Abstract. Convective self-aggregation is an atmospheric phenomenon seen in numerical simulations in a radiative convective equilibrium framework of which configuration captures the main characteristics of the real-world convection in the deep tropics. As tropical deep convection is typically embedded in a large-scale flow, we impose a background mean wind flow on convection-permitting simulations through the surface flux calculation. The simulations show that with imposing mean flow, the organized convective system propagates in the direction of the flow but slows down compared to what pure advection would suggest, and eventually becomes stationary relative to the surface after 15 simulation days. The termination of the propagation arises from momentum flux, which acts as a drag on the near-surface horizontal wind. In contrast, the thermodynamic response through the wind-induced surface heat exchange feedback is a relatively small effect, which slightly retards (by about 5%) the convection relative to the mean wind.

1 Introduction

In simulations of radiative convective equilibrium (RCE), a single aggregated cluster can develop from randomly distributed convective fields despite homogeneous initial conditions, boundary conditions, and forcing (e.g., Tompkins and Craig, 1998; Bretherton et al., 2005; Coppin and Bony, 2015; Hohenegger and Stevens, 2016). Convective self-aggregation exhibits many similarities to organized deep convection in the tropics including phenomena such as the Madden-Julian Oscillation (MJO), which is an eastward-propagating intraseasonal variability in the tropics (Madden and Julian, 1971, 1972). Some studies suggested that the MJO may itself be an expression of self-aggregation (Raymond and Fuchs, 2009; Dias et al., 2017). This idea is supported by recent studies showing that MJO-like phenomena are observed in rotating RCE simulations in cloud-resolving models (Arnold and Randall, 2015; Khairoutdinov and Emanuel, 2018). Further support for this point of view comes from the observational study by Tobin et al. (2013), who found that the mean state of the atmosphere during an active phase of the MJO resembles the self-aggregation state in the sense that a higher degree of the convective organization is associated with more outgoing longwave radiation.

Emanuel (1987) and Neelin et al. (1987) proposed that the interaction between wind and the surface enthalpy flux in a mean flow may be important for the MJO propagation. They demonstrated that in mean easterlies winds are amplified by the convective scale circulation to the east of convection, leading to a positive anomaly of the surface enthalpy flux. This favors the initiation of convection on the upwind side of the cluster, resulting in the upstream propagation of convection. Emanuel (1987) called this the wind-induced surface heat exchange (WISHE) feedback. Self-aggregation studies also showed that in the absence of mean wind, WISHE contributes to the maintenance of aggregation as the enhanced surface enthalpy flux favors the development of deep convection on the periphery of the existing convection (Bretherton et al., 2005; Wing and Emanuel, 2014; Coppin and Bony, 2015).

Motivated by the potential link between self-aggregation and the MJO, we investigate how convective self-aggregation is influenced by a background mean flow. As a step, we focus on how asymmetries in the surface flux, in response to a mean flow, affect the propagation of a convective cluster in RCE. We impose a large-scale mean flow in simulations of RCE in the form of a shear free wind, a setup that has not been investigated in previous simulations of RCE. We hypothesize that on the upwind side of a convective cluster, the mean flow adds constructively to the near-surface component of the convective scale circulation, enhancing the surface enthalpy flux, and vice versa on the downwind side. The asymmetry in the thermodynamic response to the mean wind leads to a slow upwind propagation of the deep convective system. In addition to the thermodynamic response, we also investigate the dynamic response to the mean flow, that is how the modified surface wind field affects the surface momentum fluxes. In the long run the equilibration of the near-surface winds, due to a mean wind contribution to the surface drag, plays a dominant role in the interaction of a large-scale convective cluster with the mean wind. We perform a mechanism denial experiment to suppress the dynamic response and quantify to what extent the propagation can be attributed to the thermodynamic response.

The simulation design including a mechanism denial experiment is described in Sect. 2. Sect. 3 shows how a convective cluster propagates in the mean flow with different mean wind speeds. In Sect. 4 we examine the thermodynamic response. In Sect. 5 we explore the surface momentum flux and discuss the mechanism denial experiment. Conclusions are given in Sect. 6.

2   Simulation setup

We conduct numerical simulations using the University of California Los Angeles Large-Eddy Simulation (UCLA-LES) model. The UCLA-LES solves the anelastic equations with a third-order Runge Kutta method for the temporal discretization and with centered difference in space for momentum (Stevens et al., 2005). Full radiation is computed by using Monte Carlo spectral integration (Pincus and Stevens, 2009), including radiative properties of ice clouds (Fu and Liou, 1993). A two-moment microphysical parameterization for mixed-phase clouds is used to represent cloud water, rain water, cloud ice, snow, and graupel, explicitly (Seifert and Beheng, 2006a, b). Sub-grid scale fluxes are modeled with a Smagorinsky model.

A $576 \times 576 \times 27 \, \mathrm{km}^3$ domain size is used with horizontal grid spacing of $3 \, \mathrm{km}$ to resolve deep convection. The 63 vertical grid levels are stretched, starting from a grid spacing of $75 \, \mathrm{m}$ at the first model level up to $1367 \, \mathrm{m}$ near the model top. The small vertical grid spacing near the surface allows us to better resolve the boundary layer's vertical structure. There is no rotation and

no diurnal cycle. The experimental design of the UCLA-LES simulations follows Hohenegger and Stevens (2016). In contrast to using interactive sea surface temperature (SST) of their experiments, we prescribe an SST of $301\,\mathrm{K}$.

We consider two types of simulations. In a first set of experiments we conduct numerical simulations with different background wind speeds. In an effort to isolate the thermodynamic effects of the convective circulation on the evolution of the self-aggregated convective cluster, we subject the flow to mean wind whose presence is encoded through the surface fluxes. This is equivalent to simulating a situation subject to a large-scale mean wind using a Galilean transform to avoid numerical artifacts of advection (Matheou et al., 2011) but neglecting any restoring force for the wind. Under such a transform, surface fluxes are not invariant, and the effect of the mean wind is accounted for only through the surface flux calculation, which spins down the wind. Effects of WISHE-like asymmetries in the surface fluxes will then be present in so far as they affect the flow on time-scale shorter than those associated with the spin-down of the mean wind due to surface drag. In the long run with a mean flow the surface transports its signal through the atmosphere, until the whole column is in balance again and stagnant compared to the surface. (Note that this equilibrium response is different from the equilibrium response of a nudging approach, where a background flow is maintained. For the transient response we expect a similar behavior of both approaches.) For the mechanism denial experiment a mean flow over the surface is maintained by including the influence of the mean wind only in the surface enthalpy equation but not in the surface momentum equation. The first set of experiments is described in Sect. 2.1, and the additional experiment in Sect 2.2.

2.1 Experiments with a mean wind encoded in the surface fluxes

The surface fluxes, including the momentum flux (F_m) at the surface and the surface enthalpy flux (F_h), are defined as:

$$
\begin{aligned}
F_\mathrm{m} &= \rho\,(\overline{w'u'}^2 + \overline{w'v'}^2)^{\frac{1}{2}}|_\mathrm{sfc}, \\
F_\mathrm{h} &= \rho\,(c_p\,\overline{w'\theta'} + l_\mathrm{v}\,\overline{w'q'})|_\mathrm{sfc},
\end{aligned}
\tag{1}
$$

with ρ being the air density at the surface, c_p the isobaric specific heat and l_v the specific enthalpy of vaporization. The covariances $\rho\overline{w'u'}$ and $\rho\overline{w'v'}$ represent the x- and y-component of momentum fluxes in kinematic units, respectively. The terms $\overline{w'\theta'}$ and $\overline{w'q'}$ represent the near-surface turbulent fluxes of potential temperature and specific humidity, respectively. The turbulent fluxes are calculated from the turbulence scales of velocity u_*, temperature θ_* and humidity q_* as $\overline{w'u'}^2 + \overline{w'v'}^2 = -u_*^2$, $\overline{w'\theta'} = -u_*\theta_*$ and $\overline{w'q'} = -u_*q_*$. The scale values are computed from profiles of horizontal velocity, temperature and humidity in the boundary layer based on similarity functions (Ψ_m, Ψ_h) proposed by Dyer and Hicks (1970), Businger (1973), and Dyer (1974). In the model, u_* is proportional to the near-surface horizontal wind u_h which is defined as the wind at the first level above the surface, which is at $37.5\,\mathrm{m}$ in our case. We modify u_h by adding a mean flow u_b to it:

$$
u_\mathrm{h} = \sqrt{(u + u_\mathrm{b})^2 + v^2}.
\tag{2}
$$

The modification makes the model see the x-component wind of $u + u_\mathrm{b}$ in the surface flux formulation. Physically, this is equivalent to the Galilean transform that works as if we move the surface with a velocity of $-u_\mathrm{b}$, so that it is analogous to

85 putting the atmospheric system on a conveyor belt. This surface flux modification allows us to have a shear free mean flow in the simulations.

The aggregated state in simulations of RCE reveals hysteresis; it hardly returns to the random occurrence of convection once an aggregated state is established (Khairoutdinov and Emanuel, 2010; Muller and Held, 2012). We start from an aggregated state in order to separate the effect of a mean wind on the evolution of self-aggregation from its initiation. For this purpose, we

90 run a simulation without a mean wind for 26 days until the convection is fully aggregated. The time scale of self-aggregation in our simulations is comparable to other self-aggregation studies in a square domain (Wing and Emanuel, 2014; Holloway et al., 2017; Arnold and Putman, 2018). We then restart the simulations from the aggregated state, but with a mean wind imposed. The specification of the surface fluxes are described above. Each experiment with u_{b} ranging from 0 to $4\,\mathrm{m\,s^{-1}}$ is simulated for additional 20 days. Organized convection disaggregates when u_{b} is stronger than $4\,\mathrm{m\,s^{-1}}$. Since disaggregation of organized

95 convection is not the focus of this study, the experiments for u_{b} of 0, 2 and $4\,\mathrm{m\,s^{-1}}$ are discussed and will be denoted by UB0, UB2 and UB4, respectively.

2.2 Mechanism denial experiment

UB0, UB2 and UB4 indicate that the dynamic feedback significantly modulates the propagation of the convective system, as the surface momentum flux F_{m} interacts with the near-surface wind u_{h} through the velocity scale u_* (Sect. 2.1). To isolate the

100 role of the thermodynamic feedback, we perform mechanism denial experiments wherein we suppress the influence of F_{m} on u_{h}. The surface fluxes are determined by the turbulent fluxes at the surface (Eq. 1), and the turbulent fluxes are obtained from the turbulence scales: u_*, θ_* and q_* (Sect. 2.1). We disable the effect of the surface momentum flux by setting u_* to a constant value for the computation of $\overline{w'u'}$ and $\overline{w'v'}$ (thus, F_{m}), but using the modeled u_* for computation of $\overline{w'\theta'}$ and $\overline{w'q'}$ (thus, F_{h}) as in UB0, UB2 and UB4. For the momentum flux, we prescribe u_* as a constant value of $0.09\,\mathrm{m\,s^{-1}}$ obtained by averaging

105 u_* over the simulation domain and the last 20 simulation days in UB0. For the mechanism denial experiment, u_* is temporally and spatially constant to disable the dynamic feedback, but remains variable for the surface enthalpy flux in order to retain the WISHE feedback.

In UB0 convection begins to be organized into a single cluster at around day 22, so we restart a simulation with an uncoupled F_{m} but without mean wind from day 22 in order to confirm that the suppression of the dynamic feedback does not affect the

110 aggregation. The simulation with the uncoupled F_{m} from day 22 maintains convective self-aggregation towards the end of the simulation period (day 46), and the horizontal scale of the convective cluster in this simulation is approximately $100\,\mathrm{km}$, which is comparable to that in UB0 (not shown). In the same way as the experiments with coupled F_{m} (Sect. 2.1), u_{b} of $2\,\mathrm{m\,s^{-1}}$ is imposed on the the simulation with the uncoupled F_{m} after day 26. The experiment with uncoupled F_{m} will be denoted by UB2_unius.

115 For the remainder of the study we refer to the simulation day, where we begin to impose the background wind, as day 0 (day 26 above). For example, the time when we restart the denial experiment without mean wind (day 22) would be equivalent to day -4, and the time when the mean wind is introduced to be imposed to the denial experiment (day 26) is day 0 from now on.

## 3 Propagation speed of the organized convective cluster
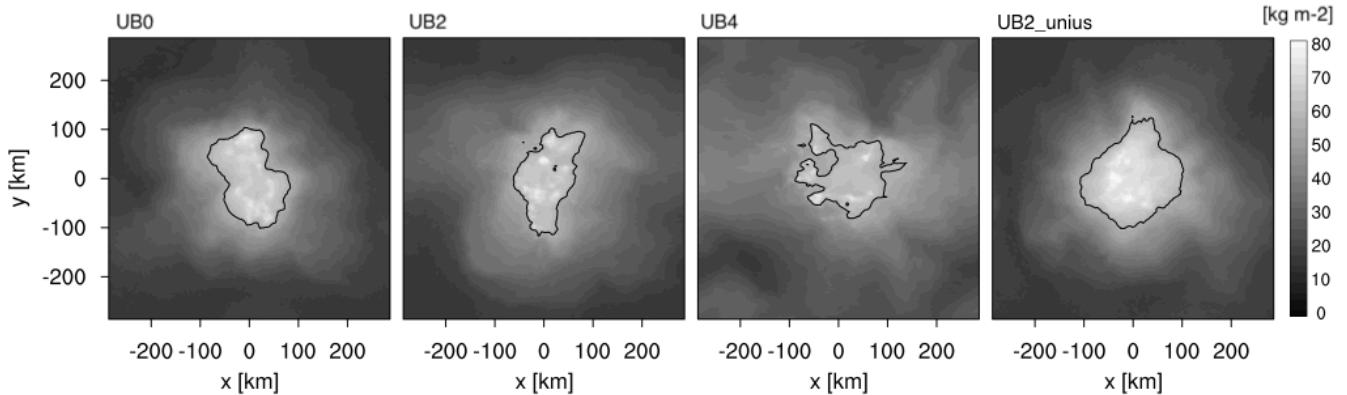

Figure 1. Daily average precipitable water on day 19. Black contours indicate where precipitable water is equal to $58\,\mathrm{kg\,m^{-2}}$.

Figure 1 illustrates the daily average spatial pattern of the convective cluster on the last day in the experiments. All simula-
tions show that the quasi-circular pattern of the convective cluster lasts until the end of the simulation period, and the horizontal
scale of the cluster size is comparable among all simulations, although the spatial variability of precipitable water is weak for
UB4 compared to the other experiments. The standard deviation of the daily average precipitable water on the last simulation
day is 14.2, 12.1 and $10.4\,\mathrm{kg\,m^{-2}}$ for UB0, UB2 and UB4, respectively. This standard deviation varies in time and, e.g., is
as low as $10.9\,\mathrm{kg\,m^{-2}}$ on day 6 in the control case UB0. The domain mean precipitable water on the last day increases with
increasing u_{b}, having the daily mean value of 26.5, 30.4 and $34.3\,\mathrm{kg\,m^{-2}}$ for UB0, UB2 and UB4. The larger domain mean
precipitable water with increasing u_{b} might be associated with our simulation setup of a propagating cluster in double periodic
boundary condition which results in nine full transits through the domain in case of UB4 (Matheou et al., 2011). Despite this
artifact, the convective cluster remains organized over the simulation period in all experiments and we expect this difference to
play a minor role in the following analysis.

We estimate the propagation speed of a convective cluster by tracking the cluster in the simulation domain. We find all grid
columns where the precipitable water (PW) is greater than $62\,\mathrm{kg\,m^{-2}}$, and define a convective cluster with the grid points
at each output time step. The motion of the cluster is determined by tracking the PW-weighted mean center of the cluster
with time. Only x-direction motion is considered because the cluster propagates in the x-direction. Changing the threshold
level does not affect the estimated propagation speed. Since in the model setup the surface effectively moves with a constant
speed below the atmospheric column, the absolute propagation velocity of the convective cluster to the model surface u_{abs} is
calculated as the sum of the relative velocity of the cluster to the model grid u_{rel} and the mean wind speed u_{b}:

$$u_{\mathrm{abs}} = u_{\mathrm{rel}} + u_{\mathrm{b}}. \tag{3}$$
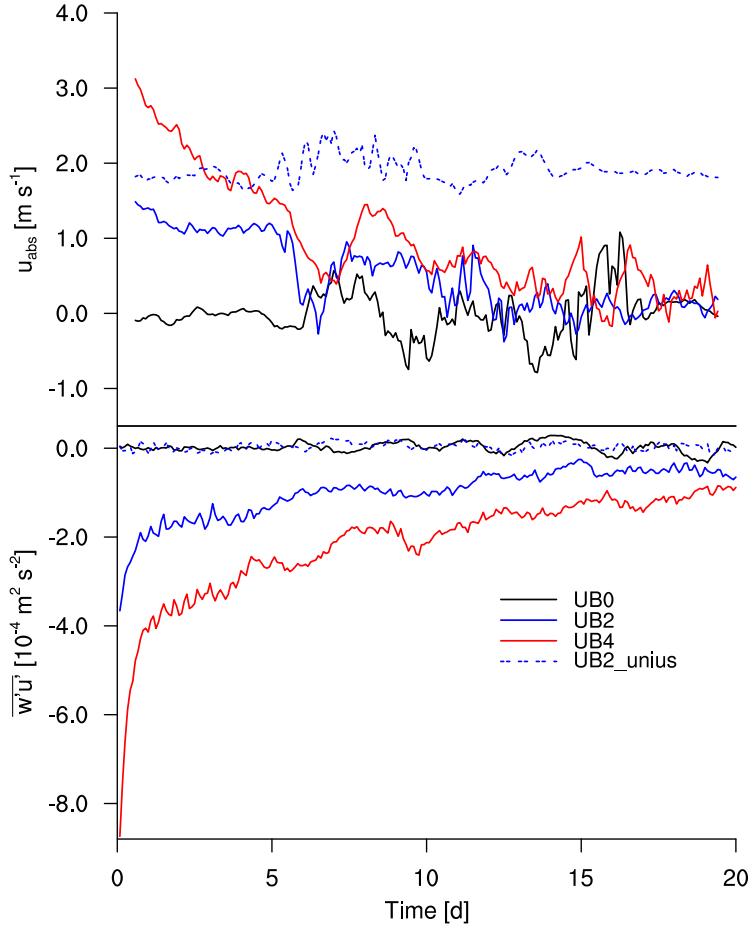

Figure 2. Temporal evolution of (top) u_{abs} in the x-direction and (bottom) domain-averaged $\overline{w'u'}$ at the surface. Day 0 corresponds to the day when u_{b} begins to be imposed.

When $u_{\mathrm{rel}} = 0\,\mathrm{m\,s^{-1}}$, the convective cluster remains motionless in the model reference frame but is effectively moving at the speed of u_{b} by virtue of the Galilean transformation (pure advection). In the case of WISHE, the convective cluster moves against the mean wind (e.g., $u_{\mathrm{rel}} < 0\,\mathrm{m\,s^{-1}}$). Thus, we expect $u_{\mathrm{abs}} < u_{\mathrm{b}}$ if the WISHE feedback regulates the propagation of the convective cluster.

Figure 2 (top) shows u_{abs} for each experiment. A 24-hour running average is applied to the temporal evolution of u_{abs} to present the long-term evolution more clearly. After imposing u_{b}, the convective cluster begins to propagate. For the simulations where the momentum fluxes are allowed to feel the effect of the mean wind, u_{abs} decreases from what pure advection would suggest to near-zero values at day 15. The decrease of u_{abs} corresponds to our hypothesis ($u_{\mathrm{abs}} < u_{\mathrm{b}}$), but is masked by the spin-down of the mean wind due to surface drag. Estimating the final value of u_{abs} by averaging it over the last five days, we arrive at 0.23 ± 0.31, 0.10 ± 0.47 and $0.29 \pm 0.76\,\mathrm{m\,s^{-1}}$ for UB0, UB2 and UB4, respectively. The strong fluctuation around

the mean is due to the oscillating features of aggregation (Bretherton et al., 2005; Windmiller and Hohenegger, 2019; Patrizio and Randall, 2019). This fluctuation hinders our ability to unambiguously distinguish between a slow propagation speed and a stationary one, although its amplitude is comparable to the one with no mean wind (UB0). Since the cluster is formed by a group of individual convective cells, the shape of cluster is not firmly fixed. The cluster expands and contracts in time (though not necessarily in all directions at the same time, see the daily PW for UB2 in Fig. 1) and sometimes smaller convective cells emerge outside the main cluster (see the cloud top height for UB0 in Fig. 6). Qualitatively the simulations indicate that the aggregated cluster initially moves with the wind. As the simulations with the mean winds proceed the convective clusters develop into the wind and as the mean wind spins down they become stationary with respect to the surface.

4 Thermodynamic process

The temporal evolution of the propagation speed demonstrates that the spin-down of the propagation speed occurs over a week whose time scale is longer than the convective adjustment time scale, which is in the order of hours, and the convective cluster settles around two weeks after it begins to propagate. We focus on two simulation periods: the transient phase for the first five days (day 0-4) when u_{abs} prominently decreases and compare it to the quasi-stationary stage for the last five days (day 15-19) when u_{abs} is near-zero. Quantities are averaged over these periods.

The surface enthalpy flux is larger on the upwind side of a convective cluster than on the downwind side through WISHE, i.e., the modulation of u_{abs}. Convection is expected to locate over the maximum boundary layer equivalent potential temperature θ_{e}. Hence to understand how WISHE affects its distribution we calculate the flux of θ_{e} approximately as $\overline{w'\theta'_{\text{e}}} \approx \overline{w'\theta'} + \frac{l_{\text{v}}}{c_p} \left(\frac{p_0}{p}\right)^{\frac{Rc_p}{c_p}} \overline{w'q'}$. Its form is analogous to the enthalpy (or moist static energy) flux. Focusing on the budget of θ_{e} allows us to investigate whether the development of convection is associated with the positive anomaly of the surface enthalpy flux.

Figure 3 (top) illustrates how $\overline{w'\theta'_{\text{e}}}$ varies from the center of the convective cluster ($r = 0\,\text{km}$) into the environment surrounding the cluster. We place the center of the convective cluster in the center of the domain at each output time step, average the physical quantities, and partition the domain diagonally into quarters, thus defining an upwind area, a downwind area and crosswind areas. Only the upwind and downwind areas are illustrated. The distribution of $\overline{w'\theta'_{\text{e}}}$ for UB0 indicates that the surface enthalpy flux is strengthened because the low-level convergence of the convective circulation intensifies the near-surface horizontal wind in the vicinity of the main convective cluster which is also observed in other RCE studies (e.g., Bretherton et al., 2005; Coppin and Bony, 2015). As we expected, for UB2 and UB4 in the transient phase $\overline{w'\theta'_{\text{e}}}$ is enhanced on the upwind side and suppressed on the downwind side. These enhancement and suppression of $\overline{w'\theta'_{\text{e}}}$ become stronger with increasing u_{b}. In the quasi-stationary stage the spatial distribution of $\overline{w'\theta'_{\text{e}}}$ becomes symmetric.

In the model, the surface enthalpy flux is determined by the difference between the wind speed near the surface and the velocity of the surface, which is equal to $0\,\text{m}\,\text{s}^{-1}$, as well as the vertical differences of specific humidity and potential temperature between the surface and the first level above the surface. The vertical differences of humidity and temperature do not have significant asymmetric features, but u_{h} shows the same transition from asymmetry to symmetry over time as seen in $\overline{w'\theta'_{\text{e}}}$ (Fig. 4). Immediately after u_{b} is imposed, u_{h} is intensified on the upwind side and reduced on the downwind side as one would
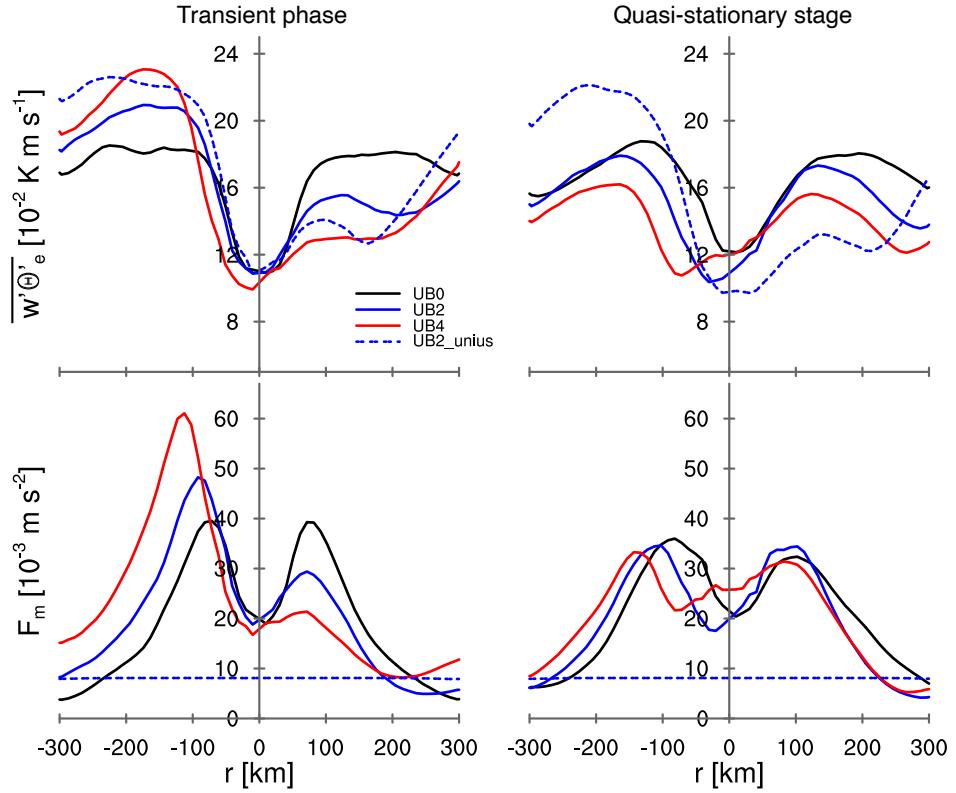

Figure 3. Radial distributions of the azimuthally averaged (top) $\overline{w'\theta'_e}$ and (bottom) F_m. Quantities are averaged over 5 days and $10\,\mathrm{km}$ in r-direction. The averaged quantities for (left) transient stage over day 0 to 4 and (right) quasi-stationary stage over 15 to 19 are illustrated. The negative and positive values of r represent the upwind area and downwind area, respectively.

180   expect from a superposition of u_b and the local circulation associated with the convective cluster. In the later stage of imposing u_b, the drag has transported its signal through the near-surface layers and u_h attains a comparable magnitude of wind speed on the upwind and downwind sides. For UB4, the off-centered local minimum of u_h around $r = 0\,\mathrm{km}$ is due to the strong modeled wind u on the downwind side in the opposite direction to u_b. The distribution of u_h indicates that the adjustment of the near-surface wind field modifies the response of the convection to the mean wind that one would expect from thermodynamic

185   consideration alone.
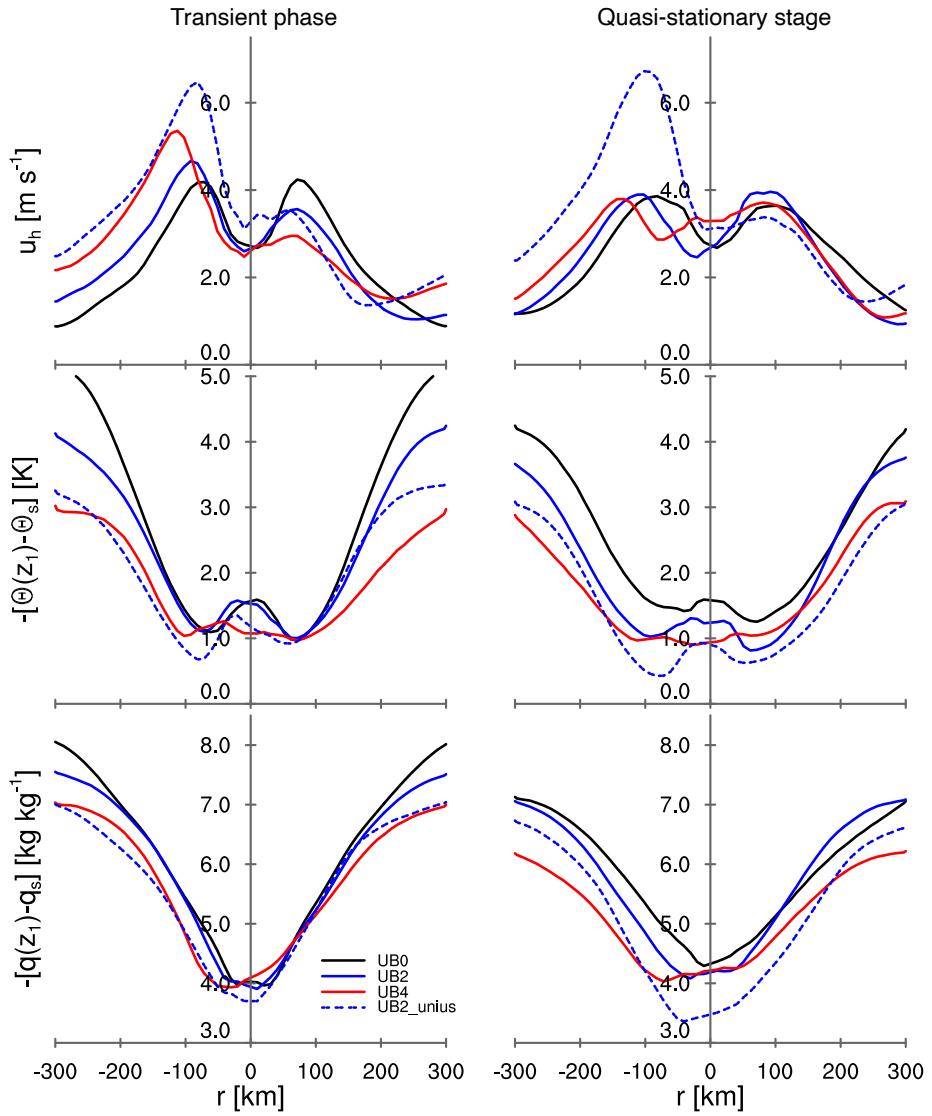

Figure 4. As in Fig. 3, but for (top) the near-surface horizontal wind u_{h}, (middle) the vertical difference of potential temperature $-\left[\theta(z_1) - \theta_s\right]$, and (bottom) the vertical difference of humidity $-\left[q(z_1) - q_s\right]$. The subscription s denotes the property at the surface and z_1 represents the first model level above the surface, which is at $37.5\,\mathrm{m}$ in our simulations.

5 Dynamic process

Without Coriolis force, the tendency of the horizontal wind is obtained as follows:

$$\frac{\partial u}{\partial t} = -\mathbf{V} \cdot \nabla u - c_p \theta \frac{\partial \pi}{\partial x} + \frac{1}{\rho} \frac{\partial \rho \overline{w'u'}}{\partial z},$$

$$\frac{\partial v}{\partial t} = -\mathbf{V} \cdot \nabla v - c_p \theta \frac{\partial \pi}{\partial y} + \frac{1}{\rho} \frac{\partial \rho \overline{w'v'}}{\partial z},$$

with $\mathbf{V}$ the vector wind, $\mathbf{V} = (u, v, w)$. The first term on the right-hand side represents the advection and the second term represents the pressure gradient force with the Exner function $\pi = \left(\frac{p}{p_0}\right)^{\frac{R_d}{c_p}}$. The third term on the right-hand side represents
190   the contribution of friction to the wind tendency and is related to F_m (Eq. 1). For UB2 and UB4 the vertical profile of the x-component of the wind in the quasi-stationary stage differs from the initially prescribed shear-free profile, while remaining constant with height for UB0 and UB2_unius (Fig. 5 left). When u_b interacts with F_m, the surface drag transports its signal through the atmosphere and the horizontal wind is substantially slowed down, particularly near the surface. The convective cluster is moving with the lower-tropospheric flow well before the whole tropospheric momentum is balanced. In the long
195   term, we expect a balance to ensue with the whole column resting compared to the surface in UB2 and UB4.

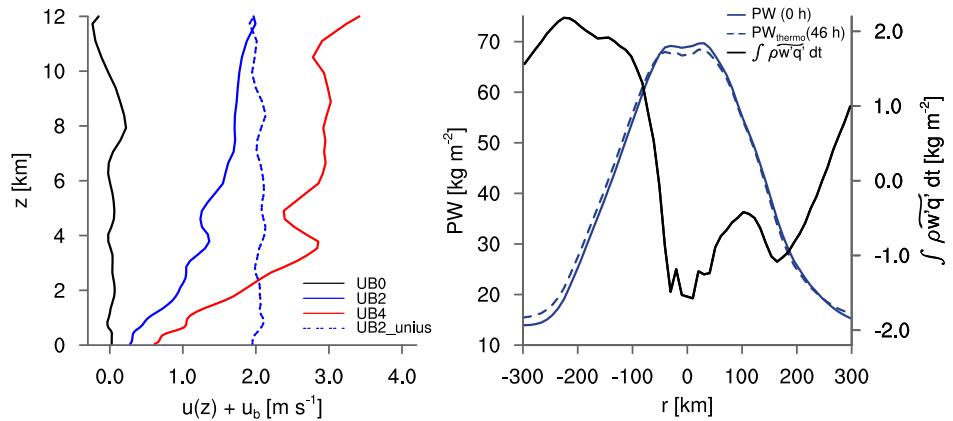

Figure 5. (Left) vertical profile of the domain-mean x-component wind as sum of the modeled wind $u(z)$ in the x-direction and u_b for the quasi-stationary stage. Note that the horizontal wind considers the Galilean transformation by including u_b. (Right) radial distributions of PW at $0\,\mathrm{h}$, the estimated PW at $46\,\mathrm{h}$ due to the thermodynamic process alone, and the accumulated surface moisture flux anomaly from $0\,\mathrm{h}$ to $46\,\mathrm{h}$. The quantities are azimuthally averaged.

As seen in $\overline{w'\theta'_e}$ and u_h, the spatial distribution of F_m shows an asymmetry with respect to the center of the convective cluster in the transient phase and a symmetry in the quasi-stationary stage (Fig. 3 bottom). A larger F_m corresponds to a stronger drag on u_h. As a result of the intensified u_h, the enhanced F_m on the upwind side exerts a strong drag on u_h in the transient phase, and consequently, reduces u_h on the upwind side in the quasi-stationary stage. In contrast, the suppressed F_m on the downwind
200   side generates a weak drag, allowing u_h on the downwind side to become stronger in the quasi-stationary stage. This difference,

10

or asymmetry, in the drag acts as a source of momentum that accelerates the mean wind until it balances the mean wind, thereby eliminating the asymmetry in the drag by symmetrizing u_{h}. As a result, the symmetric u_{h} in the quasi-stationary stage affects not only the spatial distribution of F_{m} but also that of $\overline{w'\theta'_{\mathrm{e}}}$.
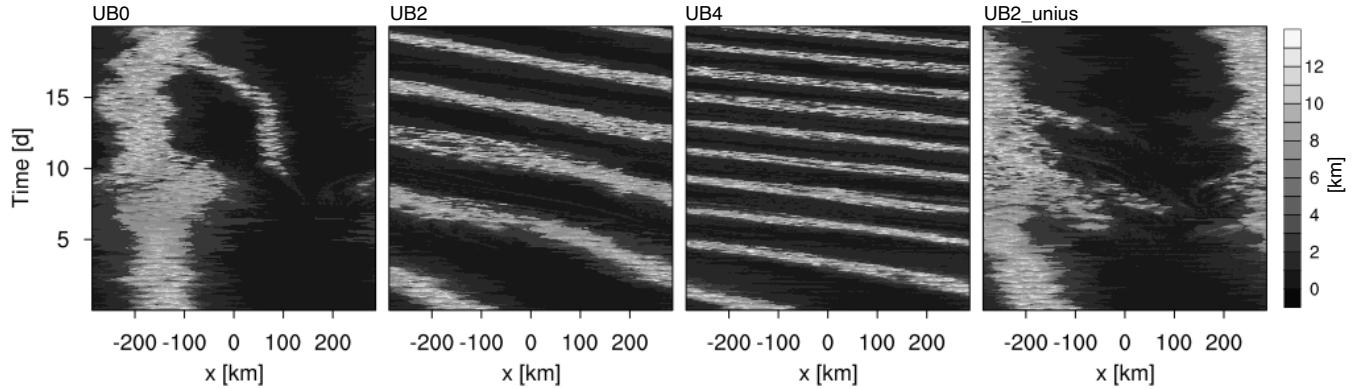

Figure 6. Hovmöller diagram of the cloud top height averaged over the y-axis for each experiment. This displays the cloud top movement with respect to the model grid, thus u_{rel} in Eq. 3.

To isolate the role of the thermodynamic feedback, we perform an additional simulation where u_* is kept constant in space and time for the calculation of F_{m} but remains interactive for $\overline{w'\theta'}$ and $\overline{w'q'}$ based on the similarity functions and we use $u_{\mathrm{b}} = 2\,\mathrm{m\,s^{-1}}$ for the suppressed F_{m} experiment (Sect. 2.2). Due to the constant value of u_*, the domain-averaged $\overline{w'u'}$ lingers close to zero with small fluctuations for the simulation with suppressed dynamic feedback, UB2_unius, while being negative immediately after imposing u_{b} for UB2 (Fig. 2 bottom). The suppression of the dynamic feedback enables u_{h} to remain asymmetric, and to show stronger maxima in u_{h} for UB2_unius than for UB2 (Fig. 4 top) and a persistent asymmetry of the surface enthalpy flux (Fig. 3 top). The long-lasting asymmetric feature does not considerably decrease the propagation speed, resulting in the final value of u_{abs} of $1.88 \pm 0.16\,\mathrm{m\,s^{-1}}$ for UB2_unius, hence propagating with a velocity only slightly slower than the mean wind speed of $2\,\mathrm{m\,s^{-1}}$. A Hovmöller diagram of the cloud top height confirms the estimated propagation speed, showing that the convective cluster indeed moves against u_{b} with a very small value of u_{rel} (Fig. 6). The propagation speed is only about $5\,\%$ smaller than u_{b} of $2\,\mathrm{m\,s^{-1}}$, suggesting that this small difference between u_{abs} and u_{b} can be associated with the thermodynamic feedback alone.

As the surface momentum flux is uncoupled from the near-surface wind field, the displacement of the convective cluster with time can be considered to be a result of the pure thermodynamic process. Assuming that the change of the lateral transport of the moisture flux is negligible, the spatial distribution of PW due to the pure thermodynamic process at a certain time $\mathrm{PW}_{\mathrm{thermo}}(t_1)$ is obtained by adding the surface moisture flux anomaly $\widetilde{\rho w'q'}$ integrated over a time period $[t_0, t_1]$ to the initial PW at t_0:

$$\mathrm{PW_{thermo}}(t_1) = \mathrm{PW}(t_0) + \int_{t_0}^{t_1} \rho \widetilde{w'q'}\, dt.$$

This simple thermodynamic argument gives us a displacement of $\mathrm{PW_{thermo}}(46\,\mathrm{h})$ from $\mathrm{PW}(0\,\mathrm{h})$ of approximately 10 km (Fig. 5 right), which corresponds to $u_{\mathrm{rel}} = -0.06\,\mathrm{m\,s^{-1}}$ and therefore $u_{\mathrm{abs}} = 1.94\,\mathrm{m\,s^{-1}}$. The estimated displacement of the precipitable water within the given time step due to the moisture flux anomaly agrees well with the estimated propagation speed of $1.88 \pm 0.16\,\mathrm{m\,s^{-1}}$ for UB2_unius (Fig. 2 top) and confirms that the thermodynamic contribution to the propagation speed of a convective cluster is small.

6   Conclusions
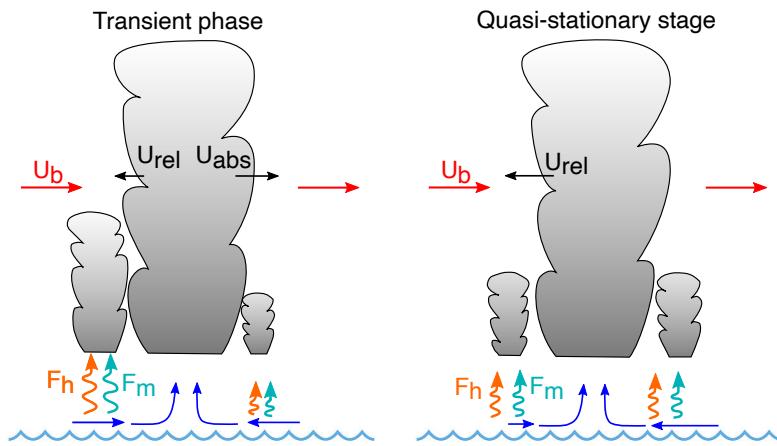

Figure 7. Sketch of the convective cluster, the surface wind field, the imposed mean wind (u_{b}), the surface enthalpy flux (F_{h}) and the momentum flux (F_{m}).

This study analyzes how organized deep convection propagates in an imposed mean flow, and which processes modulate the propagation speed of the convective cluster. For the simulations, we applied an RCE framework with a horizontal grid spacing of 3 km, with no rotation, and with a prescribed SST of $301\,\mathrm{K}$. We hypothesize that the convective cluster propagates against the mean flow through the WISHE feedback, providing a favorable environment to develop convection on the upwind side of the cluster (Fig. 7 left). Our idealized simulations with the mean flow exhibit that organized deep convection initially propagate much slower than what pure advection suggests and eventually becomes stationary towards the end of the simulation period regardless of the imposed wind speed. The near-surface wind field in response to the mean flow modifies the surface enthalpy flux and the surface momentum flux. In return, the surface momentum flux acting as a drag decreases the near-surface wind on the upwind side of the convective cluster, and increases it on the downwind side. Because of the surface drag acting on the mean background wind, the mean momentum near the surface is depleted, and on a timescale of a week the surface relative

winds and the surface-relative motion of the convective cluster vanishes (Fig. 7 right). Even in the simulation with the dynamic feedback removed and the WISHE-induced asymmetry in surface fluxes preserved, the effect on the propagation of convective clusters is small.

240   The periodic boundary conditions are limitations of our study in this regard, as they cause the effect of anomalously small fluxes to affect the inflow of the region with anomalously large fluxes in ways that damp the effect of the latter. To the extent that WISHE is important for the propagation of convective self-aggregated systems, it would favor large-scale, or solitary systems, so that the moistening that leads the disturbed phase does more than simply offset the drying that lags.

Because of the analogy of radiative convective equilibrium to tropical climate, the implication for less idealized setups and
245   tropical phenomena such as the MJO merits further investigations. Compared to typical wind speeds in the tropics, the prescribed large-scale wind speed of up to $4\,\mathrm{m\,s^{-1}}$ in this study is on the low end of the range. Also, feedbacks between the degree of organization and stronger wind speeds remain an open question. Despite these more complex interactions, the importance of surface momentum fluxes on WISHE suggests a potentially important role of dynamic feedbacks for the propagation of convection and the modification of thermodynamic feedbacks in less idealized setups.
