**Air quality and health benefits from ultra-low emission
control policy indicated by continuous emission monitoring:
A case study in the Yangtze River Delta region, China**

33 **Abstract**

34 To evaluate the improved emission estimates from online monitoring, we applied the
35 Models-3/CMAQ (Community Multi-scale Air Quality) system to simulate the air
36 quality of the Yangtze River Delta (YRD) region using two emission inventories
37 without/with incorporated data from continuous emission monitoring systems (CEMS)
38 at coal-fired power plants (Cases 1 and 2), respectively. The normalized mean biases
39 (NMBs) between the observed and simulated hourly concentrations of SO₂, NO₂, O₃
40 and PM_{2.5} in Case 2 were -3.1%, 56.3%, -19.5% and -1.4%, all smaller in absolute
41 value than those in Case 1, at 8.2%, 68.9%, -24.6% and 7.6%, respectively. The
42 results indicate that incorporation of CEMS data in the emission inventory reduced
43 the biases between simulation and observation and could better reflect the actual
44 sources of regional air pollution. Based on the CEMS data, the air quality changes and
45 corresponding health impacts were quantified for different implementation levels of
46 China's recent "ultra-low" emission policy. If the coal-fired power sector met the
47 requirement alone (Case 3), the differences in the simulated monthly SO₂, NO₂, O₃
48 and PM_{2.5} concentrations compared to those of Case 2, our base case for policy
49 comparisons, were less than 7% for all pollutants. The result implies a minor benefit
50 of ultra-low emission control if implemented in the power sector alone, attributed to
51 its limited contribution to the total emissions in the YRD after years of pollution
52 control (11%, 7% and 2% of SO₂, NO_x and primary particle matter (PM) in Case 2,
53 respectively). If the ultra-low emission policy was enacted at both power plants and
54 selected industrial sources including boilers, cement, and iron & steel factories (Case
55 4), the simulated SO₂, NO₂ and PM_{2.5} concentrations compared to the base case were
56 33%-64%, 16%-23% and 6%-22% lower respectively, depending on the month
57 (January, April, July and October 2015). Combining CMAQ and the Integrated
58 Exposure Response (IER) model, we further estimated that 305 deaths and 8744 years
59 of life loss (YLL) attributable to PM_{2.5} exposure could be avoided with the
60 implementation of the ultra-low emission policy in the power sector in the YRD
61 region. The analogous values would be much higher, at 10,651 deaths and 316,562
62 YLL avoided, if both power and industrial sectors met the ultra-low emission limits.
63 In order to improve regional air quality and to reduce human health risk effectively,
64 coordinated control of multiple sources should be implemented, and the ultra-low

65 emission policy should be substantially expanded to major emission sources in
66 non-power industries.

67 **1. Introduction**

68 Due to swift economic development and associated growth in demand for
69 electricity, coal-fired power plants have played an important role in energy
70 consumption and air pollutant emissions for a long time in China. For example, Zhao
71 et al. (2008) for the first time developed a “unit-based” emission inventory of primary
72 air pollutants from the coal-fired power sector in China and found that the sector
73 contributed 53% and 36% to the national total emissions of SO₂ and NO_x,
74 respectively, in 2005. Subsequently, SO₂ and NO_x emissions from the power sector
75 were estimated to account respectively for 28%-53% and 29%-31% of the total annual
76 emissions in China during 2006-2010 according to the Multi-resolution Emission
77 Inventory for China (MEIC: <http://www.meicmodel.org>). To reduce high emissions
78 and improve air quality in China, advanced air pollutant control devices (APCDs)
79 have been gradually applied in the power sector including flue gas desulfurization
80 (FGD) for SO₂ control, selective catalytic reduction (SCR) for NO_x control, and
81 high-efficiency dust collectors for primary particulate matter (PM) control. In recent
82 years, moreover, an “ultra-low emission” retrofitting policy has been widely
83 implemented, seeking to reduce the emission levels of coal-fired power plants to those
84 of gas-fired ones (i.e., 35, 50, and 5 mg/m³ for SO₂, NO_x and PM concentrations in
85 the flue gas). The expanded use of associated technologies has induced great changes
86 in the magnitude and spatio-temporal distribution of emissions from the power sector,
87 which have been analyzed and quantified by a series of studies (Y. Zhao et al., 2013;
88 Zhang et al., 2018; Liu et al., 2019; Tang et al., 2019; Y. Zhang et al., 2019). With the
89 updated unit-level information, for example, MEIC estimated that the power sector
90 shares of national total emissions declined from 28% to 22% and from 29% to 21%
91 for SO₂ and NO_x during 2010-2015, respectively. Incorporating data from continuous
92 emission monitoring systems (CEMS), Tang et al. (2019) found that China’s annual
93 power sector emissions of SO₂, NO_x and PM declined by 65%, 60% and 72%
94 respectively during 2014-2017, due to the enhanced control measures. With a method
95 of collecting, examining and applying CEMS data, similarly, our previous work
96 indicated that the estimated emissions from the power sector would be 75%, 63% and

97 76% smaller than those calculated without CEMS data for SO₂, NO_x and PM,
98 respectively (Y. Zhang et al., 2019).

99 Evaluations of emission estimates and the changed air quality from emission
100 abatement provide useful information on the sources of air pollution and the
101 effectiveness of pollution control measures. Air quality modeling is an important tool
102 for evaluating emission inventories, by comparing simulation results with available
103 observation data. Developed by the U.S. Environmental Protection Agency (USEPA),
104 the Models-3/Community Multi-scale Air Quality (CMAQ) system has been widely
105 used in China (Li et al., 2012; An et al., 2013; Wang et al., 2014; Han et al., 2015;
106 Zheng et al., 2017; Zhou et al., 2017; Chang et al., 2019). Han et al. (2015) conducted
107 CMAQ simulations with different emission inventories for East Asia, and found that
108 the simulated NO₂ columns using the emission inventory for the Intercontinental
109 Chemical Transport Experiment-Phase B (INTEX-B, Zhang et al., 2009) agreed better
110 with the satellite observations of the Ozone Monitoring Instrument (OMI) than the
111 simulations using the Regional Emission Inventory in Asia (REAS v1.11, Ohara et al.,
112 2007). Zhou et al. (2017) applied CMAQ to evaluate the national, regional and
113 provincial emission inventories for the Yangtze River Delta (YRD) region, and the
114 best model performance with the provincial inventory confirmed that the emission
115 estimate with more detailed information incorporated on individual power and
116 industrial plants helped improve the air quality simulation at relatively high horizontal
117 resolution. With air quality modeling, moreover, many studies have explored the
118 environment benefits of emission control measures taken in recent years (B. Zhao et
119 al., 2013; Huang et al., 2014; Li et al., 2015; Wang et al., 2015; Tan et al., 2017).
120 Wang et al. (2015) found that the implementation of the new Emission Standard of Air
121 Pollutants for Thermal Power Plants (GB13223-2011) could effectively reduce
122 pollutant emissions in China, and the ambient concentrations of SO₂, NO₂ and PM_{2.5}
123 would decrease by 31.6%, 24.3% and 14.7% respectively in 2020 compared with a
124 baseline scenario for 2010. Li et al. (2015) found that the simulated concentrations of
125 PM_{2.5} in the YRD region would decrease by 8.7%, 15.9% and 24.3% from 2013 to
126 2017 in three scenarios with weak, moderate and strong emission reduction
127 assumptions in the Clean Air Action Plan, respectively.

128 Besides air quality, the health risk caused by air pollution exposures in China is a
129 major concern, especially to PM_{2.5}, a dominant pollutant in haze conditions. Lim et al.

130 (2012) has identified air pollution as a primary cause of global burden of disease,
131 especially in low- and middle-income countries, and PM_{2.5} pollution was ranked the
132 fourth leading cause of death in China. Studies have shown that PM_{2.5} is closely
133 related to several causes of death (Dockery et al., 1993; Hoek et al., 2013; Lelieveld et
134 al., 2015; Butt et al., 2017; Gao et al., 2018; Maji et al., 2018; Hong et al., 2019). For
135 example, Lelieveld et al. (2015) estimated that nearly 1.4 million people died each
136 year due to PM_{2.5} exposure in China, 18% of which were related to the emissions from
137 the power sector. Based on simulated PM_{2.5} using WRF-Chem and the Integrated
138 Exposure Response (IER) model, Gao et al. (2018) estimated that emissions from the
139 power sector results in 15 million years of life lost per year in China. In addition to
140 assessment of health risk based on observations of actual air pollution levels, studies
141 have also analyzed the health benefits of emission control policies (Lei et al., 2015; Li
142 and Li, 2018; Dai et al., 2019; Q. Zhang et al., 2019; X. Zhang et al., 2019).
143 Combining available observation and CMAQ modeling, Q. Zhang et al. (2019)
144 identified improved emission controls on industrial and residential pollution sources
145 as the main drivers of reductions in PM_{2.5} concentrations from 2013 to 2017 in China,
146 and estimated an annual reduction of PM_{2.5}-related deaths at 0.41 million. Lei et al.
147 (2015) evaluated the health benefit of the Air Pollution Prevention and Control Action
148 Plan of China, and found that full realization of the air quality goal in this plan could
149 avoid 89 thousand premature deaths of urban residents, and reduce 120,000 inpatient
150 cases and 9.4 million outpatient service and emergency cases. Focusing more
151 regionally, X. Zhang et al. (2019) estimated the health impact of a "coal-to-electricity"
152 policy for residential energy use in the Beijing-Tianjin-Hebei (BTH) region. They
153 projected that the reduction in PM_{2.5} concentrations from the policy would avoid
154 nearly 22,200 cases of premature death and 607,800 cases of disease in the region in
155 2020. For areas with strong, industry-based economies, the impact of air quality on
156 public health can be more significant, attributed both to relatively large and dense
157 populations and to high pollution levels. Until now, however, there have been few
158 studies focusing on air quality improvement and corresponding health benefits
159 attributed to the implementation of the latest emission control policies, notably
160 China's ultra-low emission policy introduced above, at regional scale.

161 As one of the most densely populated and economically developed regions, the
162 YRD region encompassing Shanghai and Anhui, Jiangsu, and Zhejiang provinces is a

163 key area for air pollution prevention and control in China (Huang et al., 2011; Li et al.,
164 2011; Li et al., 2012). It is also one of the regions with the earliest implementation of
165 the ultra-low emission policy on the power sector in the country. Quantification of
166 emission reductions and subsequent changes in air quality is crucial for full
167 understanding of the environmental benefits of the policy. To test the possible
168 improvement in the regional emission inventory, this study evaluated the air quality
169 modeling performance without and with CEMS data incorporated in the estimation of
170 emissions of the coal-fired power sector for the YRD region. The changes in regional
171 air quality and health risk resulting from the implementation of the ultra-low emission
172 policy for key industries were quantified combining the air quality modeling and the
173 health risk model. The results provide scientific support for incorporation of online
174 monitoring data to improve the estimation of air pollutant emissions, and for better
175 design of emission control policies based on their simulated environmental effects.
176

177 **2. Methodology and data**

178 **2.1 Air quality modeling**

179 In this study, we adopted CMAQ version 4.7.1 (UNC, 2010) to conduct air
180 quality simulations and to evaluate various emission inventories for the YRD region.
181 The model has performed well in Asia (Zhang et al., 2006; Uno et al., 2007; Fu et al.,
182 2008; Wang et al., 2009). Two one-way nested domains were adopted for the
183 simulations, and the horizontal resolutions were set at 27 and 9 km square grid cells
184 respectively, as shown in Figure 1. The mother domain (D1, 177 × 127 cells) covered
185 most of China and all or parts of surrounding countries in East, Southeast, and South
186 Asia. The second modeling region (D2, 118×121 cells) covered the YRD region,
187 including Jiangsu, Zhejiang, Shanghai, Anhui and parts of surrounding provinces.
188 Lambert Conformal Conic Projection was applied for the entire simulation area
189 centered at (110°E, 34°N) with two true latitudes, 40°N and 25°N. The simulated
190 periods were January, April, July and October 2015, as representative of the four
191 seasons. The first five days in each month were set as a spin-up period to provide
192 initial conditions for later simulations. The carbon bond gas-phase mechanism (CB05)
193 and AERO5 aerosol module were adopted in all the CMAQ modules, with details of

194 the model configuration found in Zhou et al. (2017). The initial concentrations and
195 boundary conditions for the D1 mother domain were the default clean profile, while
196 they were extracted from CMAQ outputs of D1 simulations for the nested D2 domain.
197 Normalized mean bias (NMB), normalized mean error (NME), and the correlation
198 coefficient (R) between the simulations and observations were selected to evaluate the
199 performance of CMAQ modeling (Yu et al., 2006). The hourly concentrations of SO₂,
200 NO₂, O₃ and PM_{2.5} were observed at 230 state-operated ground stations of the national
201 monitoring network in the YRD region and were collected from Qingyue Open
202 Environmental Data Center (<https://data.epmap.org>).

203 The Weather Research and Forecasting (WRF) Model version 3.4
204 (<http://www.wrf-model.org/index.php>, Skamarock et al., 2008) was applied to provide
205 meteorological fields for CMAQ. Terrain and land-use data were taken from global
206 data of the U.S. Geological Survey (USGS), and the first-guess fields of
207 meteorological modeling were obtained from the final operational global analysis data
208 (ds083.2) by the National Center for Environmental Prediction (NCEP). Statistical
209 indicators including bias, index of agreement (IOA), and root mean squared error
210 (RMSE) were chosen to evaluate the performance of WRF modeling against
211 observations (Baker et al., 2004; Zhang et al., 2006). Ground observations at 3-h
212 intervals of four meteorological parameters including temperature at 2 m (T2),
213 relative humidity at 2 m (RH2), and wind speed and direction at 10 m (WS10 and
214 WD10) of 42 surface meteorological stations in the YRD region were downloaded
215 from the National Climatic Data Center (NCDC). The statistical indicators for WS10,
216 WD10, T2 and RH2 in the YRD region are summarized by month in Table S1 in the
217 Supplement. The discrepancies between WRF simulations and observations of these
218 meteorological parameters were generally acceptable (Emery et al., 2001). Better
219 agreements were found for T2 and RH2 with their biases ranging -0.62 to +0.12°C
220 and -3.20% to +6.60% respectively, and their IOAs were all within the benchmarks
221 (Emery et al., 2001). In general, WRF captured well the characteristics of main
222 meteorological conditions for the region.

223 **2.2 Emission inventories and cases**

224 The anthropogenic emissions from industry, residential and transportation sectors
225 for D1 and D2 were obtained from the national emission inventory developed in our

226 previous work (Xia et al., 2016). The total emissions excluding those of the power
227 sector of SO₂, NO_x and PM for the YRD region were estimated at 1501.0, 3468.4 and
228 2711.2 Gg for 2015, respectively. The emission inventory in Xia et al. (2016) was
229 developed using activity data at the provincial level, and the spatial distribution of
230 emissions by sector was conducted according to that of MEIC with the original spatial
231 resolution of 0.25° × 0.25° in this study. The gridded emissions were further
232 downscaled to horizontal resolutions of 27 and 9 km in D1 and D2, respectively,
233 based on the spatial distribution of population (for residential sources), industrial
234 gross domestic product (for industrial sources), and the road network (for on-road
235 vehicles). The monthly variations of emissions from each sector were assumed to be
236 the same as in MEIC. Constrained by available ground observation, a larger monthly
237 variation in the emissions of black carbon aerosols was found for the central YRD
238 region than that in MEIC. Limited improvement in air quality model performance was
239 consequently achieved, implying that the bias from the temporal variation was
240 insignificant (Zhao et al., 2019). In addition, the Model Emissions of Gases and
241 Aerosols from Nature developed under the Monitoring Atmospheric Composition and
242 Climate project (MEGAN-MACC, Guenther et al., 2012; Sindelarova et al., 2014)
243 were applied as the biogenic emission inventory, and the emissions of Cl, HCl and
244 lightning NO_x were obtained from the Global Emissions Initiative (GEIA, Price et al.,
245 1997).

246 For the power sector in the YRD region specifically, we adopted the unit-level
247 emission estimates from our previous study and allocated the emissions according to
248 the actual locations of individual units (Y. Zhang et al., 2019). As described in that
249 study, the detailed information at the power unit level was compiled based on official
250 environmental statistics including the geographic location, installed capacity, fossil
251 fuel consumption, combustion technology, and APCDs. Besides the commonly used
252 method, Y. Zhang et al. (2019) developed a new method of examining, screening and
253 applying CEMS data to improve the estimates of power sector emissions. CEMS data
254 were collected for over 1000 power units, including operation condition, monitoring
255 time, flue gas flow, and hourly concentrations of SO₂, NO_x and PM. The emissions of
256 individual unit were calculated based on the hourly concentrations of air pollutants
257 obtained from CEMS and the theoretical flue gas volume estimated based on the
258 unit-level information mentioned above. Compared to MEIC, a larger monthly

259 variation in emissions was found based on the online emission monitoring. More
260 details can be found in Y. Zhang et al. (2019). In this work, five emission cases were
261 set for the air quality simulation. Cases 1 and 2 used estimates of power sector
262 emissions without/with incorporation of CEMS data, and were compared against each
263 other to evaluate the benefit of online emission monitoring information in air quality
264 simulation. Note Case 2 was set as the base case for further analysis of the effects of
265 emission controls. Based on the unit-level information from CEMS, Case 3 assumed
266 that only power plants would meet the requirement of the ultra-low emission policy,
267 while Case 4 assumed both power plants and selected industrial sources including
268 boilers, cement, and iron & steel factories would meet the requirement. As
269 summarized in Table S2 in the supplement, the ultra-low emission limits for the flue
270 gas concentrations were obtained from the most recent national or local standards by
271 sector (Yang et al., 2021). The model performances were compared with the base case
272 to quantify the air quality improvements that result from the policy. Case 5 removed
273 all the emissions from the power sector and thus helped to specify the contribution of
274 the power sector to air pollution in the YRD region.

275 The air pollutant emissions for all the cases are summarized by sector in Table 1.
276 With the CEMS data for the power sector incorporated, the total emissions of SO₂,
277 NO_x and PM for the YRD region in Case 2 were estimated as 427, 618 and 331 Gg
278 smaller than those in Case 1, with relative reductions of 20%, 14% and 11%
279 respectively. Benefiting from the implementation of the ultra-low emission policy in
280 the coal-fired power sector, the total emissions of anthropogenic SO₂, NO_x and PM in
281 Case 3 would further decline 123, 135 and 36 Gg compared to Case 2, respectively.
282 The analogous numbers for Case 4 were 1180, 1003, and 1315 Gg, and the reduction
283 rates compared to Case 2 were 70%, 27%, and 48% for SO₂, NO_x and PM,
284 respectively. The implementation of the ultra-low emission policy for both power and
285 industry sectors would significantly reduce the primary pollutant emissions for the
286 YRD region. In Case 5 where the emissions from power sector were set as zero, the
287 total emissions of SO₂, NO_x and PM were estimated to decrease by 11%, 7% and 2%
288 respectively compared to Case 2.

289 **2.3 Health effect analysis**

290 We applied the IER model of the Global Burden of Disease Study (GBD) 2015

291 (Cohen et al., 2017) and quantified the impact of emission control policy on the
 292 human health risk due to long-term exposure of PM_{2.5} in the YRD region. The model
 293 has been well developed and widely applied in quantifying the impact of air pollution
 294 control policies on health burden (Li et al. 2019; Yue et al. 2020; Zheng et al. 2019).
 295 Compared to another widely used model Global Exposure Mortality Model (GEMM;
 296 Burnett et al., 2018), IER was expected to provide relatively conservative estimates
 297 for China (Yang et al., 2021). The number of attributable deaths and years of life lost
 298 (YLL) caused by long-term PM_{2.5} exposure for selected emission cases were
 299 calculated for various diseases in this study. In particular, YLL represents the years of
 300 life lost because of premature death from a particular cause or disease. As the number
 301 of deaths alone could not provide a comprehensive picture of the burden that deaths
 302 impose on the population, we calculated YLL caused by PM_{2.5} exposure to help
 303 describe the extent to which the lives of people exposed to air pollution were cut short.
 304 We considered the four adult diseases of the GBD study, including ischemic heart
 305 disease (IHD), stroke (STK, including ischemic and hemorrhagic stroke), lung cancer
 306 (LC), and chronic obstructive pulmonary disease (COPD), and a common disease
 307 among young children, acute lower respiratory infection (LRI).

308 The health risks in the different emission cases were estimated following Gao et
 309 al. (2018) with the updated information for 2015. First, the relative risk (RR) for each
 310 disease was calculated using eq. (1):

$$311 \quad RR_{i,j,k}(Cl) = \begin{cases} 1 + \partial_{i,j,k}(1 - e^{-\beta_{i,j,k}(Cl-C_0)^{\gamma_{i,j,k}}}), & Cl \geq C_0 \\ 1, & Cl < C_0 \end{cases} \quad (1)$$

312 where i , j , and k represent the age, gender and disease type, respectively; Cl is the
 313 annual average PM_{2.5} concentration simulated with WRF-CMAQ (the average of
 314 January, April, July and October in this work); C_0 is the counterfactual concentration;
 315 and ∂ , β and γ are the parameters that describe the IER functions, as reported by
 316 Cohen et al. (2017).

317 Secondly, the population attributable fractions (PAF) were calculated with RR
 318 following eq. (2) by disease, age and gender subgroup:

$$319 \quad PAF_{i,j,k} = \frac{RR_{i,j,k}(Cl) - 1}{RR_{i,j,k}(Cl)} \quad (2)$$

320 Moreover, the mortality attributable to PM_{2.5} exposure (ΔM) was calculated
 321 using eq. (3), where y_0 is the current age-gender-specific mortality rate, and Pop

322 represents the exposed population in the age-gender-specific group in grid cell l :

$$323 \Delta M_{i,j,k,l} = PAF_{i,j,k,l} \times y_{oi,j,k,l} \times Pop_{i,j,l} \quad (3)$$

324 The population data of the four provinces and cities in the YRD region were
325 obtained from statistical yearbooks (AHBS, 2016; JSBS, 2016; SHBS, 2016; ZJBS,
326 2016), and the gender distribution by province is shown in Table S3 in the
327 Supplement. As the high-resolution spatial pattern of age structure was unavailable,
328 we assumed the same age structure for all the model grids according to Gao et al.
329 (2018). The baseline age-gender-disease-specific mortality rates for the five diseases
330 in China for 2015 were obtained from the Global Health Data Exchange database
331 (GHDx, <https://vizhub.healthdata.org>), as shown in Table S4 in the Supplement, and
332 those by province were calculated based on the provincial proportions in Xie et al.
333 (2016). The national population with the spatial resolution at 1×1 km in 2015 was
334 provided by the Landscan Global Demographic Dynamic Analysis Database
335 developed by Oak Ridge National Laboratory (ORNL) of the U.S. Department of
336 Energy. As shown in Figure S1 in the Supplement, the population densities in the
337 YRD region are larger in Shanghai, southern Jiangsu and northern Zhejiang.

338 Finally, the year of life lost (YLL) due to $PM_{2.5}$ exposure was calculated from the
339 number of deaths multiplied by a standard life expectancy at the age at which death
340 occurs, as shown in eq. (4), where N represents the number of deaths in each
341 age-gender-specific group, and L reflects the remaining life expectancy of the group:

$$342 YLL = \sum_{i,j} N_{i,j} \times L_{i,j} \quad (4)$$

343 The remaining life expectancies by age were obtained from the life tables from
344 the World Health Organization (WHO, <https://www.who.int>), as summarized in Table
345 S5 in the Supplement. The life expectancies at birth of Chinese males and females in
346 2015 were 74.8 and 77.7 years, respectively.

347 **3. Results and discussion**

348 **3.1 Evaluation of emission estimates with air quality simulation**

349 **3.1.1 Model performances without/with CEMS data**

350 Air quality simulations based on emission inventories without/with incorporation
351 of CEMS data for the coal-fired power sector (Cases 1 and 2, respectively) were

352 conducted to test the improvement of emission estimates. Because of the combined
353 influences of regional transport and chemical reactions of air pollutants in the
354 atmosphere, nonlinear relationships were found between the changes of primary
355 emissions and ambient concentrations of air pollutants. Compared to Case 1, the
356 simulated annual average concentrations of SO₂, NO₂ and PM_{2.5} in the YRD region
357 were 10%, 7% and 6% lower respectively in Case 2, while that of O₃ was 7% higher,
358 due to combined effects of emissions of volatile organic compounds (VOCs) and NO_x
359 precursors (Gao et al., 2005; Yang et al., 2012). Previous studies have shown that O₃
360 formation in most of the YRD region is under the “VOCs-limited” regime, i.e., the
361 generation and removal of O₃ is more sensitive to VOCs and would be inhibited with
362 high NO_x concentrations in the atmosphere (Zhang et al., 2008; Liu et al., 2010;
363 Wang et al., 2010; Xing et al., 2011). Therefore, the simulated reduced NO₂
364 concentrations from greater NO_x emission control could elevate the O₃ concentration.

365 The model performance was evaluated with available ground observation. The
366 hourly concentrations were observed at 230 state-operated air quality monitoring
367 stations within YRD, and the averages of hourly concentrations of those sites were
368 compared with the simulations in Cases 1 and 2, as summarized in Table 2. Similar
369 model performances were found for the two emission cases, with overestimation of
370 SO₂, NO₂ and PM_{2.5} and underestimation of O₃. The NMEs between the simulated
371 and observed SO₂, O₃ and PM_{2.5} concentrations were all smaller than 50% for both
372 cases, and slightly worse simulation performances were found in July compared to the
373 other three months. In particular, the correlation coefficients (R) between the
374 simulated and observed SO₂ in July were only 0.17 and 0.14 for Cases 1 and 2,
375 respectively, and the NMEs between the simulated and observed NO₂ were larger than
376 100%. In addition, greater overestimation of SO₂ and PM_{2.5} by the model was found
377 in July than other months, likely attributable to the bias of WRF modeling. On one
378 hand, the simulated WS10 in the YRD region in July (2.67 m/s) was slightly lower
379 than the observation (2.75 m/s). The underestimation in wind speed could weaken the
380 horizontal diffusion and lead to overestimation in air pollutant concentrations.
381 Compared with the results from the European Centre for Medium-range Weather
382 Forecasts (ECMWF, <https://apps.ecmwf.int/datasets>), on the other hand, the simulated
383 boundary layer height (BLH) was lower in WRF for all months. The NMBs of the
384 WRF and ECMWF BLH in January, April and October were around -15%, while that

385 in July reached -24%. The lower BLH would limit the vertical convection and
386 diffusion of pollutants, and thereby increase the surface concentrations of air
387 pollutants. Similar to previous studies (An et al., 2013; Liao et al., 2015; Tang et al.,
388 2015; Gao et al., 2016; Wang et al., 2016; Zhou et al., 2017), underestimation of O₃
389 was commonly found. The NMBs between the simulation and observation for the two
390 cases ranged from -34.5% to -6.4%, and NMEs from 23.1% to 37.1%, respectively.
391 The underestimation in O₃ likely resulted from bias in the estimation of precursor
392 emissions. Suggested by the positive NMBs of NO₂ modeling in Table 2, the NO_x
393 emissions were expected to be overestimated in the two cases, even for Case 2 with
394 the CEMS data incorporated (which reflect the emission control benefits in recent
395 years, as discussed in Y. Zhang et al., 2019). In addition, underestimation of VOC
396 emissions is likely due to incomplete accounting of emission sources, particularly for
397 uncontrolled or fugitive leakage (Zhao et al, 2017). As most of YRD was identified as
398 a VOC-limited region for O₃ formation (Wang et al., 2019; Yang et al., 2021), the
399 overestimation of NO_x and underestimation of VOCs could contribute to the
400 underestimation in O₃ concentrations with air quality modeling. The simulations of
401 both cases captured well the temporal variations of PM_{2.5} concentrations, with the R
402 between the observed and simulated concentrations around 0.9.

403 In general, better modeling performance in the YRD region was found in Case 2
404 than Case 1. The NMBs between the simulated and observed concentrations of SO₂,
405 NO₂, O₃ and PM_{2.5} for the whole simulation period were -3.1%, 56.3%, -19.5% and
406 -1.4% for Case 2, smaller in absolute value than those for Case 1 at 8.2%, 68.9%,
407 -24.6% and 7.6%, respectively. The bootstrap sampling (Gleser et al., 1996; He et al.,
408 2017) was further applied to test the significance of the improvements of Case 2 over
409 Case 1. (A significant difference is demonstrated if the confidence intervals of given
410 statistical indices sampled from the two cases do not overlap.) As can be seen in Table
411 2, the modeling performances of the concerned species in Case 2 were improved
412 significantly in most instances compared to Case 1. For example, the improvement of
413 NMB for the SO₂ simulation was significant at the 99% confidence level for July and
414 October, and 95% for January. The improvement of NMB and NME for NO₂ was
415 significant at confidence levels of 99% and 95% respectively for April. The
416 improvement of NMB for O₃ was significant at the 95% confidence level for January,
417 and that of PM_{2.5} at 95% for April and 99% for July. The statistical test confirms that

418 incorporation of online monitoring data in the emission inventory can improve the
419 regional air quality modeling for the YRD region. Besides the emission data, it should
420 also be noted that the changes in model schemes would affect the model performance.
421 For example, the newer version of CMAQ incorporated the chemistry schemes of
422 bromine and iodine, and was expected to influence the O₃ simulation importantly.
423 According to our recent test in the YRD region (Lu et al., 2020), the impact of CMAQ
424 version on the simulation of difference species was inconclusive, implying the
425 necessity of further intercomparison and evaluation studies for the region.

426 Figure 2 illustrates the spatial patterns of the simulated monthly SO₂, NO₂, O₃
427 and PM_{2.5} concentrations for Case 2. For a given species, similar patterns were found
428 for different months. In general, the simulated concentrations of SO₂, NO₂ and PM_{2.5}
429 were larger in central and northern Anhui, southern Jiangsu, Shanghai and coastal
430 areas in Zhejiang, where large power and industrial plants are concentrated, as shown
431 in Figure S2 in the Supplement. In the highly populated cities (Shanghai, Nanjing,
432 Hangzhou, and Hefei; see their locations in Figure 1), the simulated concentrations of
433 pollutants were significantly larger than their surrounding areas. For example, the
434 simulated SO₂, NO₂ and PM_{2.5} concentrations in Nanjing were 1.4, 1.3 and 1.2 times
435 of those in its nearby cities. The analogous numbers for Hangzhou were 2.5, 1.5 and
436 1.3. In contrast, the simulated O₃ concentrations were smaller in urban areas and
437 larger in suburban ones. For instance, the simulated O₃ in Nanjing, Shanghai, Hefei
438 and Hangzhou were 0.7, 0.4, 0.6 and 0.6 times of those in their surrounding areas,
439 respectively. The spatial distributions of the simulated NO₂ and O₃ concentrations in
440 Figure 2 also indicated that O₃ concentrations were less in the regions with higher
441 NO₂ concentrations, such as the megacity of Shanghai. The simulated high
442 concentrations of NO₂ in urban areas promotes titration of O₃, reducing its
443 concentrations. In addition, O₃ concentrations could remain relatively high after
444 transport from urban to the suburban areas due to relatively small emissions of NO_x
445 in the latter.

446 **3.1.2 Benefits of the “ultra-low” emission controls on air quality**

447 Table 3 summarizes the absolute and relative changes of the simulated monthly
448 concentrations of the concerned air pollutants in Cases 3-5 compared to the base case
449 (Case 2). The average contributions of the power sector to the total ambient

450 concentrations of SO₂, NO₂ and PM_{2.5} for the four simulated months are estimated at
451 10.0%, 4.7%, and 2.3%, respectively, based on comparison of Cases 2 and 5. The
452 contributions to the concentrations were close to those of emissions at 10.7%, 6.6%,
453 and 1.6% for the three species (as indicated in Table 1), respectively. The larger power
454 sector contribution to the ambient PM_{2.5} concentrations than to primary PM emissions
455 reflects high emissions of precursors of secondary sulfate and nitrate aerosols. In
456 general, limited contributions from the power sector were found for all concerned
457 species except SO₂, attributed to the gradually improved controls in the sector. The
458 further implementation of the ultra-low emission policy in the sector, therefore, is
459 expected to result in limited additional benefits for air quality. As shown in Table 3,
460 the absolute changes of the simulated SO₂, NO₂, O₃ and PM_{2.5} concentrations in Case
461 3 compared to Case 2 were all smaller than 1 µg/m³ for the four months. Larger
462 changes were found for primary pollutants (SO₂ and NO₂) than those of secondary
463 ones (O₃ and PM_{2.5}): the simulated monthly concentrations of SO₂ and NO₂ were
464 2.7%-6.1% and 2.0%-2.9% lower, while PM_{2.5} was only 0.1%-1.3% lower and O₃
465 0.8%-2.2% higher, respectively. Much larger benefits were found when the ultra-low
466 emission policy was broadened from the power sector to the industrial sector (Case 4),
467 attributed to the dominant role of industry in air pollutant emissions in the YRD
468 region (Table 1). The simulated monthly concentrations of SO₂, NO₂ and PM_{2.5} were
469 1.5-2.0, 2.5-3.7, and 4.6-6.5 µg/m³ lower compared to the base case, respectively, or
470 reduction rates of 32.9%-64.1%, 16.4%-22.8%, and 6.2%-21.6%. In contrast, the
471 simulated O₃ concentration was 0.8-4.8 µg/m³ higher, with growth rates ranging
472 2.6%-14.0%. As mentioned earlier, the YRD was identified as a VOC-limited region,
473 and reducing NO_x emissions without any VOC controls would enhance O₃
474 concentrations. Currently, CEMS does not report VOCs concentration in the flue gas,
475 and the “ultra-low emission” policy does not include VOC limit, either. In order to
476 alleviate regional air pollution including O₃, coordinated controls of NO_x and VOC
477 emissions are urgently required. These would include measures to reduce large
478 sources of VOCs, notably in non-power industries such as chemicals and refining and
479 in solvent use (Zhao et al., 2017).

480 The relative changes in the simulated pollutant concentrations varied by month,
481 due to the combined influences of meteorology and secondary chemistry, and larger
482 relative changes were found for SO₂ and PM_{2.5} in summer. As shown in Table 3, for

483 example, the average simulated PM_{2.5} concentrations in July were 0.4 and 6.5 μg/m³
484 lower respectively under Cases 3 and 4 compared to Case 2, with the larger reduction
485 than other three months. This could result partly from the faster response of ambient
486 concentrations to the changed emissions of air pollutants with shorter lifetimes in
487 summer. The formation of secondary pollutants like PM_{2.5} would be enhanced in
488 summer, with more oxidative atmospheric conditions under high temperature and
489 strong sunlight. Moreover, the relatively low concentrations in summer also
490 contributed to the largest percentage changes in SO₂ and PM_{2.5} simulation for the
491 season.

492 Figures 3 and 4 illustrate the spatial distributions of the relative changes of
493 simulated pollutant concentrations in Cases 3 and 4 compared to Case 2, respectively.
494 As shown in Figure 3, the overall changes across the region due to ultra-low emission
495 controls in the power sector only were less than 10% for primary pollutants SO₂ and
496 NO₂, and 5% for secondary pollutants PM_{2.5} and O₃. Larger changes in simulated SO₂
497 concentrations were found in central and northern Anhui as well as central and
498 southern Jiangsu, with relatively concentrated distribution of coal-fired power plants.
499 The changes of simulated SO₂ and NO₂ in Shanghai were tiny, due to few remaining
500 power plants subject to the ultra-low emission policy and thus few emission
501 reductions. Compared to Case 2, the SO₂ and NO_x emissions in Case 3 were
502 estimated to be 2.2% and 0.8% lower respectively for Shanghai, much smaller than
503 for other provinces (6.1% and 2.5% for Anhui, 9.5% and 4.4% for Jiangsu, 5.5% and
504 2.7% for Zhejiang). The results suggest that the potential of emission reduction and
505 air quality improvement is limited from implementation of more stringent control
506 measures in the power sector alone, particularly in highly developed cities where air
507 pollution controls have already reached a relatively high level.

508 In Case 4, where both power plants and selected industrial sources meet the
509 ultra-low emission requirement, the average reduction rates of simulated SO₂ and NO₂
510 concentrations compared to Case 2 were above 40% and 25% respectively for the
511 whole region, and the changes of secondary pollutants O₃ and PM_{2.5} were also
512 significantly larger than those of Case 3 in most of the region. The relative changes of
513 SO₂ were found to be more significant than other species, as the SO₂ concentrations
514 are greatly affected by primary emissions. Due to the large number and wide
515 distribution of industrial plants throughout the YRD, moreover, there was little

516 regional disparity in the changed ambient SO₂ levels. Compared to other areas, the
517 relatively less reduction in the simulated NO₂ in central YRD resulted in significant
518 enhancement of O₃ concentrations (note that much more reduction in NO₂ resulted in
519 similar enhancement of O₃ in southern Anhui for October). The comparison implies
520 that the O₃ formation in central YRD was more sensitive to NO_x emission abatement
521 than other VOC-limited regions in YRD. The result suggests particularly great
522 challenge of O₃ pollution control in central YRD, and more efforts on VOC emission
523 abatement would be required for those developed areas.

524 **3.2 Evaluation of health benefits**

525 **3.2.1 PM_{2.5} exposures in the YRD region**

526 Figure 5 illustrates the spatial distributions of PM_{2.5} concentrations for the base
527 case (Case 2) and the differences of Cases 3 and 4 compared to the base case. The
528 reduction of PM_{2.5} concentrations from the implementation of the ultra-low emission
529 policy in the power sector was less than 1 µg/m³ over the YRD region (Figure 5b).
530 Larger reductions (above 0.4 µg/m³) were found in northern Anhui and northern and
531 southern Jiangsu provinces, as those regions are the energy base of eastern China,
532 with abundant coal mines and power plants with large installed capacities. With the
533 policy expanded to certain industrial sectors, the simulated average PM_{2.5}
534 concentrations were 5.8 µg/m³ lower for the whole region (Figure 5c). In particular,
535 the difference was greater than 10 µg/m³ along the Yangtze River, as there are many
536 industrial parks located along the river containing a large number of big cement, iron
537 & steel, and chemical industry plants. Stringent emission controls at those plants
538 would result in significant benefits in air quality for local residents.

539 We further calculated the fractions of the population with different annual
540 average PM_{2.5} exposure levels in Cases 2-4, as shown in Figure 6. Compared to Case
541 2, slight differences in the population distribution by exposure level were found in
542 Case 3, while the differences were much more significant in Case 4. The population
543 fractions exposed to the average annual concentrations of PM_{2.5} smaller than 35 µg/m³,
544 35-45 µg/m³ and 45-55 µg/m³ were estimated to grow from 14% in Case 2 to 21% in
545 Case 4, from 11% to 16%, and from 16% to 30%, respectively (note 35 µg/m³ is the
546 annual PM_{2.5} concentration limit in the current National Ambient Air Quality Standard

547 for China). Accordingly, the fraction exposed to PM_{2.5} concentrations larger than 55
548 µg/m³ declined from 59% to 33%. The implementation of ultra-low emission policy
549 on both power plants and industry sources thus proved an effective way in limiting the
550 population exposed to high PM_{2.5} levels.

551 **3.2.2 Human health risk with base case emissions**

552 The mortality and YLL caused by atmospheric PM_{2.5} exposure with the base case
553 emissions (Case 2) in the YRD region are shown in Table 4. The values in brackets
554 represent the 95% confidence interval (CI) attributed to the uncertainty of IER curves
555 (i.e., uncertainties from other sources were excluded in the 95% CI estimation such as
556 air quality model mechanisms, emission inventories, and population data). With the
557 base case emissions, the NMB of the simulated and observed annual PM_{2.5}
558 concentrations (based on the four representative months) was calculated at -1.4% for
559 the YRD region. Therefore, the influence of the biases between the simulations and
560 observations on the estimated health risks was negligible and thus not considered in
561 this study. The total attributable deaths due to all diseases caused by PM_{2.5} exposure in
562 the YRD region were estimated at 194,000 (114,000-282,000), with STK, IHD and
563 COPD causing the most deaths, accounting for 29%, 32% and 22% of the total
564 respectively. With larger populations in Anhui and Jiangsu (32% and 37% of the
565 regional total respectively), more deaths caused by PM_{2.5} exposure were found in
566 these two provinces, at 34% and 41% of the total deaths respectively. Among all the
567 diseases, STK was found to cause the largest number of mortalities (19,600) in Anhui
568 with PM_{2.5} exposure, IHD in Jiangsu (31,300), and COPD in Shanghai (4,400) and
569 Zhejiang (10,800). The total YLL caused by PM_{2.5} exposure in the YRD region was
570 5.11 million years (3.16 - 7.18 million years). More YLL caused by PM_{2.5} exposure
571 was found in Anhui and Jiangsu, accounting for 34% and 37% of the total in the YRD
572 region respectively. YLL caused by COPD were the largest in all the provinces, with
573 0.66, 0.19, 0.56 and 0.47 million years estimated for Anhui, Shanghai, Jiangsu and
574 Zhejiang, respectively. The spatial distribution of attributable deaths and YLL caused
575 by PM_{2.5} exposure was basically consistent with that of population in the YRD region,
576 with correlation coefficients of 0.94 and 0.96 respectively. As shown in Figure 7,
577 higher health risks attributed to PM_{2.5} pollution in the base case (Case 2) were
578 commonly found in the areas with larger population densities, including the areas

579 along the Yangtze River, central Shanghai and some urban areas in Anhui. We further
580 compared the population deaths attributable to PM_{2.5} exposure calculated in this study
581 with the reported total deaths in provincial statistical yearbooks (AHBS, 2016; JSBS,
582 2016; SHBS, 2016; ZJBS, 2016), and found that the deaths caused by PM_{2.5} exposure
583 accounted for 18%, 14%, 15% and 11% of the total deaths in Anhui, Jiangsu,
584 Shanghai and Zhejiang respectively for 2015. The numbers were larger than the
585 estimate (6.9%) by Maji et al. (2018), which focused on 161 cities in China. As one of
586 the most developed and industrialized regions in China, YRD suffered higher PM_{2.5}
587 pollution level than the national average, leading to the larger fraction of premature
588 death due to PM_{2.5} exposure. Moreover, the baseline disease-specific mortality rates
589 applied in this study (from GHDx) were commonly higher than those in Maji et al.
590 (2018) except for LRI, resulting in the larger estimate of death rates exposed to PM_{2.5}.

591 Many studies have focused on the human health risks attributable to air pollution
592 in China, with considerable disparities between them due to different estimation
593 methods and health endpoints selected. Figure 8 compares the estimates of premature
594 deaths caused by PM_{2.5} exposure in the YRD region in this and previous studies.
595 Relatively close results are found between studies for the same regions and periods.
596 For example, Hu et al. (2017) and Liu et al. (2016) estimated that the premature
597 deaths of adults (>30 years old) due to PM_{2.5} exposure were 223,000 and 245,000
598 respectively in 2013 in the YRD region. However, the health endpoints in these two
599 studies were not completely consistent. COPD, LC, IHD and CEV (cerebrovascular
600 disease) were selected in Hu et al. (2017), while COPD, LC, IHD and STK were
601 chosen by Liu et al. (2016). The deaths caused by PM_{2.5} exposure in Shanghai were
602 estimated at 19,000, 15,000, and 16,000 respectively in Maji et al. (2018), Song et al.
603 (2017) and this study, respectively. The IER model and the same health endpoints
604 were adopted in all three studies, while the PM_{2.5} concentrations were derived from
605 ground observations in the former two studies instead of air quality simulation in this
606 study. The premature deaths attributable to PM_{2.5} exposure in the YRD region in 2015
607 were estimated at 122,000 in Maji et al. (2018) and 194,000 in this study respectively.
608 Besides the different baseline mortality rates adopted in the two studies as mentioned
609 earlier, the smaller estimate by Maji et al. (2018) could also result partly from
610 inclusion of only typical cities instead of all cities in the YRD region. There are clear
611 disparities in estimates of premature deaths for different years. For example, the death

612 estimates caused by PM_{2.5} exposure in 2015 were generally smaller than those in 2013.
613 As the population and age distributions remained relatively stable over the two years
614 (AHBS, 2016; JSBS, 2016; SHBS, 2016; ZJBS, 2016), the reduced estimated
615 premature deaths result to some extent from emission abatement and air quality
616 improvement. According to relevant studies of Shanghai in particular (Lelieveld et al.,
617 2013; 2015; Liu et al., 2016; Xie et al., 2016; Hu et al., 2017; Song et al., 2017; Maji
618 et al., 2018), the premature deaths attributable to PM_{2.5} exposure increased from 2005
619 to 2013 and then declined afterwards, reflecting the health benefit of air pollution
620 control measures in Shanghai in recent years.

621 **3.2.3 Benefits of emission controls on human health**

622 Tables 5 and 6 respectively summarize the avoided premature deaths and YLL by
623 disease and region that would result from implementation of the ultra-low emission
624 control policy and thereby reduced PM_{2.5} pollution in the YRD region. If only the
625 coal-fired power sector meet the ultra-low emission limits (Case 3), nearly 305
626 premature deaths would be avoided compared to the base case emissions in 2015,
627 with a tiny reduction rate of only 0.16%. If the policy is strictly implemented for
628 selected industrial sectors as well (Case 4), 10,651 premature deaths could be avoided
629 with a reduction rate at 5.50%. The largest numbers of avoided premature deaths were
630 found in Anhui and Jiangsu, accounting collectively for 88.2% and 68.7% of the total
631 avoided deaths in Cases 3 and 4 respectively. The greatest impacts from reduced
632 PM_{2.5} concentrations were found for STK, of which the avoided deaths were
633 calculated at 85 and 2848 in Cases 3 and 4, respectively. The health effects of
634 emission control policies in the YRD region have been investigated in previous
635 studies. Using the IER model, Dai et al. (2019) chose the premature deaths from IHD,
636 CEV, COPD and LC as health endpoints, and found that the Clean Air Action Plan
637 would avoid 3,439 deaths caused by PM_{2.5} exposure in Shanghai, more than those in
638 both Case 3 and Case 4 in this study (5 and 1,185 respectively). Applying
639 environmental health risk and valuation methods, Li and Li (2018) found that 15,709
640 premature deaths attributable to air pollution could be avoided in 2015 if the PM_{2.5}
641 concentrations in Jiangsu province were assumed to meet the National Ambient Air
642 Quality Standard (GB3095-2012, 35 µg/m³ as the annual average). The estimate is
643 much more than those calculated in Case 3 and Case 4 (177 and 4,114 deaths

644 respectively). The larger health benefits estimated in those two studies result from
645 their assumption of emission control measures covering a much wider range of sectors
646 including energy, industry, transportation, construction, and agriculture, while only the
647 ultra-low emission policy was assumed for the power and industry sectors in this
648 study. The comparisons illustrate that the health benefits from emission control in the
649 power sector alone is limited, and that controls in other sectors are essential. In
650 addition, the different methods and inconsistent data sources partly led to the
651 discrepancies. For the particle exposure estimation, as an example, Dai et al. (2019)
652 adopted the BENMAP-CE model (Environmental Benefits Mapping and Analysis
653 Program-Community Edition, Yang et al. (2013)) to simulate the ambient PM_{2.5}
654 concentrations, while Li and Li (2018) used the average of monitored PM_{2.5}
655 concentrations. As shown in Table 6, the avoided YLL for Case 3 and Case 4 were
656 estimated at 8744 and 316,562 years respectively compared to the base case,
657 confirming again the greatly improved health benefits from implementation of
658 ultra-low emission policy for the industry sector in addition to the power sector. The
659 largest avoided YLL were found in Anhui and Jiangsu in the YRD region, accounting
660 collectively for 86% and 65% of the total avoided YLL in Cases 3 and 4 respectively.
661 Compared to Case 3, the fractions of Shanghai and Zhejiang to total YRD for both
662 avoided deaths (Table 5) and YLL (Table 6) were clearly higher in Case 4, implying a
663 greater health benefit of emission controls at industry sources in these relatively
664 industrialized urban regions. The reduced PM_{2.5} concentrations led to the largest
665 avoided YLL of COPD in both cases (3,118 and 119,300 years in Cases 3 and 4,
666 respectively).

667 Figure 9 illustrates the spatial distributions of the avoided deaths and YLL from
668 the ultra-low emission policy in the YRD region. When the policy was implemented
669 only for coal-fired power plants, the health benefits were small and the regional
670 differences relatively insignificant, with the avoided deaths and YLL smaller than 10
671 persons and 100 years respectively for all of the grid cells (Figure 9a and 9b). When
672 the policy was implemented both in power and industry sectors, more avoided deaths
673 (>40 person/grid cell) and YLL (>400 years/grid cell) were found in northern Anhui,
674 southern Jiangsu, central Shanghai and northern Zhejiang (Figure 9c and 9d). The
675 spatial correlation coefficient between the avoided YLL in Case 4 and population was
676 0.93, indicating that the implementation of the emission control policy would lead to

677 greater health benefits for areas with intensive economic activity and dense
678 populations.

679

680 **4. Conclusions**

681 We evaluated the improvement of emission estimation by incorporating CEMS
682 data for the power sector, and explored the air quality and health benefits from the
683 ultra-low emission control policy for the YRD region through air quality modeling. In
684 general, the bias between ground observations and simulations based on the emission
685 inventory with CEMS data incorporated was smaller than that without, suggesting that
686 appropriate use of online monitoring information helped improve the emission
687 estimation and model performance. Compared to the base case in which CEMS data
688 were incorporated in emission estimation, the simulated monthly concentrations of all
689 the concerned species (SO₂, NO₂, O₃, and PM_{2.5}) differed less than 7% when the
690 ultra-low emission policy was enacted only in the coal-fired power sector, given its
691 small fraction of total emissions. When the policy was implemented for selected
692 industrial sectors as well, larger differences in air quality from the base case were
693 found, with the simulated concentrations of SO₂, NO₂ and PM_{2.5} respectively
694 33%-64%, 16%-23% and 6%-22% lower and O₃ 3%-14% higher, depending on the
695 month.

696 Nearly 305 premature deaths and 8,744 years of YLL would be avoided if the
697 policy was implemented for the power sector alone, and benefits would reach 10,651
698 premature deaths and 316,562 YLL avoided with the policy enacted for both power
699 and industrial sectors. The study revealed the limited potential for further emission
700 reduction and air quality improvement via controls in the power sector alone. Along
701 with stringent emission control in that sector, the coordinated control of emissions
702 from non-power industrial sources would be essential to effectively improve air
703 quality and reduce associated human health risks. Moreover, more attention needs to
704 be paid to control of VOC to limit O₃ formation resulting from reduction of NO_x in
705 the region.

706

707 **Data availability**

708 All data in this study are available from the authors upon request.

709 **Author contributions**

710 YZhang developed the strategy and methodology of the work and wrote the draft.
711 YZhao improved the methodology and revised the manuscript. MG provided useful
712 comments on the health risk analysis. XB provided emission monitoring data. CPN
713 revised the manuscript.

714 **Competing interests**

715 The authors declare that they have no conflict of interest.

716 **Acknowledgments**

1017 Figure 2. The spatial distributions of the simulated monthly SO₂, NO₂, O₃ and PM_{2.5}
1018 concentrations for Case 2 in D2 (unit: μg/m³).

1019 Figure 3. The spatial distributions of the relative changes (%) in the simulated
1020 monthly SO₂, NO₂, O₃ and PM_{2.5} concentrations between Cases 2 and 3 in D2 ((Case
1021 3-Case 2)/Case 2).

1022 Figure 4. The spatial distributions of the relative changes (%) in the simulated
1023 monthly SO₂, NO₂, O₃ and PM_{2.5} concentrations between Cases 2 and 4 in D2 ((Case
1024 4-Case 2)/Case 2).

1025 Figure 5. The spatial distributions of the annual PM_{2.5} concentrations (average of
1026 January, April, July and October) for Case 2 (a) and the reduced annual PM_{2.5}
1027 concentrations for Cases 3 (b) and 4 (c) in the YRD region (unit: μg/m³). Note the
1028 different color ranges in the panels for easier visualization.

1029 Figure 6. The population fractions exposed to different levels of PM_{2.5} in the YRD
1030 region for Cases 2 (a), 3 (b), and 4 (c).

1031 Figure 7. The spatial distributions of the mortality (a) and YLL (b) attributable to
1032 PM_{2.5} exposure in Case 2 at a horizontal resolution of 9 km.

1033 Figure 8. Comparisons of the estimated mortality attributable to PM_{2.5} exposure in
1034 various studies for the YRD region.

1035 Figure 9. The spatial distributions of the avoided deaths and YLL attributable to the
1036 reduced PM_{2.5} exposure with ultra-low emission policy implementation at a horizontal
1037 resolution of 9 km. Note the different color ranges in the panels for easier
1038 visualization.

Tables

Table 1 The air pollutant emissions by sector for Cases 1-5 in YRD (Unit: Gg).

Case	Power			Industry			Residential			Transportation			Total		
	SO ₂	NO _x	PM	SO ₂	NO _x	PM	SO ₂	NO _x	PM	SO ₂	NO _x	PM	SO ₂	NO _x	PM
Case 1	606.8	863.4	376.2	1305.5	1294.6	1817.9	133.5	326.6	787.5	62.0	1847.1	105.9	2107.8	4331.7	3087.4
Case 2	179.4	245.5	45.1	1305.5	1294.6	1817.9	133.5	326.6	787.5	62.0	1847.1	105.9	1680.5	3713.8	2756.4
Case 3	56.0	110.0	8.8	1305.5	1294.6	1817.9	133.5	326.6	787.5	62.0	1847.1	105.9	1557.0	3578.4	2720.0
Case 4	56.0	110.0	8.8	249.4	426.8	539.6	133.5	326.6	787.5	62.0	1847.1	105.9	500.9	2710.6	1441.7
Case 5	0.0	0.0	0.0	1305.5	1294.6	1817.9	133.5	326.6	787.5	62.0	1847.1	105.9	1501.0	3468.4	2711.2

Note: Case 1: The emissions of coal-fired power sector were estimated based on the emission factor method without CEMS data. Case 2: The emissions of coal-fired power sector were estimated based on the improved method by Y. Zhang et al. (2019), with CEMS data incorporated. Case 3: All the coal-fired power plants in the YRD region were assumed to meet the requirement of the ultra-low emission policy. Case 4: All the coal-fired power plants and certain industrial sources including boilers, cement, and iron & steel factories in the YRD region were assumed to meet the requirement of the ultra-low emission policy. Case 5: The emissions of all coal-fired power plants were set at zero.

Table 2 Comparison of the observed and simulated hourly SO₂, NO₂, O₃ and PM_{2.5} concentrations by month for Cases 1 and 2 in the YRD region. Totally 230 state-operated observation sites were included in the comparison.

Pollutant	R		NMB (%)		NME (%)		
	Case 1	Case 2	Case 1	Case 2	Case 1	Case 2	
SO ₂	Jan	0.72	0.89↑	11.44	0.52↑**	26.83	24.22↑

	Oct	0.75	0.75	5.40	-11.80	23.34	22.28

Note: The arrows represent that the simulation in Case 2 were improved compared to Case 1. *, **, and *** indicate the improvements are statistically significant with confidence levels of 90%, 95%, and 99 %, respectively. The R, NMB and NME were calculated using the following equations (P , O , \bar{P} , and \bar{O} represent the simulation, observation, averaged simulation and averaged observation values, respectively):

$$NMB = \frac{\sum_{i=1}^n (P_i - O_i)}{\sum_{i=1}^n O_i} \times 100\% \quad ; \quad NME = \frac{\sum_{i=1}^n |P_i - O_i|}{\sum_{i=1}^n O_i} \times 100\% \quad ;$$

$$R = \frac{\sum_{i=1}^n (P_i - \bar{P})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^n (P_i - \bar{P})^2 \sum_{i=1}^n (O_i - \bar{O})^2}}$$

Table 3 The relative (%) and absolute changes ($\mu\text{g}/\text{m}^3$, in parentheses) of the simulated monthly pollutant concentrations in different cases relative to Case 2 in the YRD region.
