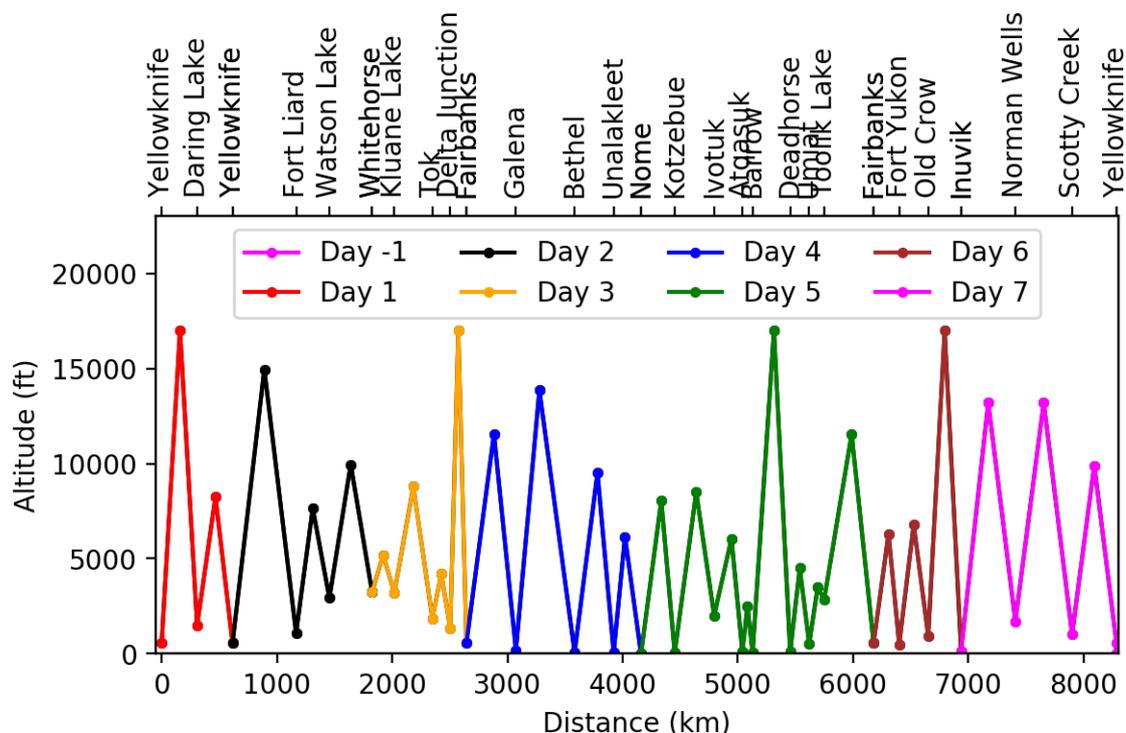

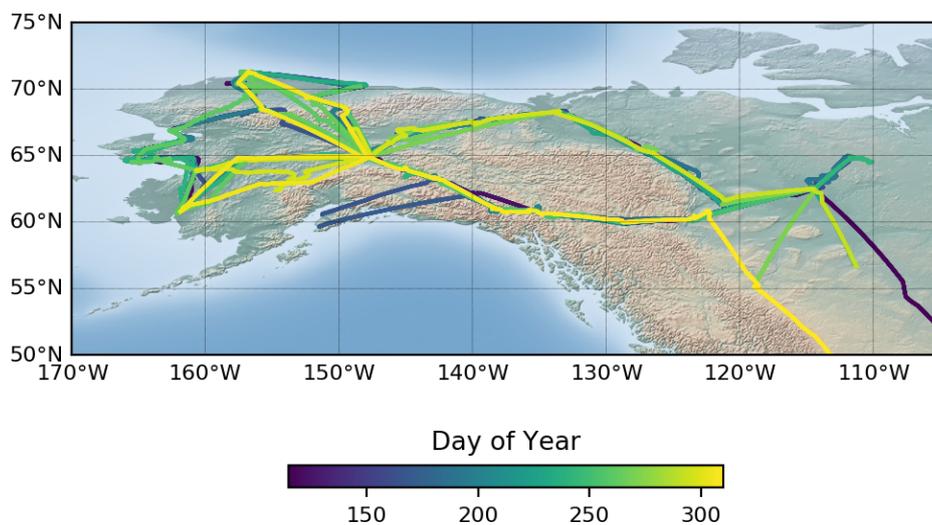

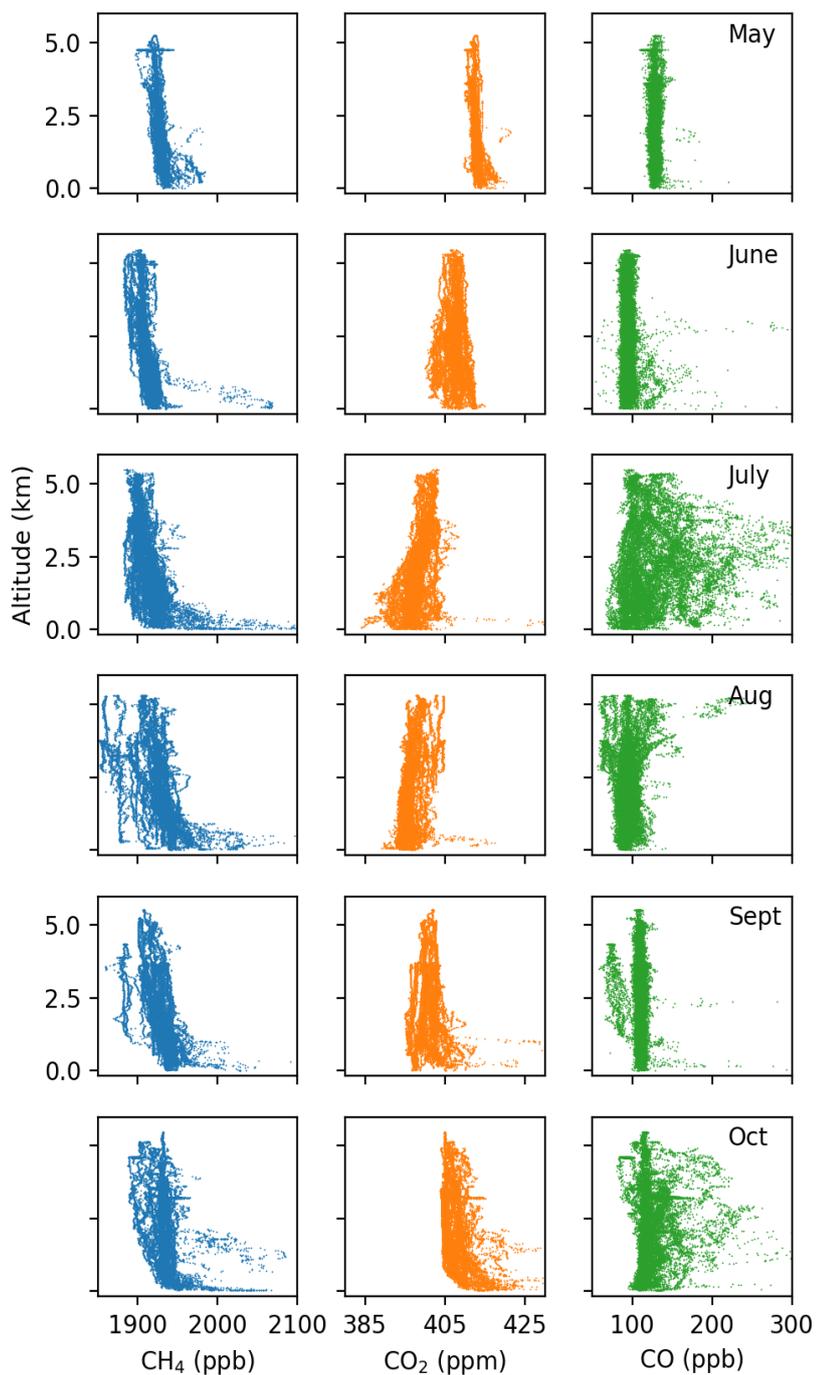

Figure 2. Locations and maximum altitudes of the 25 vertical profiles that were acquired during each Arctic-CAP campaign. The colors match the flight lines illustrated in Fig. 1.

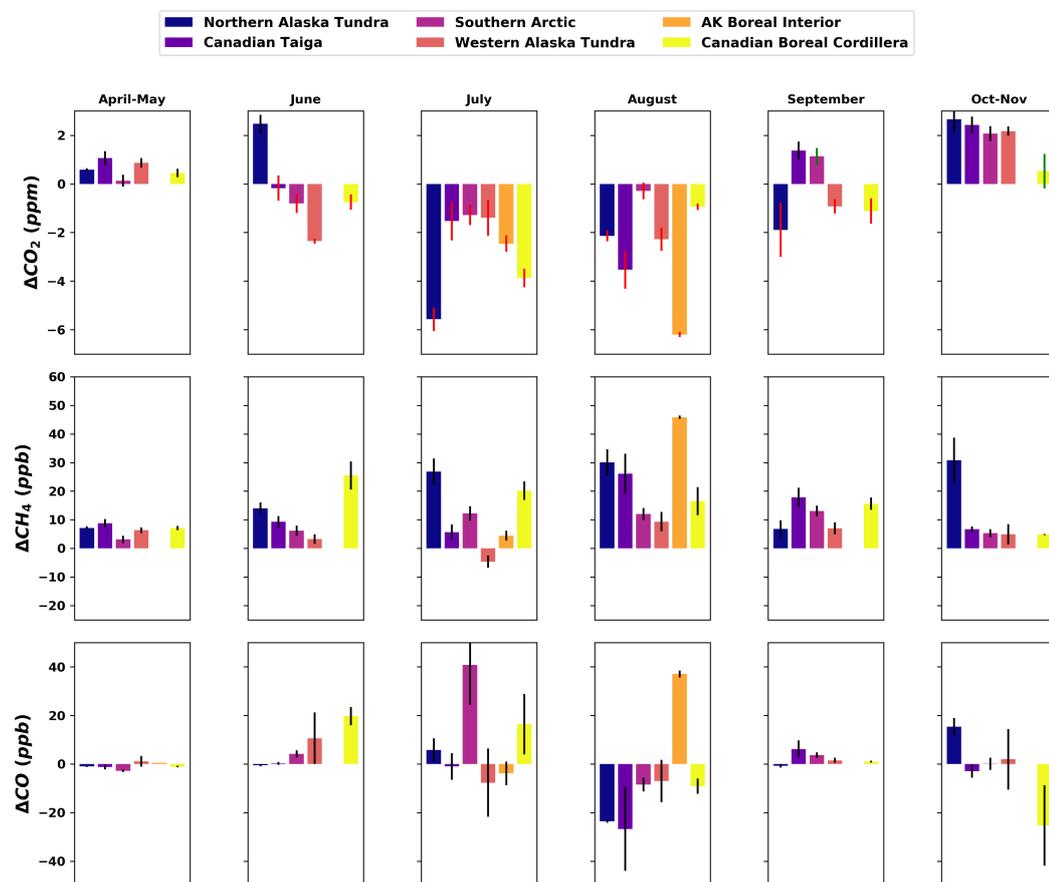

765

Figure 3 Arctic-CAP flight paths colored by day of year (DOY). Later paths are plotted on top, masking flights from earlier in the year along the same routes. Profile locations span 50-75 °N and 105-165 °W and sampled environmental conditions from the spring thaw (~DOY 125) through the early cold season (> DOY 300) (© Google Maps).

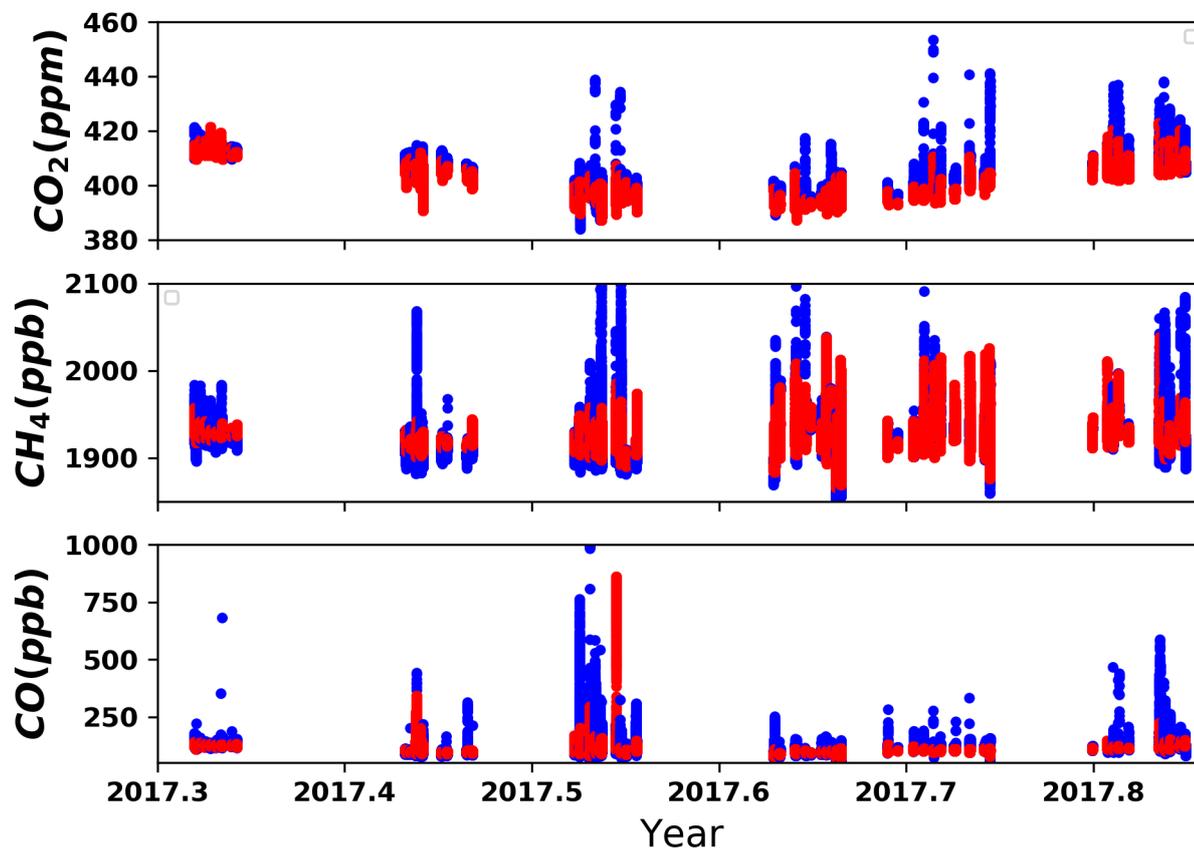

770

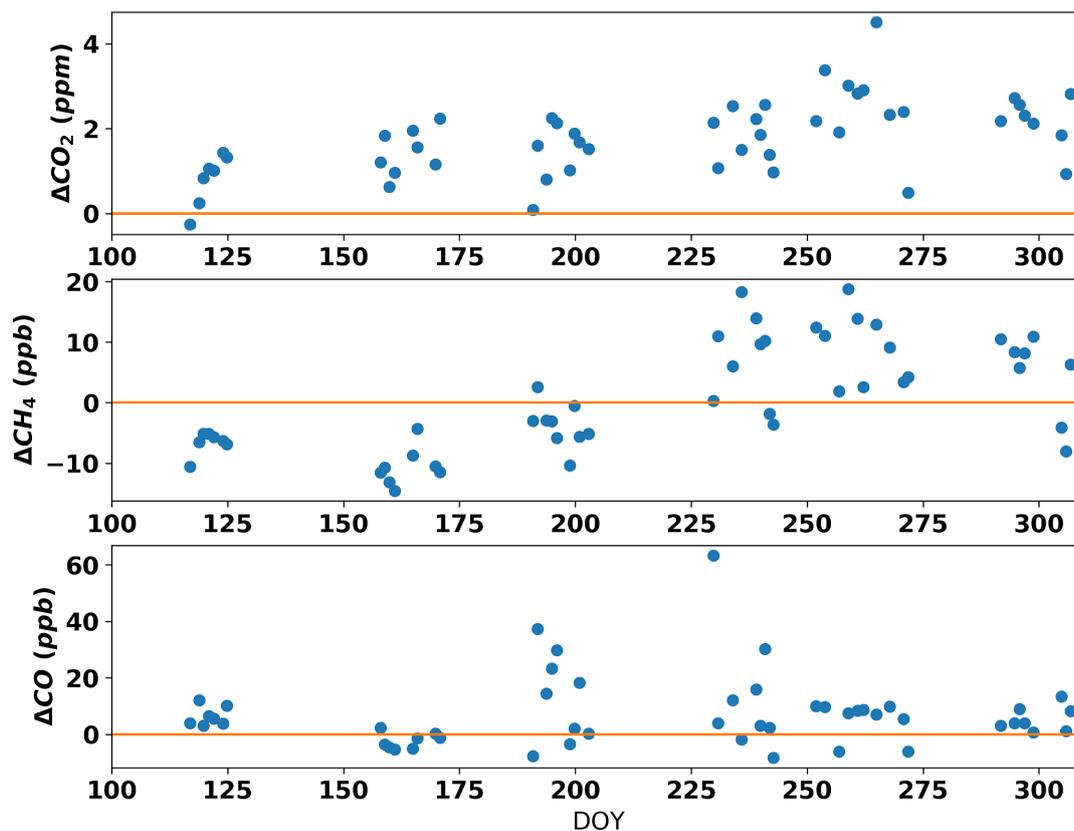

**Figure 4. Composite plots of the CH<sub>4</sub> (left column), CO<sub>2</sub> (center column) and CO (right column) measurements acquired during the Arctic-CAP airborne campaign in 2017.**

775 **Figure 5.** Average gradient between the mean free daily troposphere (> 3000 masl for  $\text{CO}_2$  and  $\text{CH}_4$  and 4000 masl for  $\text{CO}$ ) and measurements made below 3000 masl during each campaign. Colors refer to the six ecoregions identified in Fig. 1.

780 Figure 6. Comparisons of GEOS simulated atmospheric CO<sub>2</sub>, CH<sub>4</sub> and CO (red points) versus observed CO<sub>2</sub>, CH<sub>4</sub> and CO (blue points) during the Arctic-CAP 2017 campaign show good agreement across campaigns, although the observed data exhibit larger extremes.

785 **Figure 7.** Difference (observations-model) between mean daily free troposphere (3000-5000 masl for CO<sub>2</sub> and CH<sub>4</sub> and 4000-5000 masl for CO) for GEOS simulated and Arctic-CAP observed mole fractions. The GEOS simulations systematically underestimate the mean CO<sub>2</sub> in all months, while the model overestimates CH<sub>4</sub> before DOY 200 and underestimates CH<sub>4</sub> after DOY 200. Simulated CO observations generally agree with the atmospheric observations, although there are sporadic underestimates likely associated with incorrectly modeled fire plumes.

790

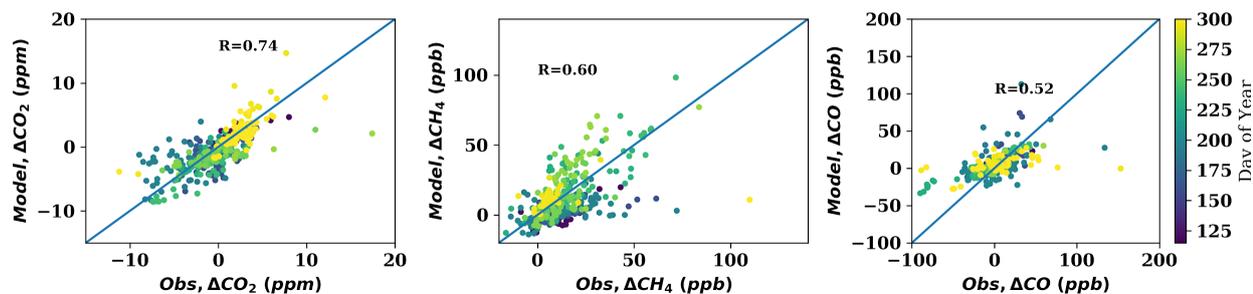

Figure 8. Modeled versus observed average boundary layer enhancements or depletions in CO<sub>2</sub>, CH<sub>4</sub> and CO for individual profiles from 3000 masl down to the surface level.

795

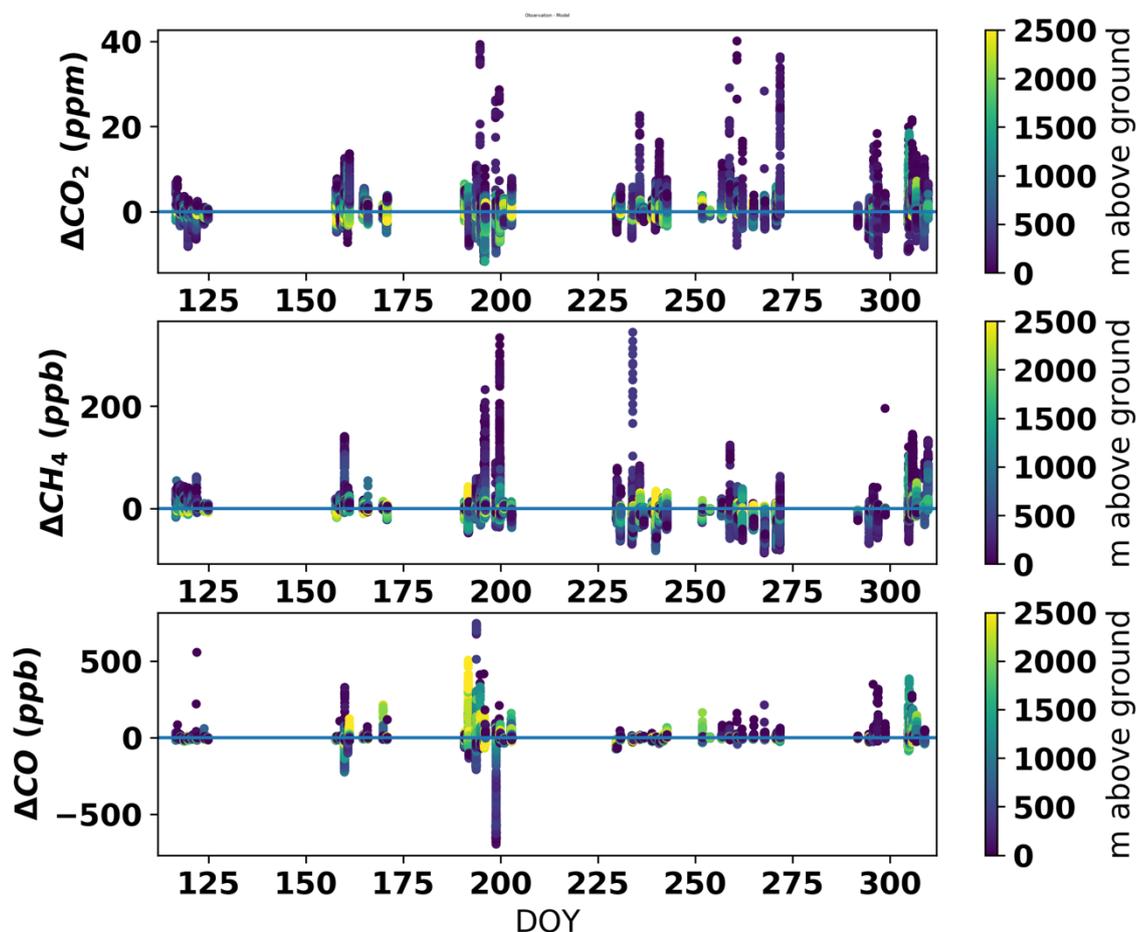

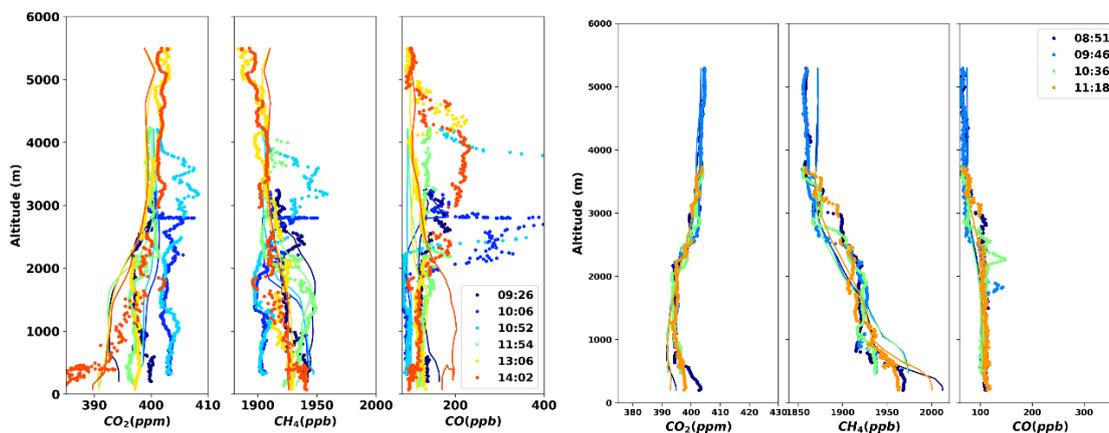

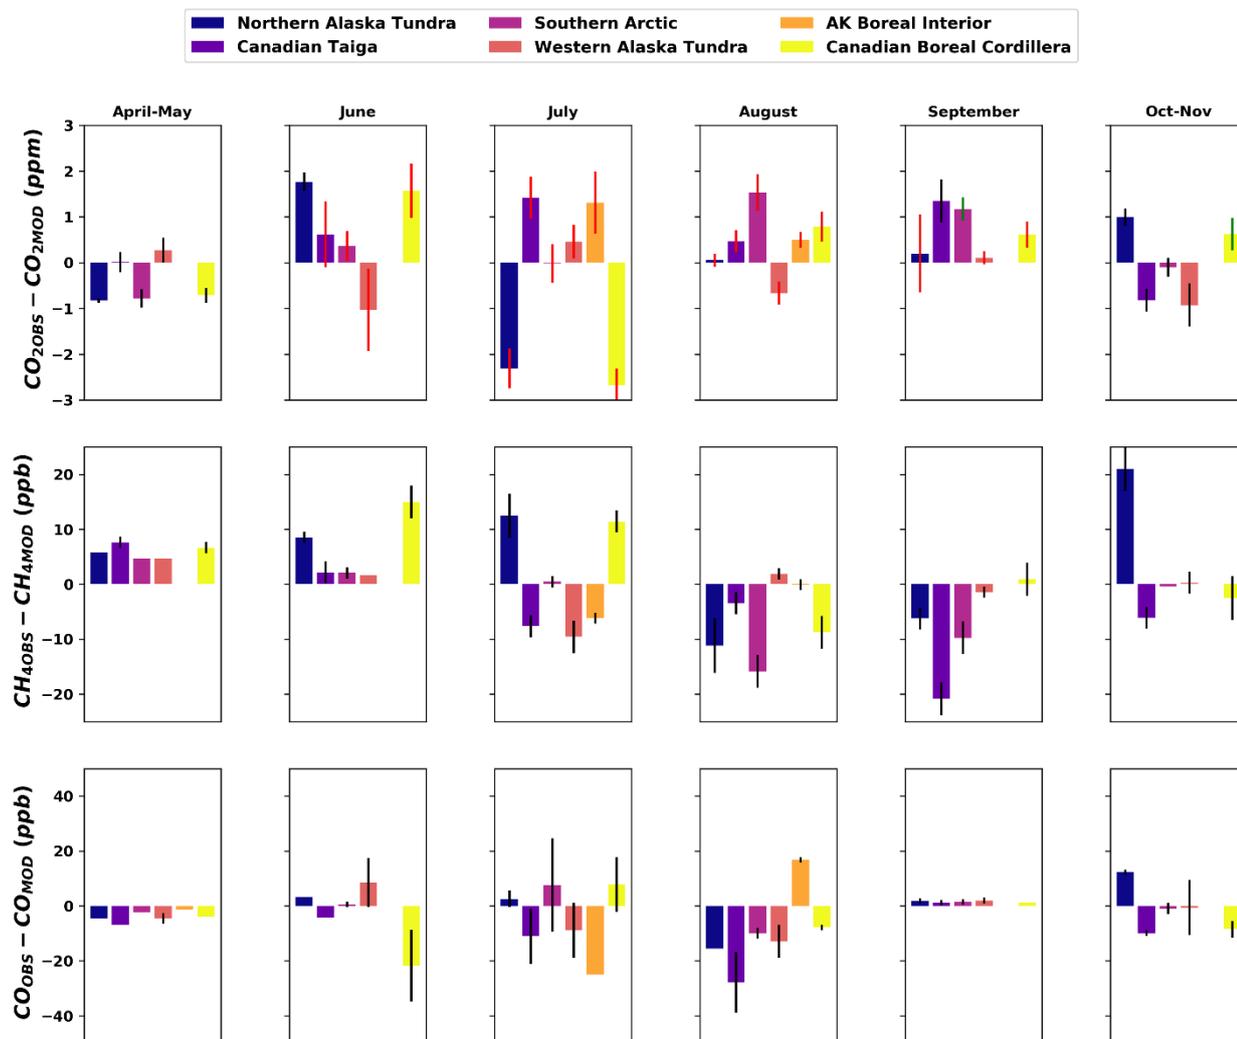

Figure 9. Observation-model differences in mole fractions below 3000 masl. Corrections have been made for observation-model offsets above 3000 masl (Fig. 7). Colors show the altitude of each deviation. Dark blue indicates differences near the surface while yellow indicates differences near 3000 masl.

800

**Figure 10. Observation (dotted lines) and model estimates (thin lines) of profiles on July 10, 2017 (left) and August 30, 2017 (right) from a transect up the Mackenzie River in the Northwest Territory of Canada. Dotted lines show observations and thin lines show model estimates corresponding to specific times during the transect.**

805 **Figure 11. Average observation–model integrated enhancement differences by ecoregion. Standard deviation of differences for each region are shown with black and red bars. Red (black) bars signify a negative (positive) average enhancement below 3000 meters relative to the daily mean tropospheric value above 3000 masl for CO<sub>2</sub> and CH<sub>4</sub> and above 4000 masl for CO.**
