37 Abstract:

38 The atmospheric carbon dioxide (CO₂) mixing ratio and its carbon isotope ($\delta^{13}\text{C-CO}_2$) composition
39 contain important CO₂ sink and source information spanning from ecosystem to global scales. The
40 observation and simulation for both CO₂ and $\delta^{13}\text{C-CO}_2$ can be used to constrain regional emissions and
41 better understand the anthropogenic and natural mechanisms that control $\delta^{13}\text{C-CO}_2$ variations. Such work
42 remains rare for urban environments, especially megacities. Here, we used near-continuous CO₂ and
43 $\delta^{13}\text{C-CO}_2$ measurements, from September 2013 to August 2015, and inverse modeling to constrain the
44 CO₂ budget and investigate the main factors that dominated $\delta^{13}\text{C-CO}_2$ variations for the Yangtze River
45 Delta (YRD) region, one of the largest anthropogenic CO₂ hotspots and densely populated regions in
46 China. We used the WRF-STILT model framework with category-specified EDGAR v4.3.2 CO₂
47 inventories to simulate hourly CO₂ mixing ratios and $\delta^{13}\text{C-CO}_2$, evaluated these simulations with
48 observations, and constrained the total anthropogenic CO₂ emission. We show that: (1) Top-down and
49 bottom-up estimates of anthropogenic CO₂ emissions agreed well (bias < 6%) on an annual basis; (2) The
50 WRF-STILT model can generally reproduce the observed diel and seasonal atmospheric $\delta^{13}\text{C-CO}_2$
51 variations; (3) Anthropogenic CO₂ emissions played a much larger role than ecosystems in controlling the
52 $\delta^{13}\text{C-CO}_2$ seasonality. When excluding ecosystem respiration and photosynthetic discrimination in the
53 YRD area, $\delta^{13}\text{C-CO}_2$ seasonality increased from 1.53‰ to 1.66‰; (4) Atmospheric transport processes in
54 summer amplified the cement CO₂ enhancement proportions in the YRD area, which dominated monthly
55 δs (the mixture of $\delta^{13}\text{C-CO}_2$ from all regional end-members) variations. These findings support that the
56 combination of long-term atmospheric carbon isotope observations and inverse modeling can provide a
57 powerful constraint on the carbon cycle of these complex megacities.

71 1. Introduction

72 Urban landscapes account for 70% of global CO₂ emissions and represent less than 3% of Earth's land
73 area (Seto et al., 2014). Such CO₂ hotspots play a dominant role in controlling the rise in atmospheric CO₂
74 concentrations, which exceeded 412 ppm in December 2019 for global monthly average observations
75 (<https://www.esrl.noaa.gov/gmd/ccgg/trends/>). Furthermore, the carbon isotope ratio of CO₂ (i.e. $\delta^{13}\text{C} =$
76 $^{13}\text{C}/^{12}\text{C}$ ratio in delta notation) at the representative Mauna Loa site, USA, has steadily decreased to
77 around -8.5‰, in December 2019 (<https://www.esrl.noaa.gov/>). Anthropogenic CO₂ emission is produced
78 from fossil fuel burning and cement production. As the urban population is expected to increase by 2.5 to
79 6 billion people in 2050, anthropogenic CO₂ emissions are projected to increase dramatically, especially
80 in developing regions and countries (Sargent et al., 2018; Ribeiro et al., 2019). Under such a scenario, the
81 observations of atmospheric CO₂ and $\delta^{13}\text{C}\text{-CO}_2$ in urban landscapes are of great importance to monitoring
82 these potential CO₂ emissions hotspots (Lauvaux et al., 2016; Nathan et al., 2018; Graven et al., 2018;
83 Pillai et al., 2016; Staufer et al., 2016).

84 Countries are required to report their CO₂ emissions according to the Intergovernmental Panel on Climate
85 Change guidelines (IPCC, 2019), and many “bottom-up” methods have long been used to estimate CO₂
86 emissions worldwide, but such methods have high uncertainties for CO₂ emissions at regional (20%) to
87 city (50 to 250%) scales (Gately & Hutyra, 2017; Gately et al., 2015). These large uncertainties are
88 propagated into the estimation of biological fluxes in atmospheric inversions (Zhang et al., 2014; Jiang et
89 al., 2014; Thompson et al., 2016). By using CO₂ observations, the “top-down” atmospheric inversion
90 approach is a useful tool to evaluate “bottom-up” inventories (Graven et al., 2018; L. Hu et al., 2019;
91 Lauvaux et al., 2016; Nathan et al., 2018). Previous research has shown that additional information, such
92 as data on atmospheric $\Delta^{14}\text{CO}_2\text{-CO}_2$, $\delta^{13}\text{C}\text{-CO}_2$, and CO, is needed to better distinguish CO₂ emissions
93 from different sources and to assess their uncertainties (Chen et al., 2017; Graven et al., 2018; Nathan et
94 al., 2018; Cui et al., 2019). The use of hourly $\delta^{13}\text{C}\text{-CO}_2$ observation in urban areas remains rare in
95 inversion studies, yet such observations contain invaluable information of anthropogenic CO₂ from
96 different categories.

97 Traditional estimates of $\delta^{13}\text{C}\text{-CO}_2$ using isotope ratio mass spectrometry (IRMS) are very limited because
98 flask air sample collection requires long preparation time and is expensive. Consequently, there is a lack
99 of high temporal and long-term observations of $\delta^{13}\text{C}\text{-CO}_2$ (Sturm et al., 2006). Isotope ratio infrared
100 spectroscopy technology (IRIS) has overcome these limitations. As a result, *in situ* air sample analyses
101 using IRIS analyzers are resulting in dense time series of $\delta^{13}\text{C}\text{-CO}_2$. However, most of the established

102 long-term IRMS and IRIS $\delta^{13}\text{C}$ -CO₂ measurement sites are representative of “background”, natural, or
103 agricultural ecosystems at locations far away from urban landscapes (Chen et al., 2017; Griffis, 2013).

104 To date, long-term (> 1 year) and continuous observations of both CO₂ and $\delta^{13}\text{C}$ -CO₂ have been reported
105 for only five cities, including Bern, Switzerland (Sturm et al., 2006); Boston, USA (McManus et al.,
106 2010); Salt Lake City, USA (Pataki et al., 2006); Beijing, China (Pang et al., 2016); and Nanjing, China
107 (Xu et al., 2017). In these previous investigations, significant diel and seasonal variations of $\delta^{13}\text{C}$ -CO₂
108 have been observed; these patterns were modulated by fossil fuel combustion, plant respiration and
109 photosynthesis, and changes in the height of the atmospheric boundary layer (Sturm et al., 2006; Guha
110 and Ghosh, 2010). No study has quantified the impact of each factor on the seasonal variation of $\delta^{13}\text{C}$ -
111 CO₂. This represents an important knowledge gap in understanding the underlying mechanisms of carbon
112 cycling in complex urban ecosystems.

113 The traditional $\delta^{13}\text{C}$ -CO₂ isotope partitioning methods (including Miller-Tans and the Keeling plot
114 approaches) have been used to constrain different CO₂ sources worldwide (Keeling, 1960; Vardag et al.,
115 2015; Newman et al., 2016; Pang et al., 2016; Xu et al., 2017). These methods are based on the
116 assumption that partitioned atmospheric CO₂ enhancement components from different sources can
117 represent CO₂ emissions at the “target area” (Miller and Tans, 2003; Ballantyne et al., 2011). Carbon
118 dioxide emissions are highly inhomogeneous at the urban scale, with extremely strong point/line sources,
119 and the final partitioning results are highly uncertain without considerations of source footprint
120 characteristics (Gately & Hutyra, 2017; Cui et al., 2019; Martin et al., 2019). Atmospheric transport
121 models can help to resolve such problems, and the coupling of atmospheric transport models with isotope
122 observations have recently been applied in global and regional CO₂ partitioning studies (Chen et al., 2017;
123 Cui et al., 2019; Graven et al., 2018; C. Hu et al., 2018b). Although urban CO₂ inversions have been
124 applied successfully in several studies in Europe and the United States (Bréon et al., 2015; Turnbull et al.,
125 2015; Pillai et al., 2016; Brioude et al., 2013; Turner et al., 2016), urban CO₂ inversions in China are
126 rare (Berezin et al., 2013; C. Hu, 2018a; Worden et al., 2012), presumably because of the scarcity of high
127 quality $\delta^{13}\text{C}$ -CO₂ and CO₂ observations.

128 The Yangtze River Delta (YRD) ranks as one of the most densely populated regions in the world and is
129 an important anthropogenic CO₂ hotspot. Major anthropogenic sources include the power industry, oil
130 refineries/transformation and cement production. Having the largest source of cement-derived CO₂
131 production across China and the world (Cai et al., 2015), the YRD contributed 20% of national cement
132 production, nearly 12% of world’s total cement output in 2014 (USGS, 2014; Xu et al., 2017; Yang et al.,
133 2017). In addition to anthropogenic factors, natural ecosystems and croplands act as significant CO₂ sinks
134 and sources within the YRD. Independent quantification of the fossil and cement CO₂ emission and

135 assessment of their impact on atmospheric $\delta^{13}\text{C-CO}_2$ have potential to improve our understanding of
136 urban CO_2 cycling. Further, the observations and simulations of both atmospheric CO_2 and $\delta^{13}\text{C-CO}_2$ can
137 help us relate atmospheric CO_2 dynamics with future emission control strategies.

138 Here, we combine long-term (>2 years) CO_2 and $\delta^{13}\text{C-CO}_2$ observations with atmospheric transport
139 model simulations to study urban atmospheric CO_2 and $\delta^{13}\text{C-CO}_2$ variations. The objectives were to: (1)
140 Constrain anthropogenic CO_2 emissions and determine the main sources of uncertainty for $\delta^{13}\text{C-CO}_2$
141 simulations, and (2) Quantify the relative contributions of each factor (i.e. background, anthropogenic
142 CO_2 emissions especially for cement production, ecosystem photosynthesis and respiration) to seasonal
143 variations of atmospheric $\delta^{13}\text{C-CO}_2$.

144 2. Materials and methods

145 2.1 Observations of atmospheric CO_2 mixing ratio, $\delta^{13}\text{C-CO}_2$ and supporting variables

146 The observation site is located on the Nanjing University of Information Science and Technology campus
147 (hereafter NUIST, $32^\circ 12' \text{N}$, $118^\circ 43' \text{E}$, green dot in Figure 1a). Continuous atmospheric CO_2 mixing
148 ratios and $\delta^{13}\text{C-CO}_2$ were measured at a height of 34 m above ground with an IRIS analyzer (model
149 G1101-i, Picarro Inc., Sunnyvale, CA). The observation period extended from September 2013 to August
150 2015. Calibrations for CO_2 mixing ratio and $\delta^{13}\text{C-CO}_2$ were conducted with standard gases traceable to
151 NOAA/GML (NOAA Global Monitoring Laboratory) standards. Calibration details are provided by Xu et
152 al. (2017). Based on Allan variance analyses, the hourly precisions of CO_2 and $\delta^{13}\text{C-CO}_2$ were 0.07 ppm
153 and 0.05‰, respectively. We note that the $\delta^{13}\text{C-CO}_2$ IRIS (model G1101-i) measurements are sensitive to
154 water vapor concentration. Sensitivity tests reveal that the $\delta^{13}\text{C-CO}_2$ IRIS measurements are biased high
155 (less than 0.74‰) when water vapor mole fraction exceeds 2%. The data presented here have been
156 corrected following the procedures outlined in Xu et al. (2017).

157 We separated the two-year study period into seasons (autumn: September, October, November; winter:
158 December, January, February; spring: March, April, May; summer: June, July, August). Further, for an
159 annual comparison, we examined the period from September 2013 to August 2014 (Year 2014) versus
160 September 2014 to August 2015 (Year 2015).

161 The YRD is a cement production hotspot in China (Figure 1b). It had a total population of 190 million in
162 2018 (Figure 2a) with 24.2 million in the city of Shanghai, 9.8 million in Hangzhou city (provincial
163 capital of Zhejiang), 8.4 million in Nanjing city (provincial capital of Jiangsu), and 8.1 million in Hefei
164 city (provincial capital of Anhui). The CO_2 related production data (i.e. cement) and energy consumption
165 data (i.e. coal and natural gas) were obtained from local official sources using the same method described
166 in Shen et al. (2014).

167 To examine the effects of plant photosynthesis on atmospheric CO₂ variations, we used NDVI
 168 (Normalized Difference Vegetation Index), SIF (solar-induced chlorophyll fluorescence) and GPP (gross
 169 primary productivity) information. These three products have a global distribution with spatial resolution
 170 of 0.05° by 0.05°. The NDVI has a temporal resolution of 16 days and SIF and GPP products have a
 171 temporal resolution of 8 days (Li & Xiao, 2019; <http://globalecology.unh.edu/data/>). Land-use and land-
 172 cover classification in Yangtze River Delta for 2014 was applied by using NDVI data from MOD13A2.

173 2.2 Simulation of atmospheric $\delta^{13}\text{C-CO}_2$

174 2.2.1 General equations

175 The simulation of atmospheric $\delta^{13}\text{C-CO}_2$ is based on mass conservation. First, we briefly describe the
 176 simulation of atmospheric CO₂ mixing ratios (more details are provided in Section 2.2.2), following the
 177 previous work of Hu et al., (2018b), where atmospheric CO₂ was simulated (CO_{2_sim}) as the sum of
 178 background (CO_{2_bg}) and the contribution from all regional sources/sinks ($[\Delta\text{CO}_{2_sim}]_i$), as

$$179 \quad \text{CO}_{2_sim} = \text{CO}_{2_bg} + \sum_{i=1}^n [\Delta\text{CO}_{2_sim}]_i \quad (1)$$

180 Note that ΔCO_2 is the sum of all simulated sources/sinks $[\Delta\text{CO}_{2_sim}]_i$ and represents the total simulated
 181 CO₂ enhancement. We use ΔCO_{2_obs} as the observed CO₂ total enhancement, which can be calculated by
 182 using the CO₂ observation minus the CO₂ background values. Based on mass conservation, we estimated
 183 the ¹³CO₂ composition by multiplying the left- and right-hand sides of equation (1) by $\delta^{13}\text{C}$,

$$184 \quad \delta^{13}\text{C}_{a_sim} = \frac{\delta^{13}\text{C}_{bg} \times \text{CO}_{2_bg} + \sum_{i=1}^n \delta_i^{13} \times [\Delta\text{CO}_{2_sim}]_i}{\text{CO}_{2_sim}} \quad (2)$$

185 where $\delta^{13}\text{C}_{a_sim}$ and $\delta^{13}\text{C}_{bg}$ represent the simulated atmospheric $\delta^{13}\text{C-CO}_2$ and background $\delta^{13}\text{CO}_2$, δ_i^{13} is
 186 the $\delta^{13}\text{C-CO}_2$ for end-member i (including anthropogenic and biological source categories). The $\delta^{13}\text{C-}$
 187 CO₂ contributions from all regional sources/sinks can be further reformatted as equation 3,

$$188 \quad \sum_{i=1}^n \delta_i^{13} \times [\Delta\text{CO}_{2_sim}]_i = \delta_{s_sim} \times \sum_{i=1}^n [\Delta\text{CO}_{2_sim}]_i \quad (3)$$

189 where δ_{s_sim} is the simulated enhancement-weighted mean of all regional end-members. We use δ_s as the
 190 observed term to distinguish it from δ_{s_sim} (Newman et al., 2008), which will be described in detail in
 191 section 2.2.5. The product on the right-hand side of equation 3 is the simulated regional source term that

192 is added to the background value and contains both enhancement and $\delta^{13}\text{C-CO}_2$ signals contributed by
 193 different CO_2 sources/sinks. This product can also be treated as an observed term when using the derived
 194 δ_{s_obs} and observed ΔCO_{2_obs} values.

195 To date, there are no available global $\delta^{13}\text{C-CO}_2$ background products and the choice of $\delta^{13}\text{C}_{bg}$ is essential
 196 to simulating $\delta^{13}\text{C}_a$. Here, we apply three strategies. First, we used discrete $\delta^{13}\text{C-CO}_2$ flask observations
 197 at Mount Waliguan (hereafter WLG, 36°17'N, 100°54'E; <https://www.esrl.noaa.gov/gmd/dv/data/>) to
 198 represent the $\delta^{13}\text{C-CO}_2$ background signal at our site. These observations were measured at weekly
 199 intervals to the end of 2015. A digital filtering curve fitting (CCGCRV) regression method was applied to
 200 derive hourly background values following Thoning et al. (1989). There are, however, reasons why WLG
 201 may not be an ideal background site for our study domain. For example, based on the previous simulation
 202 results for the CO_2 background sources, most of the back trajectories originate from the free atmosphere
 203 or 1000 m higher above the ground (Hu et al., 2019). Further, the footprint at the north/west edge of
 204 Domain 1 is relatively small, indicating that most back trajectories were observed above the planetary
 205 boundary layer height (hereafter PBLH). Here, the WLG observations were made near the surface.
 206 Further, WLG is not located at the border of our simulation domain 1. Therefore, the strong vertical $\delta^{13}\text{C-}$
 207 CO_2 gradients between the boundary layer and the free tropospheric atmosphere (Chen et al., 2006; Guha
 208 et al., 2010; Sturm et al., 2013) can cause a low bias in the $\delta^{13}\text{C-CO}_2$ background when using this
 209 approach.

210 In the second approach, the $\delta^{13}\text{C-CO}_2$ background signal was estimated with wintertime “clean” air CO_2
 211 and $\delta^{13}\text{C-CO}_2$ observations at the NUIST site, using the following equation

$$212 \quad \delta^{13}C_{bg} = \frac{\delta^{13}C_a \times \text{CO}_2 - \sum_{i=1}^n \delta_i^{13} \times [\Delta\text{CO}_{2_sim}]_i}{\text{CO}_{2_bg}} \quad (4)$$

213 where $\delta^{13}\text{C}_a$ and CO_2 represent atmospheric $\delta^{13}\text{C-CO}_2$ and CO_2 observations at the NUIST site under
 214 clean conditions. Note that $\delta^{13}\text{C}_a$ represents the observed $\delta^{13}\text{C-CO}_2$ not the simulated $\delta^{13}\text{C-CO}_2$ ($\delta^{13}\text{C}_{a_sim}$)
 215 as shown in equation 2. $[\Delta\text{CO}_{2_sim}]_i$ is the simulated category-specified CO_2 enhancements. We defined
 216 clean conditions as the bottom 5% wintertime CO_2 observations to minimize simulated CO_2 enhancement
 217 errors from both biological and anthropogenic CO_2 simulations on $\delta^{13}\text{C-CO}_2$ background calculation. The
 218 CO_{2_bg} is obtained from heights 1000 m above ground level (see Section 2.2.3).

219 In the third approach, we avoid the use of modeled $[\Delta\text{CO}_{2_sim}]_i$ results and replaced the simulated regional
 220 source term in equation 4 with observed $\delta_{s_obs} \times \Delta\text{CO}_{2_obs}$, as described in equation 3, and used the Miller-

221 Tans regression method to calculate monthly δ_{s_obs} . This approach does not require simulation of $[\Delta CO_2]_i$
 222 or the corresponding $\delta^{13}C-CO_2$ signals. The hourly $\delta^{13}C-CO_2$ background value can be derived by using
 223 δ_{s_obs} , CO_2 background, observed atmospheric $\delta^{13}C_a$ and CO_2 (see details in Section 2.3 and supplement
 224 materials). Comparison of these three strategies will be evaluated and discussed in Section 3.2.1. Similar
 225 methods used to derive other background tracers have included CO_2 (Alden et al., 2016; Verhulst et al.,
 226 2017), CO (Wang et al., 2010; Ruckstuhl et al., 2012) and CH_4 (Zhao et al., 2009; Verhulst et al., 2017;
 227 Hu et al., 2019). To analyze the controlling factors for the $\delta^{13}C-CO_2$ seasonality, the CCGCRV (a digital
 228 filtering curve fitting program developed by the Carbon Cycle Group, NOAA, USA) regression was
 229 applied to the background, observations, and simulations. Finally, we derived CCGCRV curve fitting
 230 lines by using 11 regressed parameters, which were based on the hourly time series of
 231 observations/simulations, and defined the difference between peak and trough in one year as the
 232 seasonality of $\delta^{13}C-CO_2$.

233 2.2.2 Simulation of atmospheric CO_2 mixing ratios

234 In equation 1, the CO_{2_bg} is obtained from the Carbon Tracker 2016 product, which provides global CO_2
 235 distributions from the ground level up to a height of 50 km. We used the averaged concentration above
 236 the latitude and longitude where the released particles entered the study domain 1 (Figure 1a). The
 237 variable ΔCO_{2_sim} was derived by multiplying the simulated hourly footprint function with the hourly CO_2
 238 fluxes (Hu et al., 2018a; b). Considering the diurnal variations of both anthropogenic and biological CO_2
 239 fluxes, 168 footprints were obtained representing each simulated hour. This accounted for the back
 240 trajectory of particle movement for 168 hours (i.e. 24 hours per day for 7 days) of transport. The 168
 241 footprints are multiplied by the corresponding hourly CO_2 flux. The CO_2 fluxes contain anthropogenic
 242 CO_2 emissions, biological CO_2 flux and biomass burning. Here the anthropogenic CO_2 emission sources
 243 include power industry, combustion for manufacturing, non-metallic minerals production (cement), oil
 244 refineries/transformation industry, energy for building and road transportation. Theoretically, ΔCO_{2_sim}
 245 represents the CO_2 changes contributed by every pixel within the simulated domain. As shown by Hu et al.
 246 (2018a), most of the ΔCO_{2_sim} is contributed by sink/source activity within the YRD area. In order to
 247 quantify the relative contributions within the YRD area, we separated the study domain into 5 zones
 248 based on provincial administrative boundaries including Jiangsu, Anhui, Zhejiang, Shanghai, and the
 249 remaining area outside the YRD (Figure 2). The modeled CO_2 was calculated as follows:

$$250 \quad \Delta CO_{2_sim} = \sum_{i=1}^{168} flux_i \times footprint_i \quad (5)$$

251 where flux_i (units: $\text{mol m}^{-2} \text{s}^{-1}$) corresponds to each CO_2 flux category simulated for each domain for a
252 specific hour i , and footprint (units: $\text{ppm m}^2 \text{s}/\mu\text{mol}$) is the model simulated sensitivity of observed CO_2
253 enhancement to flux changes in each pixel. The i contains the hourly footprint during trajectory of particle
254 movement for 168 hours as described above. The CO_2 enhancement from each of the 5 zones were
255 simulated by multiplying CO_2 emissions in each province with the corresponding footprint.

256 2.2.3 WRF-STILT model configuration

257 The Stochastic Time-Inverted Lagrangian Transport (hereafter STILT) model was used to generate the
258 above footprint, which is defined as the sensitivity of atmospheric CO_2 enhancement to the upwind flux at
259 the receptor site (observation site). The meteorological fields used to drive the STILT model were
260 simulated with the Weather Research and Forecasting Model (WRF3.5) at high spatial and temporal
261 resolutions. The innermost nested domain (D3, $3 \text{ km} \times 3 \text{ km}$, Figure 1) contains the YRD area, where the
262 most sensitive footprint is located, and the intermediate domain (D2, $9 \text{ km} \times 9 \text{ km}$) and outermost (D1, 27
263 $\text{km} \times 27 \text{ km}$) represent Eastern China and Central and Eastern China, respectively. The same physical
264 schemes and parameter setup for the WRF meteorological fields simulation and the Domain in the STILT
265 model have been used previously for inverse analyses (Hu et al., 2019). These previous studies at the
266 NUIST observation site have shown very good performance in simulating the meteorological fields,
267 which is essential for reliable STILT simulations. The hourly footprint was simulated by releasing 500
268 particles from the NUIST measurement site and tracking their backward locations every 5 minutes for a
269 period of 7 days. Particle numbers and their residence time within half of the PBLH were used to
270 calculate the footprint over the 7 day period. For the CO_2 background of each hour, we tracked the
271 sources of air particles back trajectory for 7 days, and defined these CO_2 mixing ratios in Carbon Tracker
272 as the hourly CO_2 background values (Peters et al., 2007).

273 2.2.4 A priori anthropogenic CO_2 emissions and net ecosystem exchange

274 The Emission Database for Global Atmospheric Research (EDGAR v4.3.2) inventory was selected as the
275 *a priori* anthropogenic CO_2 emissions (Figure 2a), which is based on the International Energy Agency's
276 (IEA) energy budget statistics and provides detailed CO_2 source maps (29 categories, including both
277 organic and fossil emissions, IEA, 2012) with global coverage at high spatial resolution ($0.1^\circ \times 0.1^\circ$). The
278 EDGAR CO_2 emissions are the most up-to-date global inventory with sectoral detail (Janssens-Maenhout
279 et al., 2017; Schneising et al., 2013). Other inventories, including the Fossil Fuel Data Assimilation
280 System (FFDAS, Rayner et al., 2010) and the Open-source Data Inventory for Anthropogenic CO_2
281 (ODIAC, Oda et al., 2018) also provide global CO_2 emissions. However, these inventories only provide
282 total CO_2 emissions or have very limited emission categories, which limit our ability to provide isotope

283 end-member information. EDGAR v4.3.2 provides emission estimates at a monthly time scale. Here, we
 284 applied hourly scaling factors for different categories following Hu et al., (2018a). EDGAR v4.3.2 with
 285 monthly resolution is available only for 2010. We assume that each CO₂ category changes linearly from
 286 its 2010 value (Peters et al., 2007) and apply an annual scaling factor of 1.145 to derive CO₂ emissions for
 287 2014 and 2015. This scaling factor is based on Carbon Tracker, dividing the same anthropogenic CO₂
 288 emissions for YRD in years 2014-2015 by that in 2010.

289 The biological flux or net ecosystem CO₂ exchange (NEE) and biomass burning CO₂ emissions come
 290 from Carbon Tracker *a posteriori* flux at 3-hour intervals and at a spatial resolution of 1° × 1°. Because
 291 NEE is much smaller than the anthropogenic CO₂ emissions in such densely developed urban landscapes,
 292 we homogeneously distributed this flux at a spatial resolution of 0.1° within each grid to match the
 293 footprint.

294 2.2.5 Simulation of the carbon isotope ratio of all sources (δ_{s_sim})

295 The carbon isotope ratio of all the surface sources was calculated as (Newman et al., 2008):

$$296 \quad \sum_{i=1}^n \delta_i \times p_i = \delta_{s_sim} \quad (6)$$

297 where δ_i is the $\delta^{13}\text{C-CO}_2$ value from source category i , and p_i is the corresponding enhancement
 298 proportion (i.e. proportions of a specific enhancement i to total CO₂ enhancement). We define δ_{s_sim} as the
 299 simulated carbon isotope ratio of all sources to differentiate it from the observed δ_{s_obs} . Based on fossil
 300 fuel usage characteristics in YRD, we reassigned the EDGAR v4.3.2 categories according to fuel types.
 301 Coal was the fuel type for manufacturing, oil for oil refinery, natural gas for buildings, and diesel and
 302 gasoline for transportation. The power industry consumed 5% natural gas and 95% coal based on local
 303 activity data in YRD (China statistical Yearbook, 2015). The non-metallic mineral production was mainly
 304 for cement. Since there is a lack of detailed information for non-metallic mineral production, we
 305 simply attributed 100% of it to cement production. Chemical processes were mainly ammonia
 306 synthesis. Based on a literature review and our previous work (Xu et al., 2017), typical $\delta^{13}\text{C-CO}_2$ values
 307 for natural gas ($-39.06\text{‰} \pm 1.07\text{‰}$), coal ($-25.46\text{‰} \pm 0.39\text{‰}$), fuel oil ($-29.32\text{‰} \pm 0.15\text{‰}$), gasoline
 308 ($-28.69\text{‰} \pm 0.50\text{‰}$), ammonia synthesis ($-28.18\text{‰} \pm 0.55\text{‰}$), and diesel ($-28.93\text{‰} \pm 0.26\text{‰}$), pig iron
 309 ($-24.90\text{‰} \pm 0.40\text{‰}$), crude steel ($-25.28\text{‰} \pm 0.40\text{‰}$), cement ($0\text{‰} \pm 0.30\text{‰}$), biofuel combustion and
 310 biological emissions ($-28.20\text{‰} \pm 1.00\text{‰}$) were used in this study. We also applied a value of -28.20‰
 311 for photosynthesis (Griffis et al., 2008; Lai et al., 2014) because YRD is a region dominated by C₃ plants.
 312 Since CO₂ emissions associated with human respiration (Prairie and Duarte, 2017; Turnbull et al., 2015;

313 Miller et al., 2020) are relatively small (3.7% of anthropogenic emissions in the YRD area, Xu et al.,
314 2017), and given that the local food diet is dominated by C₃ grains that have a similar $\delta^{13}\text{C-CO}_2$ value as
315 the biological CO₂ flux of -28.20‰, we assume it has the same isotope signals as local C₃ plants and
316 ecosystem respiration. Further, the biological CO₂ flux from the Carbon Tracker assimilation system
317 considered anthropogenic as fixed and attributed the remainder to the biological CO₂ flux (Peters et al.,
318 2007). Consequently, we believe the uncertainty in the biological CO₂ flux will include the small
319 proportion of human respiration.

320 To evaluate the simulated δ_{s_sim} , we applied the Miller-Tans and Keeling plot approaches to derive δ_{s_obs}
321 from the observed concentration and atmospheric ¹³CO₂-CO₂ (Xu et al. 2017). We then used the results to
322 evaluate the calculations made with Equation (6).

323 2.3 Independent IPCC method for anthropogenic CO₂ emissions

324 Large differences among inventories have been previously found even for the same region (Berezin et al.,
325 2013; Andrew, 2019). For comparison with the EDGAR v4.3.2 inventory results, we derived the
326 anthropogenic CO₂ emissions by using an independent IPCC method. Here, we illustrate the calculation
327 for cement CO₂ emissions. Note that the IPCC only recommended an EF for clinker, which is an
328 intermediate product of cement. To calculate cement CO₂ emissions, we need to calculate it based on
329 clinker production, as shown in Equation (7),

$$330 \quad CO_2[\text{cement}] = M_{\text{cement}} \times C_{\text{clinker}} \times EF_{\text{clinker}} \quad (7)$$

331 where CO₂[cement] is the chemical process CO₂ emissions for cement production, M_{cement} is the
332 production of cement, C_{clinker} represents the clinker to cement ratio (%), and EF_{clinker} is the CO₂ emission
333 factor for clinker production. The IPCC recommended an EF_{clinker} value of 0.52 ± 0.01 tonne CO₂ per
334 tonne clinker produced, where CaO content for clinker is assumed to be 65% with 100% CaO from
335 calcium carbonate material (IPCC 2013). The EF appears to be well constrained, showing little variation
336 among provinces with mean values ranging from 0.512 to 0.525 (Yang et al., 2017). For the C_{clinker} values,
337 it generally showed a decreasing trend from 64.5% in 2004 to 56.9% in 2015 for all of China (Figure S1),
338 with an average value of 57.0% during 2014 and 2015.

339 2.4 Multiplicative scaling factor method

340 To quantify anthropogenic CO₂ emissions and to compare them with EDGAR products, we first derived
341 the monthly scaling factors for anthropogenic CO₂ emissions using a multiplicative scaling factor
342 (hereafter MSF) method (Sargent et al., 2018; He et al., 2020), and then obtained annual averages. The
343 monthly scaling factors (SFs) were calculated as:

344

$$MSF = \frac{CO_{2_obs} - CO_{2_bg} - \Delta CO_{2_bio} - \Delta CO_{2_fire}}{\Delta CO_{2_anthro}} \quad (8)$$

345 where CO_{2_obs} , ΔCO_{2_bio} , ΔCO_{2_fire} and ΔCO_{2_anthro} represent observed CO_2 mixing ratios, simulated CO_2
 346 enhancements contributed by biological flux, biomass burning, and anthropogenic emissions, respectively.
 347 Uncertainties of all factors on the final MSFs were calculated based on Monte Carlo methods, where the
 348 normal sample probability distribution was applied and the upper 97.5% and lower 2.5% of the values
 349 was considered as the uncertainty for MSF (Cao et al., 2016).

350 3. Results and Discussion

351 3.1 Evaluation of hourly CO_2 mixing ratios

352 3.1.1 Hourly and monthly CO_2 mixing ratio comparisons

353 This section examines the general performance of simulating hourly CO_2 mixing ratios. The two-year
 354 average hourly footprint is shown in Figure 2b where the source area (blue-red) indicates strong
 355 sensitivity of the CO_2 observations to regional sources. This footprint shape is representative of the YRD
 356 area. To quantify the relative contributions from each province, we calculated CO_2 enhancements
 357 contributed by Anhui, Jiangsu, Zhejiang, Shanghai, and the remaining area outside of the YRD,
 358 respectively. The results indicate that Jiangsu contributed approximately 80% of the total enhancement
 359 (discussed further in Section 3.1.2). Comparisons between simulated and observed hourly CO_2 mixing
 360 ratios are displayed in Figure 3a for both years. For all hourly data in each year, the model versus
 361 observation correlation coefficient (R) was $R = 0.38$ ($n = 8204$, $P < 0.001$) and $RMSE = 29.44$ ppm for
 362 2014, and $R = 0.35$ ($n = 7262$, $P < 0.001$) and $RMSE = 30.22$ ppm for 2015. These results indicate that the
 363 model can simulate the synoptic and diel CO_2 variations over the two-year period. The model also
 364 captured the monthly and seasonal variations of CO_2 mixing ratios (daily averages are shown in Figure
 365 S2). The simulations captured the trend of rising CO_2 mixing ratios after October and the drawdown of
 366 CO_2 to the background value during the summer.

367 Figures 3b-d illustrate the average monthly daily, nighttime (22:00-06:00, local time), and daytime
 368 (10:00-16:00) CO_2 mixing ratios. These monthly values contain the effects of atmospheric transport,
 369 background and variations in CO_2 emissions. The observed and simulated CO_2 mixing ratios showed a
 370 significant increase from September 2013 to January 2014. Here, the CO_2 mixing ratios increased by 16.0
 371 ppm according to the model results and 17.2 ppm according to the observations. The background values
 372 increased by 8.1 ppm and accounted for 47% of the total CO_2 increase, and the net CO_2 flux (*a priori*) for
 373 YRD increased by 15%. We attributed the remaining 38% increase to changes in atmospheric transport
 374 processes including lower PBLH in January 2014 than in September 2013. To quantify how variations in

375 PBLH affected CO₂ mixing ratios, we compared the simulated monthly anthropogenic CO₂ enhancement
376 differences in the same months of different years, to eliminate the influence of monthly emission
377 variations on CO₂ enhancements. Twelve monthly paired values were used and are shown in Figure 4.
378 This analysis indicates that atmospheric CO₂ mixing ratios decreased by about 3.7 ppm for an increase of
379 PBLH by 100 m. We also note that there were two months (March and August) that fall far below this
380 trend, implying that changes in the monthly footprints (source area) can also play an important role.

381 On an annual timescale, the simulated average CO₂ mixing ratios were 436.63 ppm and 437.11 ppm for
382 2014 and 2015, respectively. Since the anthropogenic CO₂ emissions used in the model are the same for
383 both years, the simulated annual average CO₂ difference can be used to quantify the influence associated
384 with meteorological factors and ecosystem carbon cycling. Between these two years, the CO₂ background
385 increased by 1.78 ppm, the biological enhancement decreased by 1.04 ppm from 2014 to 2015. The
386 remaining 0.26 ppm change between 2014 and 2015 indicates a relatively small meteorological effect for
387 the annual averages, such as a slight change in dominant wind direction or a PBLH difference.

388 The simulated annual average NEE CO₂ enhancements were 2.64 ppm and 1.60 ppm for the respective
389 years. For comparison, the annual average anthropogenic enhancements were 36.20 ppm and 34.90 ppm
390 for 2014 and 2015, respectively. The monthly NEE enhancement varied from -0.1 ppm in May 2015 to
391 +6.0 ppm July 2014, indicating NEE contributes positively for enhancement in most months (Figure 5a),
392 even though the sign of monthly averaged NEE flux in summer was negative (sinks). This positive
393 contribution was mainly caused by diel PBLH variations between daytime (smaller negative enhancement)
394 and nighttime (larger positive enhancement). To further evaluate the impact of plant photosynthetic
395 activity on the regional CO₂ cycle, we examined the NDVI, SIF and GPP seasonal patterns (Figures 5d-f).
396 These three datasets revealed two peaks during each year, which is related to increased photosynthetic
397 activity. The first peak occurred in May and the second in August-September, corresponding to the
398 growing season of wheat and corn/rice, respectively (Deng et al., 2015). We note that GPP was derived
399 from SIF, and as a result, they share a similar seasonal cycle. The land-use classification in YRD for 2014
400 (Figure S3) shows that north YRD is dominated by agricultural land and south dominated by forest land,
401 and our observation site was more surrounded by agricultural land which corresponded well with
402 observed NDVI, SIF and GPP seasonal patterns. The peak SIF and GPP signals during the summer were
403 about 20 times greater than during the winter. Consequently, we can ignore the potential influence of
404 photosynthetic activity on the regional CO₂ enhancements during the non-growing seasons.

405 3.1.2 Components of urban CO₂ enhancement

406 Here, we diagnose the source contributions to the urban CO₂ enhancement. The observed anthropogenic
407 CO₂ enhancements, which were derived by subtracting CO₂ background and simulated biological
408 enhancement from CO₂ concentration observations, were 38.36±3.32 ppm and 37.89±2.80 ppm for 2014
409 and 2015, respectively. Here, the uncertainty of the observed anthropogenic CO₂ enhancements was
410 calculated by prescribing a 2 ppm potential bias for the Carbon Tracker CO₂ fields and 50% to the
411 simulated biological CO₂ enhancement (Hu et al., 2018b). The corresponding simulated anthropogenic
412 CO₂ enhancements were 36.20 ppm and 34.90 ppm. In comparison with the simulated biological CO₂
413 enhancements displayed in Figure 5a, both the observed and simulated CO₂ enhancements are indicative
414 of a large anthropogenic (fossil fuel and cement production) CO₂ emission from the YRD.

415 Previous studies have also investigated urban CO₂ enhancements from a relatively broad range of
416 developed environments worldwide. Verhulst et al. (2017) measured CO₂ mixing ratios at seven sites in
417 Los Angeles, USA and concluded that the mean annual enhancement varied between 2.0 ppm and 30.8
418 ppm, which is considerably lower than our findings. Another study in Washington D.C., USA in February
419 and July 2013 showed that the CO₂ enhancement was less than 20 ppm (Mueller et al., 2018). The urban
420 CO₂ observations and modeling study by Martin et al. (2019) at three urban sites in eastern USA showed
421 an enhancement of ~21 ppm in February 2013, substantially lower (by ~20 ppm) than our observations.
422 The measurements at an urban-industrial complex site in Rotterdam, Netherlands, indicated a CO₂
423 enhancement of only 11 ppm for October to December 2014 (Super et al., 2017). Our enhancements were
424 significantly higher than all of these previous reports of other urban areas.

425 The anthropogenic components and source area contributions are displayed in Figure 5b-c. During the
426 study period the average anthropogenic enhancements were 5.1%, 80.2%, 1.9%, 4.4%, and 8.5% for
427 Anhui, Jiangsu, Zhejiang, Shanghai, and the remaining area outside the YRD, respectively. Although
428 Shanghai's area is the smallest within the YRD region and relatively distant (~300 km) from our
429 observation site, its maximum source contribution at times exceeded 50% (i.e. on 19th September 2013,
430 not shown) *via* long-distance transport. In general, power industry, manufacturing, non-metallic mineral
431 production, oil refinery, and other source categories contributed 41.0%, 21.9%, 9.3%, 11.5%, and 16.3%
432 to the total anthropogenic CO₂ enhancement, respectively. The proportions of corresponding CO₂
433 emission categories to the total anthropogenic emissions of the YRD were 39.8%, 28.4%, 7.4%, 4.1%,
434 and 24.4%, respectively. The comparisons between the proportions of simulated enhancement and
435 proportions of corresponding CO₂ emissions can illustrate whether CO₂ enhancement partitions is a good
436 tracer for emissions in complex urban area. We found a relatively large difference between the
437 enhancement proportion and the emission proportion for oil refineries (from 11.5% to 4.1%) as compared
438 to other categories. This may be because power industry, manufacturing and non-metallic mineral

439 production were more homogeneously distributed compared to oil refineries, which were closer to our
440 CO₂ observation site. Further, changes in source footprint caused by wind direction variations likely
441 played an important role.

442 3.1.3 Constraints on monthly anthropogenic CO₂ emissions

443 To provide a robust comparison of bottom-up CO₂ emissions for YRD, we calculated anthropogenic CO₂
444 emissions from both EDGAR v4.3.2 and with activity data provided by local governments (Table 1) and
445 the default IPCC emission factors (<https://www.ipcc-nggip.iges.or.jp/EFDB/>). The total anthropogenic
446 CO₂ emissions in 2014-2015 were 24.4×10^{11} kg and 23.5×10^{11} kg according to our own inventory and
447 EDGAR v4.3.2 CO₂, respectively, indicating excellent agreement (within 4%) between these approaches.
448 We constrained the monthly anthropogenic CO₂ emissions by using the MSF method (equation 8) and
449 computed the 12-month average to represent the years of 2014 and 2015. The *a posteriori* results indicate
450 that the annual scaling factors were 1.03 ± 0.10 for 2014 and 1.06 ± 0.09 for 2015. The monthly scaling
451 factors derived from using daytime and all-day observations are also shown in Figure S4. These factors
452 vary seasonally with higher values observed in summer. When using daytime values only, the scaling
453 factors were much larger than the all-day values. This can be seen in Figure 3 by comparing the simulated
454 and observed CO₂ mixing ratios. We should note here that the larger scaling factors based on the daytime
455 data could be caused by bias in the *a priori* daily scaling factors used to generate the hourly CO₂
456 emissions (Hu et al., 2018b); the monthly anthropogenic averages; and bias in negative biological CO₂
457 enhancement. Since our study is mainly focused on the seasonality of all-day observations, the monthly
458 scaling factors derived from the all-day approach will be used for the following analyses. The
459 anthropogenic CO₂ emissions in year 2015 did not show a significant change compared to 2014, and the
460 overall estimates were within the uncertainty of the estimates. After applying the average scaling factors
461 for 2014 and 2015, the *a posteriori* anthropogenic CO₂ emissions were $24.6 (\pm 2.4) \times 10^{11}$ kg for the YRD
462 area. The application of the MSF method provides an overall constraint on the anthropogenic CO₂
463 emissions (also displayed in Table 1).

464 The main uncertainties associated with the simulation of hourly CO₂ and $\delta^{13}\text{C-CO}_2$ are uncertainty in
465 meteorological fields, transport model (i.e. number of released particles), and *a priori* CO₂ fluxes. At the
466 annual scale the main uncertainty is attributed to the PBLH simulations and *a priori* anthropogenic CO₂
467 emissions. The anthropogenic CO₂ emissions biases were < 6% as described above, and the bias
468 associated with PBLH uncertainty was typically <13% (Hu et al., 2018a; 2018b). There, we attribute a 20%
469 uncertainty to the simulated CO₂ and $\delta^{13}\text{C-CO}_2$ signals on an annual time scale.

470 3.2 Simulation of atmospheric $\delta^{13}\text{C-CO}_2$

471 3.2.1 Background atmospheric $\delta^{13}\text{C-CO}_2$

472 To obtain the best representative $\delta^{13}\text{C-CO}_2$ background value for the study domain we examined the
473 values from the three strategies described above (Figure 6). We also compared the $\delta^{13}\text{C-CO}_2$ at the WLG
474 background site with observations at NUIST during winters (Figure S5). This was performed to help
475 simplify the comparison by removing the effects of plant photosynthetic discrimination. The $\delta^{13}\text{C-CO}_2$ at
476 the WLG site was relatively more depleted in the heavy carbon isotope (or negative, by up to 0.5‰) than
477 that observed at NUIST for many periods. Theoretically, there are two key factors that can cause the
478 urban atmospheric $\delta^{13}\text{C-CO}_2$ to be relatively more enriched in the heavy carbon isotope (or positive)
479 compared to the background values including: 1) Discrimination associated with ecosystem
480 photosynthesis; and 2) Enrichment of isotopic signature associated with the CO_2 derived from cement
481 production. As shown earlier, the biological CO_2 enhancement was positive in winter, which implies a
482 positive biological CO_2 signal where ecosystem respiration is more important than photosynthesis.
483 Further, sensitivity tests for cement CO_2 sources showed its influence is much smaller than the observed
484 difference in Figure S5 (discussed in section 3.3.3). Based on the above analyses and methods introduced
485 in Section 2.3, we concluded that the WLG $\delta^{13}\text{C-CO}_2$ signal is not an ideal choice for representing the
486 background value. The wintertime $\delta^{13}\text{C-CO}_2$ background values, based on strategy 2, were -7.78‰ and -
487 7.61‰ for 2013-2014 and 2014-2015, respectively (Figure 6). The corresponding values, based on
488 strategy 3, were -7.70‰ and -7.53‰. These background values are more enriched compared to the WLG
489 observations by 0.80‰ to 1.01‰. These derived values agree well with the monthly $\delta^{13}\text{C-CO}_2$ simulation
490 results of Chen et al. (2006) who showed that $\delta^{13}\text{C-CO}_2$ is 0.6‰ higher above the PBL than in the surface
491 layer near the ground. Recently, Ghasemifard et al. (2019) showed that hourly $\delta^{13}\text{C-CO}_2$ values at Mount
492 Zugspitze, the highest (2650 m) mountain in Germany, varied between -7‰ and -12‰ in the winter for
493 2013. During two especially clean air events (in October and February) at Mount Zugspitze, the $\delta^{13}\text{C-CO}_2$
494 was approximately -7‰, during which the CO_2 mixing ratios varied between 390 and 395 ppm. This is
495 consistent with our estimates using strategies 2 and 3. Based on the evidence presented above, we believe
496 that strategy 3 is the most robust way to derive a background $\delta^{13}\text{C-CO}_2$ for the study domain.

497 3.2.2 Evaluation of $\delta^{13}\text{C-CO}_2$ simulations

498 Figure 7a shows the hourly $\delta^{13}\text{C-CO}_2$ simulations over a two-year period. To the best of our knowledge,
499 this is the first time that $\delta^{13}\text{C-CO}_2$ has been simulated at an hourly time scale for an urban region. The
500 simulations are consistent with the observations at daily, monthly and annual time scales, where the
501 average value of observations (simulations) were -8.69‰ (-8.68‰) and -8.52‰ (-8.45‰) for 2014 and
502 2015, respectively. The corresponding correlation was $R = 0.54$ ($P < 0.001$) and $R = 0.52$ ($P < 0.001$).

503 The root mean square error between observations and simulations was 1.07‰ for 2014 and 1.10‰ for
504 2015 (Table 2). Further, the observed and simulated $\delta^{13}\text{C-CO}_2$ values showed seasonal variations that
505 increased in summer and decreased in winter. This pattern mirrored the CO_2 mixing ratios for both
506 observations and simulations (Figures 3a and 8). Similar relations and seasonal variations of $\delta^{13}\text{C-CO}_2$
507 have been reported in other urban areas (Sturm et al., 2006; Guha & Ghosh, 2010; Moore & Jacobson,
508 2015; Pang et al., 2016). The simulated hourly NEE CO_2 enhancement is also shown in Figure 7b. Note
509 that negative values indicate net CO_2 sinks and positive values indicate net CO_2 sources. We can see large
510 hourly variations in the growing seasons and positive enhancements during nighttime that are generally
511 larger than negative enhancements during daytime. This shows the potential influence of NEE on $\delta^{13}\text{C-CO}_2$
512 CO_2 seasonality. To date, no study has quantified the relative contributions to the $\delta^{13}\text{C-CO}_2$ seasonality.
513 Here, we re-evaluate and quantify the main factors contributing to its seasonality based on the
514 combination of $\delta^{13}\text{C-CO}_2$ observations and simulations in the following section.

515 Here, we examine the comparisons for winter and summer in greater detail. The simulations showed that
516 the model can generally capture the diel variations of observed hourly $\delta^{13}\text{C-CO}_2$ variations (Figure 8).
517 Statistics between observations and simulations for two seasons are shown in Table 2. The observed
518 seasonal average increased substantially, by 1.18‰, from winter 2013-2014 (-9.27‰) to summer 2014 (-
519 8.09‰). The simulations showed a similar seasonal increase of 1.35‰. Some large discrepancies are
520 evident and generally caused by the simulated total CO_2 enhancement biases (potentially caused by
521 poorly simulated PBLH during these periods) and the negative relationship between $\delta^{13}\text{C-CO}_2$ and the
522 CO_2 enhancement as shown in Figure S6.

523 Comparisons between observations and simulations for daily average CO_2 mixing ratio and $\delta^{13}\text{C-CO}_2$ are
524 also shown in Figure 9. Although the data are distributed around the 1:1 line for both seasons, there is less
525 scatter and higher correlation in the winter than in the summer. We attributed this to the more complex
526 biological CO_2 sinks in the summer, which are not adequately resolved by the relatively coarse model
527 grid (1° by 1°). We also performed comparisons by only choosing the daytime observations. The results
528 indicated that daytime CO_2 mixing ratio simulations in the summer were slightly underestimated. This
529 caused $\delta^{13}\text{C-CO}_2$ to be overestimated (Figure S7). The simulations for winter generally captured the
530 trends for both CO_2 and $\delta^{13}\text{C-CO}_2$ when the biological CO_2 enhancement played a relatively small role
531 compared to anthropogenic emissions. The larger bias in the summer could result from the relatively
532 coarse spatial-temporal resolution (aggregation error) of the Carbon Tracker biological CO_2 flux, which
533 was 1×1 degree with three-hour average. As shown in Figure S3, the spatial distribution of land use is far
534 more heterogeneous. This will smooth the stronger biological CO_2 signals by averaging it over the large

535 1×1 degree grid, while the urban biological CO₂ flux occurs at much finer spatial scales and likely varies
536 at shorter time intervals.

537 3.2.3 Mechanisms controlling the $\delta^{13}\text{C}$ -CO₂ seasonality

538 The mechanisms driving these seasonal variations are examined below. The peak and trough in the
539 observed $\delta^{13}\text{C}$ -CO₂ signal was observed in December and July (Figure 10a), respectively, yielding an
540 amplitude of 1.51‰. This was consistent with the simulated amplitude of 1.53‰. These results support
541 that the simulated $\delta^{13}\text{C}$ -CO₂ seasonality agreed well with the observations (Figure 10), and can be used to
542 further diagnose the mechanisms contributing to the $\delta^{13}\text{C}$ -CO₂ seasonality. According to equation 2, the
543 $\delta^{13}\text{C}$ -CO₂ seasonality can be attributed to four factors including: (1) A change in the background $\delta^{13}\text{C}$ -
544 CO₂ value from -7.64‰ in December to -6.66‰ in July; (2) A change in CO₂ background from 399 ppm
545 to 398 ppm; (3) The total CO₂ enhancement change from 45.7 ppm to 37.3 ppm; and (4) The change in
546 the isotope composition of the CO₂ enhancements causing δs to vary from -26.1‰ to -22.8‰.

547 To quantify each mechanism's contribution to the seasonality of atmospheric $\delta^{13}\text{C}$ -CO₂, we recalculated
548 $\delta^{13}\text{C}$ -CO₂ by using the monthly averages as described above. First, we calculated $\delta^{13}\text{C}$ -CO₂ in December
549 and July, which were -9.54‰ and -8.04‰, respectively, with amplitude of 1.50‰. Next, we replaced the
550 $\delta^{13}\text{C}$ -CO₂ background value in December (-7.64‰) with July (-6.67‰). The recalculated $\delta^{13}\text{C}$ -CO₂ was -
551 8.66‰ in December, indicating that the change in $\delta^{13}\text{C}$ -CO₂ background value caused a change of 0.88‰
552 (9.54‰ minus -8.66‰) to the seasonality. By changing both the total CO₂ enhancement and background
553 values, the recalculated $\delta^{13}\text{C}$ -CO₂ was -8.32‰, contributing a 0.34‰ change in the seasonality (-8.66‰
554 minus -8.32‰). Finally, by changing δs from -26.1‰ to -22.8‰, together with the change in background
555 value, the recalculated $\delta^{13}\text{C}$ -CO₂ was -8.32‰ a change of 0.34‰ (i.e. -8.66‰ minus -8.32‰). This
556 indicates that both the total CO₂ enhancement and change in δs contributed equally to the regional source
557 term, causing a variation of 0.62‰ (i.e. 1.50‰ minus 0.88‰). Based on the above analyses, we attributed
558 59% and 41% of the $\delta^{13}\text{C}$ -CO₂ seasonality to the changing $\delta^{13}\text{C}$ background term and regional source
559 terms, respectively. Further, the total CO₂ enhancement and change in δs , sum of both can be treated as
560 regional source term, contributed equally (about 20%) to the $\delta^{13}\text{C}$ -CO₂ seasonality.

561 To investigate how ecosystem photosynthetic discrimination and respiration affected atmospheric $\delta^{13}\text{C}$ -
562 CO₂ seasonality, we simulated the $\delta^{13}\text{C}$ -CO₂ again for two cases: (1) excluding negative NEE when
563 photosynthesis is stronger than respiration, and (2) excluding both photosynthetic discrimination and
564 respiration. Note that only NEE was used in our study with no partitioning between photosynthesis and
565 respiration in the daytime. The only role of photosynthetic discrimination should be stronger than in case
566 1 when only negative NEE is used. The results are shown in Figure 10 b-c. Overall, the negative CO₂

567 enhancement caused atmospheric $\delta^{13}\text{C-CO}_2$ to become more enriched in the baseline simulations with
568 maximum values around 1‰ between April and October (Figure 10b), and positive CO_2 enhancement (i.e.
569 via net respiration) caused atmospheric $\delta^{13}\text{C-CO}_2$ to become more depleted compared to the baseline
570 simulations through the whole year (Figure 10c). By applying the CCGRCV fitting technique to the $\delta^{13}\text{C-}$
571 CO_2 for the above two cases, we found that the $\delta^{13}\text{C-CO}_2$ seasonality decreased to 1.45‰ in case 1,
572 indicating ecosystem photosynthetic discrimination explained $> 0.08\%$ of the seasonality (1.53‰ minus
573 1.45‰). For case 2, the $\delta^{13}\text{C-CO}_2$ trough in winter slightly increased by 0.08‰ and peak in summer
574 increased by 0.20‰, these two factors finally lead the seasonality increase to 1.66‰, which were caused
575 by much larger respiration CO_2 enhancement in summer than in winter (Figure 7b). These results indicate
576 that biological respiration reduced the $\delta^{13}\text{C-CO}_2$ seasonality by 0.20‰, and that negative NEE
577 (photosynthetic discrimination) acted to increase the $\delta^{13}\text{C-CO}_2$ seasonality by 0.08‰. Generally, both
578 ecosystem photosynthesis and respiration played minor roles in controlling the atmospheric $\delta^{13}\text{C-CO}_2$
579 seasonality within this urban area. In other words, the anthropogenic CO_2 emissions played a much larger
580 role than the plants.

581 As shown in Figure 5, CO_2 sources from power industry, combustion for manufacturing, non-metallic
582 mineral production and oil refineries and transformation industry were the top 4 contributors to the CO_2
583 enhancements. We simulated atmospheric $\delta^{13}\text{C-CO}_2$ by assuming that no CO_2 was emitted from each of
584 these 4 categories. The simulations were performed by excluding one category at a time. The results
585 indicated that atmospheric $\delta^{13}\text{C-CO}_2$ seasonality was 1.30‰, 1.57‰, 1.30‰, and 1.47‰, if excluding
586 power industry, combustion for manufacturing source, oil refineries/transformation industry, and non-
587 metallic mineral production sources, respectively. In other words, power industry and oil refineries/
588 transformation industry together contributed 0.40‰ to the total regional source term of 0.62‰. The
589 cement sources played a role in enriching 0.07‰ the atmospheric $\delta^{13}\text{C-CO}_2$ in the heavy isotope, contrary
590 to all other anthropogenic CO_2 sources.

591 3.3 Sensitivity analysis

592 3.3.1 Comparison of $\delta\text{s}\cdot\Delta\text{CO}_2$

593 Based on equation 2, the regional source term determines the hourly/daily variations of $\delta^{13}\text{C-CO}_2$, which
594 is treated as a signal added to the background signal. To evaluate the model simulated regional source
595 term with respect to the observations we examined daily averages for winter to minimize the influence of
596 photosynthesis. In Figure 11a, the observed daily $\delta\text{s}\cdot\Delta\text{CO}_2$ values are compared with the simulated values
597 using the *a priori* anthropogenic CO_2 emissions. Here ΔCO_2 represents the total CO_2 enhancement for
598 both observations and simulations. The product $\delta\text{s}\cdot\Delta\text{CO}_2$ can be interpreted as the regional source term.

599 The average values were -1009.0 (and -841.9) ppm·‰ for observations and -1096.7 (and 1000.5) ppm·‰
600 for model results in 2014 (and 2015). The slope of the regression fit was 0.99 (± 0.12) and the intercept
601 was -151.7 (± 130.1) for all data during the two winters. After applying the monthly scaling factors to
602 constrain the anthropogenic CO₂ emissions, the re-calculated results were closer to the 1:1 line with a
603 slightly improved correlation (R increased from 0.47 to 0.50; Figure 11b). Note that the application of the
604 monthly scaling factors only impacts the ΔCO_2 but not δ_s . The uncertainty in δ_s will be discussed next.

605 3.3.2 Comparison between δ_{s_sim} and δ_s

606 To evaluate the δ_s simulations, we compared observed and simulated δ_s as displayed in Figure 12a for all-
607 day and nighttime conditions. Here, nighttime simulations were selected to minimize the effects of
608 ecosystem photosynthesis and to mainly focus on the anthropogenic CO₂ sources. Two methods were
609 used to calculate δ_s from the observations including the Miller-Tans and Keeling plot methods. Although
610 δ_s differed between these two methods, both displayed similar seasonal variations with higher values
611 ($\delta^{13}\text{C}$ enrichment) in summer and lower values in winter. Such seasonal variations were also observed at
612 other urban sites including Beijing, China (Pang et al., 2016), Bern, Switzerland (Sturm et al., 2006),
613 Bangalore city, India (Guha and Ghosh, 2010), Wroclaw, Poland (Górka and Lewicka-szczebak, 2013).

614 If the CO₂ sources/sinks are homogeneously distributed and without monthly variations, the atmospheric
615 CO₂ enhancement components would remain unchanged, and there would be no seasonal changes in δ_s .
616 In reality, variations in atmospheric transport processes interact with regional CO₂ sink/source changes
617 that cause monthly variations in δ_s . The comparison of δ_s between simulations and observations indicated
618 that the model performed well in capturing the mixing and transport of CO₂ from different sources. We
619 can also infer from their difference that the proportions of some CO₂ categories were biased in the *a*
620 *priori* emission map. This can be caused by both the downscaling of EDGAR inventory distribution to
621 0.1° and the magnitude of some emissions categories. Among all anthropogenic sources, the most
622 significant linear relations were found between the simulated anthropogenic δ_s and cement CO₂
623 proportions for these 24 months, with slopes of 0.33‰ for nighttime and 0.35‰ for all-day conditions (R^2
624 = 0.97, $p < 0.001$; Figure 12 b & c). These results also indicated that cement CO₂ emissions dominated
625 monthly δ_s variations in the YRD region.

626 3.3.3 Sensitivity of atmospheric $\delta^{13}\text{C}\text{-CO}_2$ and δ_s to cement CO₂ emissions

627 The discrepancy between simulated and observed δ_s highlights that some CO₂ sources were biased in the
628 *a priori* inventories. As discussed above, cement CO₂ emissions had the most distinct $\delta^{13}\text{C}\text{-CO}_2$ end-
629 member value of 0‰ \pm 0.30‰ when compared with the averages of other anthropogenic sources.

630 Combined with its large emission compared to other regions of the world, it had a strong potential to
631 influence δ_s and $\delta^{13}\text{C-CO}_2$. YRD represents the largest cement producing region in the world (USGS,
632 2014; Cai et al., 2015; Yang et al., 2017). Its relative proportion to total national anthropogenic CO_2
633 emissions is about 5.5% to 6.5% based on IPCC method and 7.3% for EDGAR. These proportions are 50%
634 greater than the global average of 4% (Boden et al., 2016) and much larger than most countries (Andrew,
635 2018) and other large urbanized areas such as California (2%; Cui et al., 2019).

636 The local activity data reveals that the cement production increased from 3.55×10^8 tons in 2010 to $4.56 \times$
637 10^8 tons in 2014 in the YRD area. Our own calculation of the national clinker-to-cement indicated a
638 decreasing trend from 64% in 2004 to around 56% in 2015. Here, we applied the value of 61.7% for 2010
639 and the average value of 57.0% for 2014 to 2015. We then used the EF for clinker (0.52 ± 0.01 tonne CO_2
640 per tonne clinker; IPCC 2013). Finally, the calculated cement CO_2 emissions were $1.14 (\pm 0.02) \times 10^8$
641 tonne for 2010 and $1.35 (\pm 0.03) \times 10^8$ tonne for 2014, indicating an 18.4% increase over this time period.
642 This result is close to the scaling factor 1.145 for the total anthropogenic CO_2 emissions for the same
643 period.

644 The cement CO_2 emission was 1.45×10^8 tonne for the EDGAR products in 2010. Applying the scaling
645 factor of 1.184, based on our independent method, the EDGAR cement CO_2 emissions was 1.72×10^8
646 tonne for the year of 2014. The 27% difference between the EDGAR inventory and our independent
647 calculations probably resulted from large errors in the clinker-to-cement ratio and regional activity data.
648 Ke et al. (2013) reported a much higher clinker-to-cement ratio of 73% to 70% for China during 2005 and
649 2007 than the ratio of 57% in 2014 to 2015. If we applied a 70% ratio, the EDGAR cement CO_2 emission
650 would change to 1.28×10^8 tonne for 2010.

651 The monthly cement emission proportions varied from 6.21% to 8.98%, while its enhancement proportion
652 was much larger and could reach 16.85%. In other words, favorable atmospheric transport processes
653 amplified the cement CO_2 enhancement proportion at our observational site (Table S2). To quantify the
654 extent to which the cement CO_2 enhancement components can affect δ_s and atmospheric $\delta^{13}\text{C-CO}_2$ we
655 conducted sensitivity tests by changing the cement enhancement proportions to 0.8, 1.2, 1.4, 1.6, 1.8, and
656 2 times its original value. These sensitivity tests are based on two different assumptions for cement CO_2
657 enhancement changes: (1) There is no bias in the total anthropogenic CO_2 enhancement such that a
658 proportional increase/decrease in the cement component does not change the relative anthropogenic
659 contributions; (2) Only the cement enhancement changes. From equation 2, these two assumptions will
660 change both δ_s and $\delta^{13}\text{C-CO}_2$ but with different amplitude.

661 Results for the first assumption are shown in Figure 13a-b for both nighttime and all-day δ_s simulations.
662 The simulated δ_s increased linearly with the increase of cement proportions, at a rate of 2.73‰ increase
663 per 10% increase of cement proportions in the nighttime and 2.72‰ for all-day. The result for the second
664 assumption is similar to the first one, yielding a 2.32‰ increase for a 10% increase in the cement
665 proportion. As shown in Table S2, the cement CO₂ enhancement proportions increased from 5.60% - 6.77%
666 (December) to 13.16% - 16.85% (June), which is the primary cause for the observed monthly δ_s
667 variations. The high sensitivity of δ_s to cement CO₂ proportions can partly explain the relative difference
668 of modeled δ_s and indicates a potential advantage to constrain cement CO₂ emissions by using
669 atmospheric $\delta^{13}\text{C-CO}_2$ observations. Finally we calculated how cement CO₂ can change atmospheric
670 $\delta^{13}\text{C-CO}_2$ (Figure 13c). These results show that atmospheric $\delta^{13}\text{C-CO}_2$ is more sensitive to the first
671 assumption than the second assumption. These sensitivity analyses indicate that a cement CO₂
672 enhancement relative change of 20% (or absolute 1.57% increase) can cause a 0.013‰ - 0.038‰ change
673 in the atmospheric $\delta^{13}\text{C-CO}_2$. These results indicate that δ_s is sensitive to cement CO₂ emissions.

674 4 Conclusions

- 675 (1) Total annual anthropogenic CO₂ emissions for the YRD showed high consistency between the top-
676 down and bottom-up approaches with a bias less than 6%.
- 677 (2) Approximately 59% and 41% of the $\delta^{13}\text{C-CO}_2$ seasonality was attributed to the change in $\delta^{13}\text{C}$
678 background value and the regional CO₂ source term, respectively.
- 679 (3) Power industry and oil refineries/ transformation industry together contributed 0.40‰ to the
680 seasonal cycle, accounting for 64.5% in all regional source terms (0.62‰).
- 681 (4) If excluding all ecosystem respiration and photosynthetic discrimination in YRD area, $\delta^{13}\text{C-CO}_2$
682 seasonality will increase from 1.53‰ to 1.66‰.
- 683 (5) Atmospheric transport processes in summer amplified the cement CO₂ enhancement proportions in
684 the YRD area, which dominated monthly δ_s variations. δ_s calculated from simulations was shown
685 to be a strong linear relation with cement CO₂ EDGAR v4.3.2 inventory proportion in the YRD area.

929 Figure 1. (a) Weather Research and Forecasting Model simulation domains and the location of WLG site , the different region
930 colors represent three domains, (b) cement production distribution in YRD and Eastern China. Both green dot in (a) and red star
931 in (b) are NUIST observation site.

932 Figure 2. (a) Annual anthropogenic CO₂ emissions for study domain (units: mol m⁻² s⁻¹) and population density in 4 megacities
933 (units: people per hectare) including Nanjing, Hefei, Zhejiang, and Shanghai for the year of 2015, (b) Two-year average
934 concentration footprint (units: ppm m² s/μmol).

935 Figure 3. (a) Comparisons of hourly CO₂ mixing ratios between observations and model simulation from September 2013 to
936 August 2015, and monthly averages for (b) whole day, (c) nighttime (22:00-06:00, local time) and (d) daytime (10:00 - 16:00);
937 Model results (red), observations (black), and background (grey).

938 Figure 4. Relation between monthly PBLH and change in CO₂ mixing ratio, here these dots represent difference of monthly
939 averages in two different years for all hours.

940 Figure 5. (a) Comparisons of simulated and observed CO₂ enhancement, note ‘model’ represents the sum of both anthropogenic
941 and biological CO₂ enhancement simulations, (b) CO₂ enhancement contributions from different provinces, (c) simulated
942 anthropogenic CO₂ enhancement proportion for the main sources; Time series (2013 to 2015) of (d) NDVI, (e) SIF, and (f) GPP.
943 The distance indicates the radius of area centered with NUIST observation site, and the NDVI, SIF, GPP values are averages in
944 these areas.

945 Figure 6. Comparisons among three strategies for calculating the background δ¹³C-CO₂ . Strategy 1 (WLG discrete: weekly
946 discrete observations at WLG site, WLG CCGCRV: derived hourly data with WLG observations and CCGCRV method);
947 Strategy 2 (Calculated: by choosing clean air in winter); and strategy 3 (M-T method: derived results with observations and M-T
948 approach, M-T CCGCRV: derived hourly results with M-T approach and CCGCRV method, see details in section 2.2.1).

949 Figure 7. (a) Comparisons of observed and modeled hourly δ¹³C-CO₂ from September 2013 to August 2015, where the grey line
950 represent derived δ¹³C-CO₂ background, and (b) Simulated hourly biological CO₂ enhancement. The shade and lines in both
951 subfigures represent the periods for winter and summer, respectively.

952 Figure 8. Comparisons of observed and modeled (a) CO₂ mixing ratio and (b) δ¹³C-CO₂ from December 2013 to February 2014;
953 (c) CO₂ mixing ratio and (b) δ¹³C-CO₂ from December 2014 to February 2015; (e) CO₂ mixing ratio and (f) δ¹³C-CO₂ from
954 June 2014 to August 2014; (g) CO₂ mixing ratio and (h) δ¹³C-CO₂ from June 2015 to August 2015.

955 Figure 9. Scatter plots of observed versus modeled (a) winter time CO₂ mixing ratios, (b) winter time δ¹³C-CO₂, (c) summer time
956 CO₂, and (d) summer time δ¹³C-CO₂ for both years, here these dots are daily averages.

957 Figure 10. Digital filtering curve fitting (CCGCRV) for background, observations, normal simulations, case 1 (excluding
958 negative NEE when photosynthesis is stronger than respiration), and case 2 (excluding respiration and photosynthesis) in both
959 years, (b) δ¹³C-CO₂ comparisons between normal simulations and case 1, and (c) δ¹³C-CO₂ comparisons between normal
960 simulations and case 2.

961 Figure 11. Comparisons of winter time δs·ΔCO₂ using (a) *a priori* and (b) constrained anthropogenic CO₂ emissions.

962 Figure 12. (a) Comparisons between observed and modeled δ_s, (b) relationship between cement CO₂ enhancement proportion and
963 simulated anthropogenic δs for nighttime and (c) all-day.

964 Figure 13. Sensitivity tests showing the influence of cement CO₂ emissions on δ_s for (a) nighttime, (b) all-day, and (c) the
965 relation between cement CO₂ and $\delta^{13}\text{C}$ for simulation strategies 1 (There is no bias in the total anthropogenic CO₂ enhancement
966 such that a proportional increase/decrease in the cement component does not change the relative anthropogenic contributions) and
967 2 (only the cement enhancement changes). Note that the numbers in brackets indicate changes in $\delta^{13}\text{C}$ with cement CO₂
968 enhancement proportion (the fraction of cement CO₂ enhancement to simulated total CO₂ enhancement) increase by 0.2 times.
969 The x-axis values indicate changing cement enhancement proportions to 0.8 1.2, 1.4, 1.6, 1.8, and 2 times the original values.

Figure 13. Sensitivity tests showing the influence of cement CO_2 emissions on δ_s for (a) nighttime, (b) all-day, and (c) the relation between cement CO_2 and $\delta^{13}\text{C}$ for simulation strategies 1 (There is no bias in the total anthropogenic CO_2 enhancement such that a proportional increase/decrease in the cement component does not change the relative anthropogenic contributions) and 2 (only the cement enhancement changes). Note that the numbers in brackets indicate changes in $\delta^{13}\text{C}$ with cement CO_2 enhancement proportion (the fraction of cement CO_2 enhancement to simulated total CO_2 enhancement) increase by 0.2 times. The x-axis values indicate changing cement enhancement proportions to 0.8 1.2, 1.4, 1.6, 1.8, and 2 times the original values.
