13 **Abstract**

14 A critical step in satellite retrievals of trace gas columns is the calculation of the air mass factor
15 (AMF) used to convert observed slant columns to vertical columns. This calculation requires *a*
16 *priori* information on the shape of the vertical profile. As a result, comparisons between satellite-
17 retrieved and model-simulated column abundances are influenced by the *a priori* profile shape.
18 We examine how differences between the shape of the simulated and *a priori* profile can impact
19 the interpretation of satellite retrievals by performing an adjoint-based 4D-Var assimilation of
20 synthetic NO₂ observations for constraining NO_x emissions. We use the GEOS-Chem Adjoint
21 model to perform assimilations using a variety of AMFs to examine how *a posteriori* emission
22 estimates are affected if the AMF is calculated using an *a priori* shape factor that is inconsistent
23 with the simulated profile. In these tests, an inconsistent *a priori* shape factor increased root
24 mean square errors in *a posteriori* emission estimates by up to 30% for realistic conditions over
25 polluted regions. As the difference between the simulated profile shape and the *a priori* profile
26 shape increases, so do the corresponding assimilated emission errors. This reveals the importance
27 of using simulated profile information for AMF calculations when comparing that simulated
28 output to satellite retrieved columns.

29

30 **1. Introduction**

31 Satellite observations provide a wealth of information on the abundance of trace gases in
32 the troposphere (Fishman et al., 2008). The next generation of satellite instruments, including the

33 upcoming geostationary constellation of TEMPO (Chance et al., 2013; Zoogman et al., 2017),
34 Sentinel-4 (Bazalgette Courrèges-Lacoste et al., 2011; Ingmann et al., 2012), and GEMS (Bak et
35 al., 2013; Kim, 2012), will provide information on NO₂ and other air quality relevant pollutants
36 on unprecedented spatial and temporal scales. Insight into processes that affect atmospheric
37 composition, including emissions (Streets et al., 2013), lifetimes (Fioletov et al., 2015; de Foy et
38 al., 2015; Laughner and Cohen, 2019), and deposition (Geddes and Martin, 2017; Kharol et al.,
39 2018) can be gained by interpreting this information with atmospheric chemistry models.

40 There are three main stages in retrieving trace gas abundances from ultraviolet and
41 visible solar backscatter radiance measurements: calculating a light-path “slant column” by
42 fitting observed spectra to known spectral signatures of trace gases, removing the stratospheric
43 portion of the column, and converting the slant column to a vertical column density using an air
44 mass factor (AMF). AMFs are calculated using a radiative transfer model and are a function of
45 viewing geometry, surface reflectance, clouds, and radiative transfer properties of the
46 atmosphere. AMF calculations also require an *a priori* estimate of the trace gas vertical profile
47 and are sensitive to the profile shape (Eskes and Boersma, 2003; Palmer et al., 2001).
48 Uncertainties in AMF calculations are the dominant source of uncertainty in satellite NO₂
49 retrievals over polluted regions (Boersma et al., 2007; Martin et al., 2002) largely due to
50 sensitivity to surface reflectance, clouds, aerosols, and *a priori* profile information (Lorente et
51 al., 2017).

52 Boersma et al. (2016) highlighted the issue of representativeness errors in comparing
53 model simulated values with UV-Vis satellite-retrieved columns. Vertical representativeness
54 errors arise from the satellite’s altitude-dependent sensitivity due to atmospheric scattering and
55 can degrade the quality of model-measurement comparisons beyond errors that arise from either
56 modeling or measurements alone. A consistent accounting of the altitude-dependent sensitivity is
57 necessary to limit these errors.

58 Two common methods are used to account for vertical representativeness. In one method,
59 observed slant columns are converted to vertical columns using an air mass factor calculated
60 with scattering weights to represent instrument vertical sensitivity and shape factors to represent
61 the vertical profile (Palmer et al., 2001). Another commonly used method employs an AMF
62 provided with the retrieval to convert slant columns to vertical columns, and then applies an
63 averaging kernel to the simulated profile to resample the simulated profile in a manner that

64 mimics the satellite vertical sensitivity (Eskes and Boersma, 2003). In this method both the
65 averaging kernel and the retrieval AMF are calculated using an *a priori* NO₂ profile that may
66 have a different shape than the simulated profile, which may introduce errors in the observation-
67 simulation comparison (Zhu et al., 2016).

68 A common application of comparisons between satellite observed columns and model
69 simulations is to constrain NO_x emissions (e.g. Ding et al., 2018; Ghude et al., 2013; Lamsal et
70 al., 2011; Martin et al., 2003; Vinken et al., 2014). One such approach is the use of four-
71 dimensional variational (4D-Var) data assimilation, which seeks to minimize a cost function that
72 accounts for the difference between simulated and retrieved values. As the cost function is a
73 difference between observed and simulated NO₂ columns, it is susceptible to vertical
74 representativeness errors resulting from inconsistent *a priori* vertical profile information.

75 In this work we examine how *a priori* profile assumptions impact satellite-model
76 comparisons and use the GEOS-Chem adjoint as a case study to assess how this impact can
77 affect the interpretation of satellite observations. Section 2 provides the mathematical framework
78 for AMF calculations and satellite-model comparisons. Section 3 describes the adjoint model and
79 synthetic observations for the case study. Section 4 discusses the results.

80

81 **2. Mathematical frameworks**

82 **2.1 AMFs and averaging kernels**

83 The air mass factor translates the line-of-sight slant column abundances (Ω_s) retrieved
84 from satellite observed radiances into vertical column abundances (Ω_v). An air mass factor is the
85 ratio of Ω_s to Ω_v and depends on the atmospheric path as determined by geometry, NO₂ vertical
86 profile (\mathbf{n}), surface reflectance, and radiative transfer properties of the atmosphere. Here we use
87 $M(\mathbf{n})$ to represent an air mass factor derived using the vertical number density profile \mathbf{n} :

$$M(\mathbf{n}) = \frac{\Omega_s}{\Omega_v} \quad (1)$$

88

89 In the method described by Palmer et al. (2001), a radiative transfer model is used calculate
90 scattering weights $w(z)$ (also known as box air mass factors) which characterize the sensitivity of
91 backscattered radiance I_B to the abundance of a trace gas at altitude z :

92

$$w(z) = -\frac{1}{M_G} \frac{\alpha_{a,z}}{\alpha_{eff}} \frac{\partial \ln(I_B)}{\partial \tau} \quad (2)$$

93 where $\alpha_{a,z}$ is the temperature-dependent absorption cross section ($\text{m}^2 \text{molec}^{-1}$), α_{eff} is the effective
 94 (weighted average) absorption cross section ($\text{m}^2 \text{molec}^{-1}$) and $\partial \tau$ is the incremental trace gas
 95 optical depth. M_G represents a geometric path correction accounting for the satellite viewing
 96 geometry:

$$M_G = \sec \theta_o + \sec \theta \quad (3)$$

97 where θ is the solar zenith angle and θ_o is the satellite viewing angle. This information is then
 98 combined with an *a priori* NO_2 shape factor (i.e. normalized vertical profile)

$$S(z) = \frac{\mathbf{n}(z)}{\Omega_v} \quad (4)$$

99 typically calculated with an atmospheric chemistry model to provide an air mass factor via:

100

$$M(\mathbf{n}) = \int_0^{\text{tropopause}} \mathbf{w}(z) S(z) dz \quad (5)$$

101 where $S(z)$ is calculated using vertical profile $\mathbf{n}(z)$. An attribute of the formulation of Palmer et
 102 al. (2001) is the independence of atmospheric radiative transfer properties $\mathbf{w}(z)$ and the vertical
 103 trace gas profile $S(z)$. The AMF definition in Equation (1) combined with Eq. (4) indicates that a
 104 slant column can be calculated from a known vertical profile via:

$$\Omega_s = \int_0^{\text{tropopause}} \mathbf{w}(z) \mathbf{n}(z) dz \quad (6)$$

105

106 In an alternative formulation, the air mass factor is represented as part of an averaging
 107 kernel. As formulated by Rodgers and Connor (2003), the averaging kernel (\mathbf{A}) provides the
 108 information needed to relate the retrieved quantity $\hat{\mathbf{n}}$ to the true atmospheric profile \mathbf{n} :

109

$$\hat{\mathbf{n}} - \mathbf{n}_a = \mathbf{A}(\mathbf{n} - \mathbf{n}_a) \quad (7)$$

110 where \mathbf{n}_a is an assumed *a priori* profile of number density. The elements of the column
 111 averaging kernel are related to the scattering weights by:

$$\mathbf{A}(z) = \frac{\mathbf{w}(z)}{M(\mathbf{n}_a)} \quad (8)$$

112 where $M(\mathbf{n}_a)$ is an air mass factor calculated using *a priori* vertical profile information. It is

113 important to note that unlike scattering weights, averaging kernels depend on the *a priori*
114 assumed vertical profile shape.

115 A lexicon is given in Table 1 as notation used to describe these treatments has varied
116 across the literature. We choose M for air mass factor as a single letter is clearer in equations, w
117 for scattering weights to maintain the original formulation of Palmer et al. (2001), n for number
118 density following IUPAC recommendations, and Ω for column densities as is common in
119 radiative transfer literature.

120 Figure 1 shows examples of typical shape factor, scattering weight, and averaging kernel
121 profiles for a range of atmospheric conditions. NO_2 shape factors have significant variability;
122 Shape factors peak near the surface in urban regions due to local pollution sources, but peak in
123 the upper troposphere in more remote regions due to lightning. The shape of a scattering weight
124 profile depends strongly on surface reflectance and cloud conditions. Sensitivity in the lower
125 troposphere increases over reflective surfaces. Clouds increase sensitivity above due to their
126 reflectance but shield the satellite from observing the atmosphere below. Averaging kernels have
127 similarities with scattering weights but depend on both the shape of the prior and the satellite
128 sensitivity. As AMF calculations are a convolution of the shape factor and the scattering weight
129 profiles, these shapes affect NO_2 retrievals. For these examples, the AMF for a clear sky
130 observation with surface reflectance of 0.01 can range from 0.7 in an urban region to 1.7 in a
131 remote region. This large difference demonstrates the importance of the assumed profile shape to
132 the retrieval process.

133

134 **2.2 Comparing satellite observations to simulated values**

135

136 The following section expresses mathematically how satellite-model comparisons are made
137 using various *a priori* profiles.

138

139 **2.2.1 Using scattering weights**

140 Following Palmer et al. (2001), a retrieved vertical column ($\widehat{\Omega}_{v,o}$) is estimated using an
141 observed slant column $\Omega_{s,o}$ and a simulation-based air mass factor $M(\mathbf{n}_m)$, which can be
142 calculated with Eq. (5) using the model-simulated NO_2 profile (\mathbf{n}_m):

143

$$\widehat{\Omega}_{v,o} = \frac{\Omega_{s,o}}{M(\mathbf{n}_m)} \quad (9)$$

144

145 The difference Δ_m between the estimated retrieved column and the model-simulated vertical
 146 column ($\Omega_{v,m}$) is:

$$\Delta_m = \Omega_{v,m} - \widehat{\Omega}_{v,o} \quad (10)$$

$$\Delta_m = \left(\sum_0^{tropopause} n_m \right) - \frac{\Omega_{s,o}}{M(\mathbf{n}_m)} \quad (11)$$

147 Equation (11) describes how this comparison is used in practice. However, we can rearrange this
 148 expression in terms of model ($\Omega_{s,m}$) and observed ($\Omega_{s,o}$) slant columns using the definition of air
 149 mass factor:

$$\Delta_m = \frac{\Omega_{s,m}}{M(\mathbf{n}_m)} - \frac{\Omega_{s,o}}{M(\mathbf{n}_m)} \quad (12)$$

$$\Delta_m = \frac{1}{M(\mathbf{n}_m)} (\Omega_{s,m} - \Omega_{s,o}) \quad (13)$$

150

151 2.2.2 Using averaging kernels

152

153 Comparison of simulated and retrieved columns using the averaging kernel is described
 154 by Eskes and Boersma (2003) and in the retrieval documentation in Boersma et al. (2011). The
 155 averaging kernel is applied to the simulated profile in order to sample the simulated column in a
 156 manner that reflects the retrieval sensitivity:

$$\widehat{\Omega}_{v,m} = \sum_0^{tropopause} \mathbf{A} \mathbf{n}_m \quad (14)$$

157 The resampled simulated column is then compared to the retrieved vertical column ($\Omega_{v,o}$) using
 158 the *a priori*-based air mass factor $M(\mathbf{n}_a)$ supplied with the retrieval dataset:

159

$$\Delta_a = \widehat{\Omega}_{v,m} - \Omega_{v,o} \quad (15)$$

$$\Delta_a = \left(\sum_{i=0}^{tropopause} \mathbf{A}_i \mathbf{n}_{m,i} \right) - \frac{\Omega_{s,o}}{M(\mathbf{n}_a)} \quad (16)$$

160 Equation (16) describes how this method is used in practice. To facilitate the comparison with
 161 Eq. (13), Eq. (16) can be rewritten using an alternative formulation relating averaging kernels to
 162 scattering weights:

163

$$\Delta_a = \left(\sum_{i=0}^{tropopause} \frac{\mathbf{w}_i \mathbf{n}_{m,i}}{M(\mathbf{n}_a)} \right) - \frac{\Omega_{s,o}}{M(\mathbf{n}_a)} \quad (17)$$

$$\Delta_a = \frac{1}{M(\mathbf{n}_a)} (\Omega_{s,m} - \Omega_{s,o}) \quad (18)$$

164

165 By comparing Eq. (13) to Eq. (18), it is evident that the underlying difference between the two
 166 approaches is the choice of *a priori* profile information used to calculate the AMF, as the
 167 averaging kernel method is not independent of *a priori* profile assumptions. This bias could be
 168 addressed by replacing the *a priori* -based AMF in Eq. (18) with a simulation-based AMF using
 169 the following relationship (Boersma et al., 2016; Lamsal et al., 2010):

$$M(\mathbf{n}_m) = M(\mathbf{n}_a) \frac{\sum \mathbf{A} \mathbf{n}_m}{\sum \mathbf{n}_m} \quad (19)$$

170 It should be noted that both the averaging kernel and scattering weight methods are
 171 equivalent for comparisons that examine ratios of retrieved and modeled columns:

$$r_m = \frac{\widehat{\Omega}_{v,o}}{\Omega_{v,m}} = \frac{\Omega_{s,o} / M(\mathbf{n}_m)}{\sum \mathbf{n}_m} = \frac{\Omega_{s,o}}{\sum \mathbf{n}_m} \frac{\sum \mathbf{n}_m}{\sum \mathbf{w} \mathbf{n}_m} = \frac{\Omega_{s,o}}{\sum \mathbf{w} \mathbf{n}_m} \quad (20)$$

$$r_a = \frac{\Omega_{v,o}}{\widehat{\Omega}_{v,m}} = \frac{\Omega_{s,o} / M(\mathbf{n}_a)}{\sum \mathbf{A} \mathbf{n}_m} = \frac{\Omega_{s,o} / M(\mathbf{n}_a)}{\sum \mathbf{w} \mathbf{n}_m / M(\mathbf{n}_a)} = \frac{\Omega_{s,o}}{\sum \mathbf{w} \mathbf{n}_m} \quad (21)$$

172

173 For ratios, both methods are dependent on geophysical assumptions used to calculate scattering
 174 weights but are independent of *a priori* profile information. Lastly, some studies (e.g., Buscela et
 175 al., 2013; Qu et al., 2017) may directly assimilate slant column densities rather than vertical
 176 column densities using

$$\Delta_{s,a} = \widehat{\Omega}_{s,m} - \Omega_{s,o} \quad (22)$$

$$= \left(\sum_{i=0}^{tropopause} \mathbf{w}_i \mathbf{n}_{m,i} \right) - \Omega_{s,o} \quad (23)$$

177 This approach is also still dependent upon the scattering weights but not upon external *a priori*
 178 profile information. Overall, the choice of approach may be influenced by whether or not

179 scattering weights are available from either the NO₂ retrieval product or radiative transfer
180 calculations applied to the model. In contrast, use of Eq. (11) or (16) are applicable when these
181 are not explicitly available or provided.

182

183 **3. Tools and Methodology**

184 **3.1 GEOS-Chem and its adjoint**

185 The GEOS-Chem chemical transport model (www.geos-chem.org) is used to create
186 synthetic NO₂ observations and for their analysis. The GEOS-Chem version used here is version
187 35j of the GEOS-Chem Adjoint model. GEOS-Chem includes a detailed oxidant-aerosol
188 chemical mechanism (Bey et al., 2001; Park et al., 2004) and uses assimilated meteorological
189 fields from the Goddard Earth Observation System (GEOS-5), with 47 vertical levels up to 0.01
190 hPa and a horizontal resolution of 4°x5°. Global anthropogenic NO_x emissions are provided by
191 the Emission Database for Global Atmospheric Research (EDGAR) inventory (Olivier et al.,
192 2005) with regional overwrites over North America (EPA/NEI99), Europe (EMEP), Canada
193 (CAC), Mexico (BRAVO, (Kuhns et al., 2005)), and East Asia (Streets et al., 2006). Other NO_x
194 sources include biomass burning (GFED2 (Van der Werf et al., 2010)), lightning (Murray et al.,
195 2012), and soils (Wang et al., 1998). This model has been used previously to constrain NO_x
196 emissions (Cooper et al., 2017; Henze et al., 2009; Qu et al., 2017, 2019; Xu et al., 2013; Zhang
197 et al., 2016).

198 The GEOS-Chem adjoint (Henze et al., 2007, 2009) is used here to perform a 4D-Var
199 data assimilation. The adjoint seeks to iteratively minimize a cost function generally defined by
200 the difference between satellite retrieved and simulated columns (Δ , from either Eq. (11) if using
201 a simulation-based air mass factor or Eq. (16) if using the retrieval *a priori*-based air mass
202 factor):

$$J = \frac{1}{2} \Delta^T S_o^{-1} \Delta + \frac{1}{2} \gamma_R (E - E_a)^T S_E^{-1} (E - E_a) \quad (24)$$

203 where E and E_a are the *a posteriori* and *a priori* emissions, S_o and S_E are the retrieval and *a*
204 *priori* emission error covariance matrices, and γ_R is a regularization parameter that allows for
205 weighting the cost function towards the retrieved columns or *a priori* emissions. Tests performed
206 here required 20-30 iterations to minimize the cost function.

207

208 3.2 Experiment Outline

209 In this study we perform 4D-Var data assimilation experiments to infer surface NO_x
210 emissions using synthetic NO_2 observations. We use synthetic observations built from known
211 emission inventories to provide a “truth” that can be used to evaluate the inversion results. To
212 demonstrate how *a priori* profile information can propagate in an assimilation, we use either the
213 model profile (Δ_m , Eq. (11)) or an *a priori* profile (Δ_a , Eq. (16)) in the cost function. A one-week
214 spin-up window at the start of each adjoint iteration is used to allow NO_x to reach steady state.
215 Observation error covariances S_o are described as a relative error of 30% of the slant column
216 density, plus an absolute error of 10^{15} molecules cm^{-2} , which is representative of typical satellite
217 retrieved NO_2 column uncertainties (Boersma et al., 2007; Martin et al., 2002). We omit the *a*
218 *priori* emissions constraint in the cost function (i.e. set $\gamma_R=0$) to isolate the impact of the
219 observations.

220

221 3.2.1 Synthetic observations

222 Synthetic observations (Obs_5) are created using a GEOS-Chem simulation where random
223 Gaussian noise with a standard deviation of 5% is added to the anthropogenic NO_x emissions.
224 Additional tests using observations where noise with a standard deviation of 30% is added
225 (Obs_{30}) are also used. No additional noise is added to the individual observations to isolate the
226 impact of AMF errors against additional sources of uncertainty. Figure 2 shows the standard (*a*
227 *priori*) anthropogenic NO_x emissions and the changes used to create the “true” emissions for the
228 synthetic observations.

229 For these tests, we use one observation per hour per $4^\circ \times 5^\circ$ grid box for a period of two
230 weeks in July 2010. Observations consist of synthetic slant columns ($\Omega_{s,o}$) created by applying
231 scattering weights to the synthetic vertical profiles using Eq. (6). Scattering weights are
232 calculated using the LIDORT radiative transfer model (Spurr, 2002) by providing LIDORT with
233 the observation conditions of OMI observations during July 2010, which are used to represent
234 typical viewing conditions of low earth orbit satellite observations, and aerosol profiles from the
235 GEOS-Chem base simulation. To represent typical conditions, these representative scattering
236 weight profiles for each grid box are used to produce the synthetic slant columns. Tests
237 performed for all $4^\circ \times 5^\circ$ grid boxes used here indicate that the mean relative difference between
238 an air mass factor calculated using an average scattering weight profile and the average of air

239 mass factors using observation-specific scattering weight profiles is less than 4%.

240

241 **3.2.2 Shape Factors**

242 To test the impact of *a priori* profile information, seven different tests are performed
243 using seven different NO₂ profile shapes for AMF calculations:

- 244 • Case SF_M : The GEOS-Chem model simulated profile (n_m), updated at each iteration
245 of the adjoint run
- 246 • Case SF_{prior} : The *a priori* GEOS-Chem simulated profile, without updating.
- 247 • Case SF_{n30} : An *a priori* profile created by a GEOS-Chem simulation where global
248 anthropogenic NO_x emissions were perturbed with random Gaussian noise with a
249 standard deviation of 30%. In cases where this results in negative emissions, a value
250 of zero is used.
- 251 • Case SF_{diffem} : An *a priori* profile created by a GEOS-Chem simulation where regional
252 emission overwrites are turned off.
- 253 • Case SF_{finer} : An *a priori* profile created by a GEOS-Chem simulation run at finer
254 ($2^\circ \times 2.5^\circ$) resolution.
- 255 • Case SF_{trop} : An *a priori* profile that assumes the NO₂ profile shape is uniform from
256 the surface to the tropopause (~200 hPa).
- 257 • Case SF_{BL} : An *a priori* profile that assumes the NO₂ profile shape is uniform from the
258 surface to the boundary layer (~800 hPa).

259

260 An advantage of using scattering weights and the simulated shape factor in a 4D-Var framework
261 is that it allows for the shape factor, and thus the AMF, to be updated at each iteration. When *a*
262 *priori* profiles from an external source are used it is not possible for them to update during the
263 inversion. The SF_M and SF_{prior} cases test the impact that iterative updates to the AMF have on *a*
264 *posteriori* estimates. The additional cases test for the impact of using an averaging kernel based
265 on *a priori* profile assumptions that are inconsistent with the model. In practice, averaging
266 kernels and *a priori* profiles included in retrieval data sets are generally derived from chemical
267 transport models that have different physical processes, emissions, or spatial resolutions. The
268 SF_{n30} and SF_{diffem} tests are representative of inversions that use *a priori* profile information from
269 a different chemical transport model with similar resolution but different emissions. The SF_{finer}

270 test represents an inversion that uses *a priori* profiles from a chemical transport model with a
271 different horizontal resolution. The SF_{BL} and SF_{trop} tests do not represent any modern retrieval
272 algorithms, but are used as extreme examples of an *a priori* that assumes no spatial variability.
273 The SF_{BL} profile is representative of polluted regions as indicated by the typical urban profile in
274 Fig. 1, while the SF_{trop} profile is representative of a typical rural profile. Table 2 provides global
275 mean AMFs for these test cases, which range from 1.3-2.1, and the resulting global mean
276 observed vertical columns, which range from $0.9-1.5 \times 10^{15}$ molec/cm². Global mean ‘observed’
277 vertical columns are 33% higher for SF_{2x25} than for SF_M , and up to 66% higher for SF_{BL} . Global
278 mean ‘observed’ vertical columns for SF_{n30} and SF_{diffem} are similar to SF_M , although individual
279 observations may differ by up to 18% for SF_{n30} and 28% for SF_{diffem} .

280

281 4. Results

282 Figure 3 shows root mean square errors (RMSE) for the *a posteriori* emissions estimated
283 by the 4D-Var assimilations of Obs_5 synthetic observations. All tests successfully reduce the *a*
284 *priori* emission error by an order of magnitude or more. The SF_M has the lowest RMSE
285 indicating that it can best estimate the “true” emissions. The next lowest RMSE is for the SF_{prior}
286 test, which uses the same initial model shape factor but does not update during the adjoint
287 iterations, followed by the SF_{finer} , SF_{diffem} , SF_{n30} , SF_{trop} , and SF_{BL} tests.

288 Figure 4 shows maps of the difference in RMSE between the SF_M test and the other tests
289 for Obs_5 observations. The SF_M test has a lower RMSE than the other tests in 65-72% grid boxes
290 where the difference is nonzero. Again, the SF_{prior} test is closest to the SF_M test with a root mean
291 square difference of 2.9×10^7 molec/cm²/s, followed by SF_{finer} (3.6×10^7 molec/cm²/s), SF_{n30}
292 (3.8×10^7 molec/cm²/s), SF_{diffem} (4.0×10^7 molec/cm²/s), SF_{trop} , (7.8×10^7 molec/cm²/s), and SF_{BL}
293 (9.0×10^7 molec/cm²/s).

294 Table 3 summarizes additional error statistics focused on grid boxes with significant
295 emission sources. Errors in *a posteriori* emission estimates are correlated with the “true”
296 emissions in the SF_{trop} and SF_{n30} tests, and weakly correlated in the SF_{BL} , SF_{prior} , and SF_{diffem}
297 tests, indicating that these tests are not well constraining the emissions. Differences between tests
298 are more significant over polluted regions where AMF errors are more influential; For example,
299 in the regions with the highest NO_x emissions, RMSE values indicate SF_M outperforms SF_{n30} by
300 30% and SF_{trop} by >80%. Another sign of adjoint inversion quality is a low variance in errors.

301 While the posterior error is reduced relative to the *a priori* error in all tests, error standard
302 deviations are 30% higher for SF_{n30} and 90% higher for SF_{trop} compared to SF_M . The global
303 maximum error for the SF_{trop} test is 30% higher than for the SF_M test. All metrics indicate that
304 the SF_M test best represents the “true” emissions.

305 Tests using Obs_{30} observations and the SF_M and SF_{trop} shape factors were also performed.
306 Despite the difference between *a priori* observed vertical columns using these shape factors as
307 indicated by Table 2, these assimilations produced similar *a posteriori* results, with RMSE of
308 2.9×10^8 molec/cm²/s for SF_M and 2.8×10^8 molec/cm²/s for SF_{trop} .

309

310 **5. Discussion & Conclusions**

311 Accounting for the vertical profile dependence of satellite observations is essential to
312 accurately interpret those observations. This work examines how the choice of shape factor
313 affects differences between simulated and satellite-retrieved quantities in a data assimilation
314 framework. Examination of the mathematical frameworks behind two common methods for
315 comparing simulated and retrieved columns highlights how the method introduced by Palmer et
316 al. (2001) facilitates separation of observation sensitivity (scattering weights) from the profile
317 shape (shape factor) enabling the model-retrieval comparison to be independent of *a priori*
318 profile assumptions.

319 In these case studies, vertical representativeness errors were best reduced by using a
320 shape factor that was consistent with the model simulation. This was especially true in polluted
321 regions where the AMF errors dominate observation uncertainties, as deviations between the
322 tests were largest in these regions. The further the shape factor deviated from the model state the
323 larger the inversion errors became, as indicated by Fig. 5. The SF_{finer} test indicates that although
324 using a finer resolution model to generate *a priori* profiles is desirable for a more accurate
325 retrieval, consistency between the simulation profile and the *a priori* shape factor is of greater
326 importance explicitly for the purpose of simulation-observation comparisons to constrain
327 emissions at the simulation resolution. Comparing the SF_M and SF_{prior} tests shows that allowing
328 for the shape factor to update during the iterative adjoint process further reduces the RMSE by
329 10%. However, even without allowing for shape factor updates, using a shape factor that is
330 consistent with the initial model state produces a more accurate inversion result than using other
331 assumed profile shapes.

332 The case study presented here demonstrates that the shape factor source can have a strong
333 influence on adjoint inversion results. However, the magnitude of this influence can vary.
334 Inversion tests performed using synthetic observations based on random 30% perturbations to
335 emissions were insensitive to the AMF, despite large differences in *a priori* vertical column
336 densities. In these tests, the cost function was more sensitive to the larger difference between the
337 observed and simulated slant columns (i.e. $\Omega_{s,m} - \Omega_{s,o}$ in Eq. (13) and (19)) than to the AMF. This
338 indicates that while the cost function is mathematically dependent on the AMF, the inversion is
339 less sensitive to vertical representativeness errors in cases where emissions are poorly
340 constrained, as is the case in recent adjoint inversion studies (e.g. Qu et al., 2017). However,
341 choice of AMF will become increasingly important to adjoint inversions as emission inventories
342 improve. Furthermore, omitting the *a priori* emissions constraint in the cost function and
343 omitting noise in the observations in these tests to isolate the impact of the AMF effectively
344 assumes poorly constrained *a priori* emissions and ideal observations. In practice, cost function
345 sensitivity to AMF choice may be buffered when *a priori* emissions uncertainties and
346 observational noise are considered.

347 As it is beneficial for a consistent shape factor to be used when comparing satellite
348 retrieved values to model simulated results, it will be useful for data products to provide the
349 information required for this method to the user community. This is most straightforward when
350 scattering weights (rather than averaging kernels) are provided alongside retrieved column data,
351 as scattering weights and shape factors are independently calculated, however simulation-based
352 air mass factors can be calculated using the averaging kernel and *a priori*-based air mass factor
353 via Eq. 19.

354 In summary, when comparing a model simulation to a satellite retrieved NO₂ column in a
355 data assimilation environment utilizing column differences, calculating the AMF using the
356 simulated shape factor allows for better accuracy in inversion results. This demonstration can
357 provide general guidance for other methods of interpreting satellite observations with models, as
358 using the simulated shape factor assures consistency in the vertical representativeness between
359 model and retrieval.

360

361 **6. Author Contributions**

362 MJC and RVM designed the overall study. MJC designed and carried out the case studies and

363 their analysis. All co-authors provided guidance in analyzing results. MJC prepared the
364 manuscript with contributions from all co-authors.

365

366 **7. Competing interests**

367 The authors declare that they have no conflict of interest.

557
 558 Figure 3: Global root mean square error (RMSE) values for 4D-Var estimates of NO_x emissions
 559 for tests using various shape factors in AMF calculations.
 560

561
 562 Figure 4: Difference between root mean square error (RMSE) of adjoint tests for *Obs₅* synthetic
 563 observations. Root mean square differences between the *a posteriori* emissions estimates
 564 ($\text{molec}/\text{cm}^2/\text{s}$) are inset.
 565

566
 567 Figure 5: Scatterplot of adjoint test results. X-axis represents the deviation of the shape factor
 568 from the model simulated shape factor (root mean square difference). Y-axis represents the *a*
 569 *posteriori* emissions error from the adjoint inversion.

Variable	<i>Palmer et al., 2001</i>	<i>Eskes & Boersma, 2003</i>	<i>Boersma et al., 2016</i>	Notation used here
Air mass factor	AMF	M	M	M
Slant Column	Ω_S	S	N_S	Ω_s
Vertical Column	Ω_V	V	N_V	Ω_v
Scattering Weight	w(z)	C_1	m_1	W
Shape Factor	$S_z(z)$			S(z)
Averaging Kernel		A	A	A
Number density	n(z)	X	x_1	n(z)
Geometric AMF	AMF _G			M _G

572 Table 1: Lexicon comparing notation used in this paper to that used in previous studies.

575

576

Test name	Shape factor source	Air Mass Factor (unitless) Global Mean	Synthetic observation (<i>Obs_S</i>) vertical column density ($\times 10^{15}$ molec/cm ²)	
			Global Mean ($\times 10^{15}$ molec/cm ²)	Maximum difference from SF _M (%)
SF _M	Model	2.1	0.9	-
SF _{n30}	Model w/ 30% noise	2.1	0.9	19
SF _{diffem}	Model w/ different emissions	2.1	0.9	28
SF _{finer}	Model at finer (2°x2.5°) resolution	1.6	1.2	23
SF _{trop}	Uniform in troposphere	1.8	1.0	57
SF _{BL}	Uniform in boundary layer	1.3	1.5	27

577 Table 2: Global mean air mass factors and synthetic observation vertical column density for
578 shape factors tested here.

Test Name	Shape Factor Source	Correlation (r) of <i>a posteriori</i> error and “true” emissions	<i>a posteriori</i> RMSE ($\times 10^8$ molec/cm ² /s)		Error standard deviation ($\times 10^8$ molec/cm ² /s)		Maximum error ($\times 10^9$ molec/cm ² /s)
		if “true” emissions $> 10^{10}$ molec/cm ² /s	“true” emissions $> 10^{10}$ molec/cm ² /s	“true” emissions $> 10^{11}$ molec/cm ² /s	“true” emissions $> 10^{10}$ molec/cm ² /s	“true” emissions $> 10^{11}$ molec/cm ² /s	
SF _M	Model	0.06*	1.8	3.0	1.8	2.9	1.6
SF _{prior}	a priori	0.11	2.0	3.2	2.0	3.3	1.6
SF _{n30}	Model w/ 30% noise	0.26	2.1	3.9	2.1	3.8	1.8
SF _{diffem}	Model w/ different emissions	0.13	2.0	3.6	2.0	3.7	1.9
SF _{finer}	Model at finer (2°x2.5°) resolution	0.05*	2.1	3.2	2.1	3.2	1.8
SF _{trop}	Uniform in troposphere	0.39	2.8	5.6	2.8	5.5	2.1
SF _{BL}	Uniform in boundary layer	0.17	2.8	4.6	2.8	4.6	1.9

580 Table 3: Summary of error statistics for adjoint tests. Values marked * indicate that correlation is
581 not statistically significant ($p > 0.05$). For comparisons, mean “true” emissions for grid boxes with
582 emissions $> 10^{10}$ molec/cm²/s is 4.9×10^{10} , and mean “true” emissions for boxes with
583 emissions $> 10^{11}$ molec/cm²/s is 1.6×10^{11} molec/cm²/s.
