Abstract. Because nitrous acid (HONO) photolysis is a key source of hydroxyl (OH) radicals, identifying the atmospheric
20 sources of HONO is essential to enhance the understanding of atmospheric chemistry processes and improve the accuracy of
simulation models. We performed seasonal field observations of HONO in a coastal city of southeastern China, along with
measurements of trace gases, aerosol compositions, photolysis rate constants (J), and meteorological parameters. The results
showed that the average observed concentration of HONO was 0.54 ± 0.47 ppb. Vehicle exhaust emissions contributed an
average of 1.64% to HONO, higher than the values found in most other studies, suggesting an influence from diesel vehicle
25 emissions. The mean conversion frequency of NO_2 to HONO in the nighttime was the highest in summer due to water droplets
was evaporated under the condition of high temperatures. Based on a budget analysis, the rate of emission from unknown
sources (R_{unknown}) was highest at midday, with values of $14.78 \text{ ppb}\cdot\text{h}^{-1}$ in summer, $6.49 \text{ ppb}\cdot\text{h}^{-1}$ in autumn, and $2.18 \text{ ppb}\cdot\text{h}^{-1}$
in spring. Unknown sources made up the largest proportion of all sources in summer (84.92%), autumn (80.29%), and spring
(49.98%), whereas the main source in winter was the homogeneous reaction of NO with OH (56.15%), due to winter having
30 the highest NO concentration of the four seasons. The value of R_{unknown} had a positive logarithmic relationship with the
photolysis of particulate nitrate in spring, summer, and autumn. However, R_{unknown} was limited by particulate acidity under the

condition of photolysis of particulate nitrate ($J(\text{NO}_3^-)_R \times \text{pNO}_3^- > 1 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{s}^{-1}$ in autumn and $J(\text{NO}_3^-)_R \times \text{pNO}_3^- > 2 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{s}^{-1}$ in spring and summer. The variation of HONO at night can be exactly simulated based on the HONO/ NO_x ratio, while the main sources should be considered for daytime simulations. Compared with O_3 photolysis, HONO
35 photolysis has long been an important source of OH, particularly in the morning in spring and winter and around noon in summer and autumn. This study draws a full picture of the sources of HONO across all four seasons and improves the comprehension of HONO chemistry in southeastern coastal China.

1 Introduction

Nitrous acid (HONO) photolysis produces hydroxyl (OH) radicals, an important oxidant, in the troposphere (Zhou et al., 2011).
40 Hydroxyl radicals play an important role in triggering the oxidation of volatile organic compounds and therefore determine the fate of many anthropogenic atmospheric pollutants (Lei et al., 2018). Recent research results have shown that HONO production is the cause of an increase in secondary pollutants (Li et al., 2010; Gil et al., 2019; Fu et al., 2019). Though extensive studies have been conducted in the four decades since the first clear measurement of HONO (Perner and Platt, 1979), the HONO formation mechanisms are still elusive, especially during the daytime, when there is a large difference between
45 measured concentrations and those calculated from known gas-phase chemistry (Sörgel et al., 2011). Identification of the sources of atmospheric HONO and exploration of its formation mechanisms are beneficial for enhancing our comprehension of atmospheric chemistry processes and improving the accuracy of atmospheric simulation models.

Commonly accepted HONO sources include direct emission from motor vehicles (Chang et al., 2016; Kirchstetter et al., 1996; Kramer et al., 2020; Xu et al., 2015) or soil (Su et al., 2011; Tang et al., 2019; Oswald et al., 2013), the homogeneous
50 conversion of NO by OH (Seinfeld and Pandis, 1998; Kleffmann, 2007), and the heterogeneous reaction of NO_2 on humid surfaces (Alicke, 2002; Finlayson-Pitts et al., 2003). Other heterogeneous daytime sources, such as photosensitive reduction of NO_2 on organic surfaces (Stemmler et al., 2006) and the photolysis of particulate nitrate by ultraviolet (UV) light (Kasibhatla et al., 2018; Romer et al., 2018; Ye et al., 2017; Scharcko et al., 2014), have been identified by previous laboratory measurements and field studies. Most previous field studies have shown an absence of major HONO sources during the daytime, which is an
55 important area for further study. According to an analysis of 15 sets of field observations around the world (Elshorbany et al., 2012), the HONO/ NO_x ratio (0.02) predicts well HONO concentrations under different atmospheric conditions. To avoid the problem of underestimation, in this study, an empirical parameterization was applied to estimating the HONO concentration, because the current understanding of HONO formation mechanisms is incomplete.

Field measurements of HONO and its precursor NO_2 at sites with different aerosol load & composition, and relative humidity
60 (RH) are necessary to deepen our knowledge of the HONO formation mechanisms. Such measurements have been carried out in coastal cities in China, including Guangzhou (Qin et al., 2009), Hong Kong (Xu et al., 2015), and Shanghai (Cui et al., 2018), where the air pollution is relatively severe (Wang et al., 2017b). However, there has been a lack of research into HONO

in coastal cities with good air quality, low concentrations of NO_x and $\text{PM}_{2.5}$, but strong sunlight and high humidity. Insufficient research on coastal cities with good air quality has resulted in certain obstacles to assessing the photochemical processes in these areas. Due to different emission-source intensities and ground surfaces, the atmospheric chemistry of HONO in the southeastern coastal area of China is predicted to have different pollution characteristics from those found in other coastal cities. Furthermore, HONO contributes to the atmospheric photochemistry differently depending on the season (Li et al., 2010). Therefore, observations of atmospheric HONO across different seasons in the southeastern coastal area of China are urgently needed.

Incoherent broadband cavity-enhanced absorption spectroscopy (IBBCEAS) was employed in this study to determine HONO concentrations in the southeastern coastal city of Xiamen in August (summer), October (autumn), and December (winter) 2018 and March (spring) 2019. In addition, a series of other relevant trace gases, meteorological parameters, and photolysis rate constants were measured at the same time to provide supplementary information to reveal the HONO formation mechanisms. The main purposes of this study were to (1) quantify the gas-phase photostationary state of HONO, (2) calculate the values of unknown HONO daytime sources, (3) analyze the processes leading to HONO formation, (4) simulate HONO concentrations based on an empirical parameterization, and (5) evaluate OH production from HONO from 07:00 to 16:00 local time. All of these results were compared between the seasons.

2 Methodology

2.1 Site description

Our field observations were carried out ~80 m above the ground at a supersite located on the top of the Administrative Building of the Institute of Urban Environment (IUE), Chinese Academy of Sciences (24.61°N , 118.06°E) in Xiamen, China in August, October, and December 2018, and March 2019 (Fig. 1). The supersite was equipped with a complete set of measurement tools, including those for measuring gas and aerosol species composition, meteorology parameters, and photolysis rate constants, which provided a good chance to study the atmospheric chemistry of HONO in a coastal city of southeastern China.

2.2 Instrumentation

The atmospheric concentrations of both HONO and NO_2 were determined using IBBCEAS, which has previously been widely applied to such measurements (Tang et al., 2019; Duan et al., 2018; Min et al., 2016). Multiple reflections in the resonator cavity enhance the length of the effective absorption path, thereby enhancing the detection sensitivity of the instrument. The 1σ detection limits for HONO and NO_2 were 60 ppt and 100 ppt, respectively, and the time resolution was 1 min. The measurement error for HONO and NO_2 was estimated to be about 9%. A specific description of the structure and principle of IBBCEAS can be found in a previous report (Duan et al., 2018).

The inorganic composition of PM_{2.5} aerosols, including Cl⁻, NO₃⁻, SO₄²⁻, NH₄⁺, Na⁺, K⁺, Ca²⁺, and Mg²⁺, were determined using a Monitor for AeRosols and Gases in ambient Air (MARGA, Model ADI 2080, Applikon Analytical B.V., the Netherlands) with a temporal resolution of 1 h. The MARGA utilizes a steam-jet aerosol collector (SJAC), and online ion chromatography was applied to determine the aqueous sample streams produced by the SJAC. Specific descriptions of the SJAC can be found in previous reports (Slanina et al., 2001; Wyers et al., 1993).

Photolysis frequencies were determined using a photolysis spectrometer (PFS-100, Focused Photonics Inc., Hangzhou, China). These were calculated by multiplying the actinic flux F , quantum yield $\phi(\lambda)$ and the known absorption cross section $\sigma(\phi)$. The measurements included the photolysis rate constants J (O¹D), J (HCHO_M), J (HCHO_R), J (NO₂), J (H₂O₂), J (HONO), J (NO₃_M) and J (NO₃_R), and the spectral band ranged from 270 to 790 nm. Hemispherical (2π sr) angular response deviations were within $\pm 5\%$.

The O₃ concentration was determined by UV photometric analysis [Model 49*i*, Thermo Environmental Instruments (TEI) Inc.], and the detection limit of the TEI Model 49*i* is 1.0 ppb. The NO concentration was determined by a chemiluminescence analyzer (TEI model 42*i*) with a molybdenum converter, and the detection limit of the TEI model 42*i* is 0.5 ppb. Although the TEI model 42*i* also measures the concentration of NO₂, this value might actually include other active nitrogen components. Therefore, the NO₂ concentration as measured by IBBCEAS was used in this study. An oscillating microbalance with a tapered element was applied to determine the PM_{2.5} concentration. Meteorological parameters were determined by an ultrasonic atmospheric (150WX, Airmar, USA). The time resolution of all instruments was unified to 1 h to facilitate comparison.

3 Results and discussion

3.1 Overview of data

The average measured ambient HONO concentration at the measurement site for all measurement periods was 0.54 ± 0.47 ppb. The maximum value (3.51 ppb) appeared at 08:00 on 4 December 2018. The HONO mixing level in Xiamen was close to the values found in Rome (0.58 ppb), Nanjing (0.69 ppb), and Hong Kong (0.72 ppb), but was much lower than those in Xi'an (1.04 ppb), Kathmandu (1.05 ppb), Jinan (1.14 ppb), Santiago (2.25 ppb), or Guangzhou (2.75 ppb), as shown in Table 1. Table 1 also shows the seasonal patterns of HONO and related parameters during the night and the day.

In the daytime (06:00–18:00, including 06:00, local time (LT)), the highest concentration of HONO was found in spring and summer (0.72 ppb), followed by winter (0.61 ppb) and autumn (0.50 ppb). In short, the seasonal variation of HONO was well correlated with the seasonality of RH, with high RH in spring (83.31%) and summer (84.58%), followed by winter (75.79%) and autumn (66.47%). In conditions of low RH, the adsorption rate of NO₂ is not as rapid as that of HONO, resulting in a reduction in the conversion rate of NO₂ to HONO and thus a reduction in the concentration of HONO (Stutz et al., 2004). This seasonal variation in HONO concentration was different from those measured in Jinan (Li et al., 2018), Nanjing (Liu et al.,

2019b), and Hong Kong (Xu et al., 2015). The elevated HONO concentrations in summer, when there is strong solar radiation, suggests the existence of strong sources of HONO and its important contribution to the production of OH radicals. Interestingly, the HONO concentration in the nighttime was lower than that in the daytime in all four seasons. Most previous studies have found that the HONO concentration at night is significantly higher than that during the day (Wang et al., 2015; Liu et al., 2019c; Li et al., 2018; Elshorbany et al., 2009; Acker et al., 2006; Yu et al., 2009). Coastal cities are susceptible to sea and land breezes, with sea breezes blowing during the day and land breezes blowing during the night (Wagner et al., 2012). Therefore, the concentration of sea salt, as calculated based a previous report (Liu et al., 2020), is significantly higher during the day than that during the night ($P < 0.05$). It is possible that significantly more HONO could be produced by photolysis of sea salts against the daytime photolysis of HONO (Kasibhatla et al., 2018). Similar results were found in Hong Kong, which is also a coastal city, which further validates the rationality of this assumption (Xu et al., 2015).

The ratio of HONO to NO_x or the ratio of HONO to NO_2 have been extensively applied to indicate heterogeneous conversion of NO_2 to HONO (Li et al., 2012; Liu et al., 2019c; Zheng et al., 2020). Compared with the HONO/ NO_2 ratio, the HONO/ NO_x ratio can better avoid the influence of primary emissions (Liu et al., 2019c). In this study, the HONO/ NO_x ratios during the day were higher than those during the night, indicating that light promotes the conversion of NO_x to HONO. The highest daytime HONO/ NO_x ratio was found in summer (0.072), followed in turn by autumn (0.048), spring (0.034), and winter (0.023). The elevated HONO/ NO_x ratio in summer indicates a greater net HONO production (Xu et al., 2015). The low HONO/ NO_x ratio in winter can probably be ascribed to heavy emissions and high concentrations of NO in winter (Table 1). The HONO/ NO_x ratios during every season in Xiamen were in general higher than those found in studies of other cities, which indicates greater net HONO production in Xiamen.

The diurnal patterns of HONO, NO_x , HONO/ NO_x , and $J(\text{NO}_2)$ averaged for every hour in each season are shown in Fig. 2. As shown in Fig. 2a, the HONO concentration had similar diurnal variation patterns across the four seasons. The maximum values of the HONO concentration were 1.12 ppb in winter, 1.03 ppb in summer, 0.98 ppb in spring, and 0.65 ppb in autumn, and these occurred in the morning rush hour (07:00–08:00), which indicates that direct vehicle emissions may be a significant source of HONO. The contribution of direct vehicle emissions to HONO will be quantified in Sect. 3.2. The HONO concentration reduced rapidly from the morning rush hour to sunset, and this was caused by rapid photolysis combined with increased height of the boundary layer. The minimum values of HONO concentration were 0.47 ppb in spring, 0.23 ppb in winter, 0.21 ppb in summer, and 0.14 ppb in autumn, and these appeared at sunset, between 16:00 and 18:00. The HONO concentration increased gradually after sunset, which indicates that release from HONO sources exceeded its dry deposition (Wang et al., 2017a). There was a slight difference in the diurnal variation of HONO between autumn and the other seasons. A rapid reduction of HONO after the morning rush hour was found in spring, summer, and winter. In comparison, the HONO in autumn had an almost constant concentration between 07:00 and 11:00 because NO_x decreased slowly during this period.

As shown in Fig. 2b, NO_x concentration followed an expected profile in the four seasons, with peaks of 45.58 ppb in winter, 40.47 ppb in spring, 32.47 ppb in summer, and 20.07 ppb in autumn, each occurring in the morning rush hour at 10:00, 09:00,

155 08:00, and 07:00 local time, respectively. After these peaks, NO_x decreased during the day in each season, probably due to photochemical transformation and increasing boundary-layer depth. The NO_x concentrations then began to rise from their minima of 8.20 ppb in summer, 8.85 ppb in autumn, 18.10 ppb in winter, and 23.09 ppb in spring after 14:00, 13:00, 15:00, and 16:00 local time, respectively, which was caused by a combination of weak photochemical transformation and reduction in the boundary-layer depth. The NO_x concentrations during winter and spring were significantly higher than those during
160 autumn and summer. Both the maxima and minima of NO_x appeared later in spring and winter compared with summer and autumn.

It is possible to better describe the behavior of HONO using the HONO/ NO_x ratio. The higher HONO/ NO_x ratio found at noon in the different seasons, especially in summer and autumn (Fig. 2c), indicates an unknown daytime HONO source. It is worth noting that the maximum value of this ratio in summer (0.147) was significantly higher than the maximum in other seasons,
165 especially in winter (0.034). Fig. 2d shows that the value of the HONO/ NO_x ratio increased with the photolysis of NO_2 in summer and autumn, suggesting that the unknown HONO source is probably correlated with light (Xu et al., 2015; Wang et al., 2017a; Li et al., 2018; Li et al., 2012). The increase in the HONO/ NO_2 ratio during the day can be seen more clearly in Fig. 3, and its high value indicates a high HONO production efficiency, which cannot be ascribed to NO_2 conversion due to the weak correspondence between HONO and NO_2 in three of the seasons (excluding winter). Furthermore, high HONO/ NO_2
170 ratios were accompanied by high $J(\text{NO}_2)$ in summer, which indicates that HONO formation during the daytime is controlled by light rather than Reaction (R1).

However, the observed maxima can also be ascribed to sources independent from NO_x concentration, such as soil emissions (Su et al., 2011) and photolysis of particulate nitrate (Zhou et al., 2011; Ye et al., 2016), which are not influenced by the
175 decrease of NO_x concentration around noon. A more specific discussion of daytime HONO sources considering the photolysis of particulate nitrate will be given in Sect. 3.4.3. Although the solar radiation intensity in spring and winter was nearly equal, the difference in the HONO/ NO_x ratios in these seasons was large, indicating that the solar radiation intensity was not the only factor determining the HONO/ NO_x ratio. The HONO emissions from soil were estimated to be 2–5 ppb h^{-1} (Su et al., 2011). However, soil emission was a negligible source of HONO in this study since the surrounding soil is not used for agriculture,
180 and this greatly reduces the amount of HONO released due to no fertilization process (Su et al., 2011).

3.2 Direct vehicle emission of HONO

The consistent diurnal variations in HONO and NO_x presented in Sect. 3.1 (Fig. 2) also indicate HONO emissions from local traffic. Five criteria were applied to choose cases that guaranteed the presence of fresh plumes (Xu et al., 2015; Liu et al., 2019c): (1) $\text{UV} < 10 \text{ W} \cdot \text{m}^{-2}$; (2) short-duration air masses ($< 2 \text{ h}$); (3) HONO correlating well with NO_x ($R^2 > 0.60$, $P < 0.05$);

185 (4) $\text{NO}_x > 20$ ppb (highest 25% of NO_x value); and (5) $\text{NO}/\text{NO}_x > 0.50$. A total of 34 cases met these strict criteria for estimation of the HONO vehicle emission ratios. The slopes of scatter plots of HONO vs NO_x were used as the emission factors.

A total of 34 vehicle emission plumes are summarized in Table 2, and these were used for estimation of the vehicle emission ratios. The plumes were considered to be truly fresh because the mean $\Delta\text{NO}/\Delta\text{NO}_x$ ratio of the selected air masses was 92%. Vehicle plumes unavoidably mixing with other air masses resulted in the correlation coefficients (R^2) between HONO and
 190 NO_x varying among the cases, and these ranged from 0.61 to 0.92. The obtained $\Delta\text{HONO}/\Delta\text{NO}_x$ ratios ranged from 0.24% to 4.76%, with an average value ($\pm\text{SD}$) of (1.64 ± 0.95) %. These $\Delta\text{HONO}/\Delta\text{NO}_x$ ratios have comparability to those obtained in Guangzhou (1.4% (Qin et al., 2009); 1.8% (Li et al., 2012)) and Houston (1.7% (Rappenglück et al., 2013)), but are significantly higher than those measured in Jinan (0.53% (Li et al., 2018)) and Santiago (0.8% (Elshorbany et al., 2009)). The types of vehicle engine, the use of catalytic converters, and different fuels will affect the vehicle emission factors (Kurtenbacha
 195 et al., 2001). A potential reason for the relatively higher $\Delta\text{HONO}/\Delta\text{NO}_x$ values in our study is that heavy-duty diesel vehicles pass by on the surrounding highway (Rappenglück et al., 2013). It is necessary to examine the specific vehicle emission factors in target cities because of these differences in $\Delta\text{HONO}/\Delta\text{NO}_x$ ratios. Roughly assuming that NO_x mainly arises from vehicle emissions, a mean $\Delta\text{HONO}/\Delta\text{NO}_x$ value of 1.64% was used as the emission factor in this study, and this value was adopted to estimate the contribution of vehicle emissions P_{emis} to the HONO concentration using

$$200 \quad P_{\text{emis}} = \text{NO}_x \times 0.0164. \quad (1)$$

We can then obtain the corrected HONO concentration ($\text{HONO}_{\text{corr}}$) for further analysis from the equation

$$\text{HONO}_{\text{corr}} = \text{HONO} - P_{\text{emis}}. \quad (2)$$

3.3 Nighttime heterogeneous conversion of NO_2 to HONO

3.3.1 Conversion rate of NO_2 to HONO

205 Nighttime $\text{HONO}_{\text{corr}}$ concentrations can be estimated from the heterogeneous conversion reaction (Meusel et al., 2016; Alicke, 2002; Su et al., 2008a). Although the mechanism of the nighttime HONO heterogeneous reaction is unclear, the formula for the heterogeneous conversion (C_{HONO}^0) of NO_2 to HONO can be expressed as

$$C_{\text{HONO}}^0 = \frac{[\text{HONO}_{\text{corr}}]_{t_2} - [\text{HONO}_{\text{corr}}]_{t_1}}{(t_2 - t_1) \times \overline{[\text{NO}_2]}}, \quad (3)$$

where $\overline{[\text{NO}_2]}$ is the mean value of NO_2 concentration between t_1 and t_2 . Eq. (4) has been suggested as a way to avoid the
 210 interference of direct emissions and diffusion (Su et al., 2008a):

$$C_{\text{HONO}}^X = \frac{\left(\frac{[\text{HONO}_{\text{corr}}]_{t_2}}{[X]_{t_2}} - \frac{[\text{HONO}_{\text{corr}}]_{t_1}}{[X]_{t_1}} \right) \overline{[X]}}{(t_2 - t_1) \frac{1}{2} \left(\frac{[\text{NO}_2]_{t_2}}{[X]_{t_2}} + \frac{[\text{NO}_2]_{t_1}}{[X]_{t_1}} \right) \overline{[X]}} = \frac{2 \left(\frac{[\text{HONO}_{\text{corr}}]_{t_2}}{[X]_{t_2}} - \frac{[\text{HONO}_{\text{corr}}]_{t_1}}{[X]_{t_1}} \right)}{(t_2 - t_1) \left(\frac{[\text{NO}_2]_{t_2}}{[X]_{t_2}} + \frac{[\text{NO}_2]_{t_1}}{[X]_{t_1}} \right)}, \quad (4)$$

where $[\text{HONO}_{\text{corr}}]_t$, $[\text{NO}_2]_t$, and $[X]_t$ were the concentrations of HONO, NO_2 , and species used for normalization (including NO_2 , CO, and black carbon (BC) in this study), respectively, at time t , \bar{X} is the average concentration of reference species between t_1 and t_2 , and C_{HONO}^X represents the conversion rate normalized against reference species X (Su et al., 2008a). There
215 were 91 cases meeting the criteria. Such a large number of cases contributes to the statistical analysis of the heterogeneity of HONO formation. The average values of C_{HONO}^0 , $C_{\text{HONO}}^{\text{NO}_2}$, $C_{\text{HONO}}^{\text{CO}}$, and $C_{\text{HONO}}^{\text{BC}}$ were $0.48\% \text{ h}^{-1}$, $0.46\% \text{ h}^{-1}$, $0.47\% \text{ h}^{-1}$, and $0.46\% \text{ h}^{-1}$, respectively. The combined $C_{\text{HONO}}^{\text{C}}$ was $0.47\% \text{ h}^{-1}$. The average C_{HONO} values obtained using different normalization methods agreed well. Therefore, an estimation value of $0.47\% \text{ h}^{-1}$ should be suitable for the nighttime conversion rate from NO_2 to HONO.

220 We also compared the conversion rates calculated in this study with other experiments. As shown in Table 3, $C_{\text{HONO}}^{\text{C}}$ varied widely, from $0.29\% \text{ h}^{-1}$ to $2.40\% \text{ h}^{-1}$, which may be due to the various kinds of land surface in the various environments. The $C_{\text{HONO}}^{\text{C}}$ in Xiamen is comparable to those derived in Shanghai ($0.70\% \text{ h}^{-1}$ (Wang et al., 2013)), Jinan ($0.68\% \text{ h}^{-1}$ (Li et al., 2018)), and Hong Kong ($0.52\% \text{ h}^{-1}$ (Xu et al., 2015)), less than the values calculated from most other sites, including Xinken ($1.60\% \text{ h}^{-1}$ (Su et al., 2008a)), Guangzhou (2.40 (Li et al., 2012)), Spain (1.50 (Sörgel et al., 2011)), Beijing (0.80 (Wang et al., 2017a)), the eastern Bohai Sea ($1.80\% \text{ h}^{-1}$ (Wen et al., 2019)), and Kathmandu ($1.40\% \text{ h}^{-1}$ (Yu et al., 2009)), but more than
225 the value obtained in Shandong ($0.29\% \text{ h}^{-1}$ (Wang et al., 2015)). The highest $C_{\text{HONO}}^{\text{C}}$ was found in summer, with a value of $0.55\% \text{ h}^{-1}$, which will be explained in Sect. 3.3.2. Another study also found that the highest $C_{\text{HONO}}^{\text{C}}$ ($1.00\% \text{ h}^{-1}$) appeared in summer (Wang et al., 2017a).

3.3.2 The influence of relative humidity on HONO formation

230 The hydrolysis of NO_2 on wet surfaces producing HONO is first-order affected by the concentration of NO_2 (Finlayson-Pitts et al., 2003; Jenkin et al., 1988) and the absorption of water on the surfaces (Finlayson-Pitts et al., 2003; Kleffmann et al., 1998). A scatter plot of $\text{HONO}_{\text{corr}}/\text{NO}_2$ vs RH is shown in Fig. 4. We calculated the top-five $\text{HONO}_{\text{corr}}/\text{NO}_2$ ratios in every 5% RH interval based on a method introduced in previous literature (Li et al., 2012; Stutz et al., 2004), which will reduce the influence of those circumstances such as advection, the time of the night, and the surface density. These averaged maxima and standard
235 deviations are shown in Fig. 4 as orange squares, except where data were sparse in a particular 5% RH interval.

As for autumn and winter, the influence of RH on $\text{HONO}_{\text{corr}}/\text{NO}_2$ can be divided into two parts. The RH promoted an increase in $\text{HONO}_{\text{corr}}/\text{NO}_2$ for RH values less than 77.96% in autumn and 91.99% in winter, which is in line with the reaction kinetics of Reaction (R1). However, RH inhibits the conversion of NO_2 to HONO when RH is higher than a turning point. According to many previous studies, water droplets will be formed on the surface of the ground or of aerosols when RH exceeds a certain
240 value, thus resulting in a negative dependence of $\text{HONO}_{\text{corr}}/\text{NO}_2$ on RH (He et al., 2006; Zhou et al., 2007). A similar phenomenon was also found in Guangzhou and in Shanghai (70%, (Li et al., 2012; Wang et al., 2013)) and in Kathmandu and in Beijing (65%, (Yu et al., 2009; Wang et al., 2017a)). However, in summer, RH appeared to promote the increase of

HONO_{corr}/NO₂ without a turning point, suggesting that HONO production at night in summer strongly depends on RH. Another study also found a similar phenomenon in the summer in Guangzhou (Qin et al., 2009). This phenomenon might be caused by water droplets being destroyed by high temperatures. This is the reason for the highest C_{HONO}^C in summer. As for spring, the relationship between HONO_{corr}/NO₂ and RH is very complicated and needs to be explored further in the future.

3.3.3 The influence of aerosols on HONO formation

As shown in Fig. S1, HONO_{corr}/NO₂ reached a pseudo-steady state from 03:00 to 6:00 LT every night. A correlation analysis of HONO_{corr}/NO₂ with PM_{2.5} was carried out in the pseudo-steady state to understand the impact of aerosols on HONO production. Although we did not measure the aerosol surface density, the aerosol mass concentration can be used to replace this parameter (Huang et al., 2017; Park et al., 2004; Cui et al., 2018). The positive correlation of HONO_{corr} with PM_{2.5} (R₁ = 0.54) (Fig. 5a) may be a result of atmospheric physical processes such as convergence and diffusion. Using the HONO_{corr}/NO₂ ratio instead of a single HONO concentration for correlation analysis with PM_{2.5} reduce the impact of physical processes and indicate the extent of conversion of NO₂ to HONO. Therefore, it was more credible that HONO_{corr}/NO₂ would be moderately positively correlated with PM_{2.5} (R₂ = 0.23) during the whole observation period (Fig. 5b). As denoted by larger green squares in the figure, HONO_{corr}/NO₂ correlated well with PM_{2.5} when its concentration was higher than 35 μg·m⁻³ (R₃ = 0.47) (Fig. 5b). The larger the amount of HONO produced by the heterogeneous reaction of NO₂ on the aerosol surface, the better the correlation between HONO/NO₂ and PM_{2.5} (Cui et al., 2018; Wang, 2003; Hou et al., 2016; Li et al., 2012; Nie et al., 2015).

3.4 Daytime sources of HONO

3.4.1 HONO photostationary-state approach

Having discussed the nighttime chemical behavior of HONO, we now concentrate on the daytime chemical behavior of HONO. A calculation of the photostationary state (PSS) was conducted to preliminarily assess HONO concentrations during the daytime, especially the influence of any potential additional sources. It is hoped that HONO is in the photostationary state in the daytime due to its production from oxidation of NO by OH (Reaction (R2)), reformation of OH and NO by rapid photolysis (Reaction (R3)), and oxidation of HONO itself by OH (Reaction (R4)).

The photostationary concentration [HONO]_{PSS} was estimated by

$$[\text{HONO}]_{\text{PSS}} = \frac{k_{\text{OH}+\text{NO}}[\text{OH}][\text{NO}]}{k_{\text{OH}+\text{HONO}}[\text{OH}] + J(\text{HONO})} \quad (5)$$

275 in which $k_{\text{OH}+\text{NO}} = 7.4 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ and $k_{\text{OH}+\text{HONO}} = 6.0 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$, values taken from a previous study (Sörgel et al., 2011). The OH concentration ([OH]) was estimated in this study because no data for this value were available. An improved empirical formula, Eq. (6), was applied to estimate [OH] using the NO_2 and HONO concentrations and the photolysis rate constants (J) of NO_2 , O_3 , and HONO (Wen et al., 2019).

$$[\text{OH}] = 4.1 \times 10^9 \times \frac{J(\text{O}^1\text{D})^{0.83} \times J(\text{NO}_2)^{0.19} \times (140 \times \text{NO}_2 + 1) + \text{HONO} \times J(\text{HONO})}{0.41 \times \text{NO}_2^2 + 1.7 \times \text{NO}_2 + 1 + \text{NO} \times k_{\text{NO}+\text{OH}} + \text{HONO} \times k_{\text{HONO}+\text{OH}}} \quad (6)$$

280 During spring, summer, autumn, and winter, the average midday OH concentrations were $3.89 \times 10^6 \text{ cm}^{-3}$, $1.36 \times 10^7 \text{ cm}^{-3}$, $1.07 \times 10^7 \text{ cm}^{-3}$, and $2.97 \times 10^6 \text{ cm}^{-3}$, respectively, which were within the range of those obtained in other studies varying from $0.5 \times 10^6 \text{ cm}^{-3}$ to $4 \times 10^6 \text{ cm}^{-3}$ in winter (Wang et al., 2017a) and from $1 \times 10^7 \text{ cm}^{-3}$ to $2 \times 10^7 \text{ cm}^{-3}$ in summer (Li et al., 2012).

Clearly, the $[\text{HONO}]_{\text{PSS}}$ values cannot reproduce the daytime HONO concentration (Fig. 6). The $[\text{HONO}]_{\text{PSS}}$ does, however, replicate the diurnal variations of HONO, peaking in the morning rush hour (08:00–10:00 LT), as characterized by the high NO concentration. However, $[\text{HONO}]_{\text{PSS}}$ values reduced to zero at 17:00–18:00 LT after this morning peak, which was caused by the photolysis rate of HONO being notably faster than the rate of the only source from Reaction (R2). The value of $[\text{HONO}]_{\text{PSS}}$ showed different levels in the four seasons, with the highest values in winter and the lowest values in summer due to seasonal variation of the photolysis rate constant. This indicates that the largest unknown sources appeared in summer while the smallest unknown sources appeared in winter. This result is consistent with the quantitative results regarding daytime unknown sources, as will be presented in the next section. The $[\text{HONO}]_{\text{PSS}}$ values correlated well with NO concentrations ($R = 0.865$), while the correlations with [OH] ($R = -0.081$) and $J(\text{HONO})$ ($R = -0.072$) were weak. Therefore, the HONO gas-phase chemistry was dominated by the availability of NO. Simply considering the homogeneous gas-phase reaction is far from matching the observed HONO concentrations. The HONO values calculated based on PSS were more than an order of magnitude smaller than the observed daytime HONO values, suggesting significant unknown sources for HONO, while the gas-phase reaction (Reaction (R3)) only accounts for a small proportion of the observed values, especially in summer.

3.4.2 Budget analysis of HONO

295 From the analysis in Sect. 3.4.1, it appears that there are additional sources of HONO in the daytime, because the $[\text{HONO}]_{\text{PSS}}$ value is much lower than the observed HONO concentration. Here, R_{unknown} is used to stand for the additional sources. The value of R_{unknown} was estimated based on the balance between sources and sinks due to its short atmospheric lifetime. The sources are: (1) oxidation of NO by OH ($R_{\text{OH}+\text{NO}} = k_{\text{OH}+\text{NO}}[\text{NO}][\text{OH}]$), (2) dark heterogeneous production (P_{het}), and (3) direct vehicle emission (P_{emis}); the sinks are (1) HONO photolysis ($R_{\text{phot}} = J_{\text{HONO}}[\text{HONO}]$), (2) oxidation of HONO by OH ($R_{\text{OH}+\text{HONO}} = k_{\text{OH}+\text{HONO}}[\text{HONO}][\text{OH}]$), and (3) dry deposition (L_{dep}). The value of R_{unknown} can then be calculated according to

$$R_{\text{unknown}} = J_{\text{HONO}}[\text{HONO}] + k_{\text{OH}+\text{HONO}}[\text{HONO}][\text{OH}] + L_{\text{dep}} + \frac{\Delta[\text{HONO}]}{\Delta t} - k_{\text{OH}+\text{NO}}[\text{NO}][\text{OH}] - P_{\text{het}} - P_{\text{emis}}, \quad (7)$$

where $\frac{\Delta[\text{HONO}]}{\Delta t}$ is the observed change of HONO concentration ($\text{ppb}\cdot\text{s}^{-1}$). The value of $\frac{\Delta[\text{HONO}]}{\Delta t}$ is the concentration difference between the center of one interval (1 min) and the center of the next interval, and this accounts for changes in concentration levels (Sörgel et al., 2011). The parameter L_{dep} can be quantified by multiplying the dry deposition rate of HONO by the observed HONO concentration and then dividing by the mixing layer height ($L_{\text{dep}} = \frac{v_{\text{HONO}}^{\text{ground}} \times [\text{HONO}]}{H}$). A value of $v_{\text{HONO}}^{\text{ground}} = 2 \text{ cm}\cdot\text{s}^{-1}$ was used for the deposition rate (Sörgel et al., 2011; Su et al., 2008b). The mixing layer heights during spring, summer, autumn, and winter were 1074.4 m, 1173.8 m, 1494.6 m, and 1310.4 m, respectively (Gao, 1999). In summarizing the known HONO sources, we included the nighttime heterogeneous production as a known source based on the assumption that the day continues in the same way as the night (Sörgel et al., 2011). The term P_{het} was parameterized by NO_2 conversion at night using the formula $P_{\text{het}} = C_{\text{HONO}}^{\text{C}}[\text{NO}_2]$ (Alicke, 2002).

Figure 7 shows the contributions of each term in Eq. (6) to the HONO budgets in different seasons. Photolysis of HONO (R_{phot}) formed the largest proportion of the sinks in all four seasons, accounting for 94.69%, 96.85%, 96.10%, and 95.01% in spring, summer, autumn, and winter, respectively. The value of R_{phot} in summer was the highest ($10.69 \text{ ppb}\cdot\text{h}^{-1}$) and this was 4.95, 2.29, and 5.85 times higher than that in spring, autumn, and winter, respectively. The oxidation of HONO by OH contributed little to HONO sinks (2.49% of all sinks). Dry deposition (L_{dep}) was also very small (1.85% of all sinks). As for known sources, $R_{\text{OH}+\text{NO}}$ was the main known source in all four seasons, wherein the largest proportion was found in summer (80.73%), followed by autumn (70.98%), winter (66.27%), and spring (51.48%). Direct emission was second among the known sources, accounting for 40.83%, 15.78%, 23.55%, and 30.10% in spring, summer, autumn, and winter, respectively. Dark heterogeneous formation (P_{hete}) was almost negligible in the daytime, accounting for approximately 5.07% of known sources during the whole observation period. As for unknown sources, these made up the largest proportion of all sources found in summer (84.92%), followed by autumn (80.29%) and spring (49.98%). However, the unknown sources only accounted for 15.26% of all sources in winter. This indicates that known sources of HONO can explain the majority of sources in winter, and it is not necessary to analyze the unknown sources in this season.

The values of $R_{\text{OH}+\text{NO}}$ in different seasons all reached their maximum in the morning, and this was followed by a gradual decrease. This parameter made up the highest proportion of all sources (56.15%) in winter, followed by spring (25.75%), autumn (13.99%), and summer (12.17%). In winter, with its low light intensity and high NO concentration, the homogeneous gas-phase reaction between NO and OH accounted for the majority of the daytime HONO sources. It is worth noting that R_{unknown} exhibited a maximum at noon in all seasons except for winter. A previous study in Wangdu (Liu et al., 2019a) also found that unknown sources of HONO reached a maximum at midday, with the strongest photolysis rates in summer. In the present study, the highest R_{unknown} value at noon was $14.79 \text{ ppb}\cdot\text{h}^{-1}$ in summer, followed by $6.49 \text{ ppb}\cdot\text{h}^{-1}$ in autumn and $2.18 \text{ ppb}\cdot\text{h}^{-1}$ in spring. The R_{unknown} value peaked at 08:00 in winter, reaching $1.55 \text{ ppb}\cdot\text{h}^{-1}$. This indicates that this source

depends on the season, strengthening the validity of the assumption that the missing HONO formation mechanism is related to a photolytic source (Michoud et al., 2014). The magnitudes of these additional sources were much higher than those found in Beijing (Wang et al., 2017a) (1.3–3.82 ppb·h⁻¹), in Guangzhou (0.77 ppb·h⁻¹) (Li et al., 2012), and in Xinken (~5 ppb·h⁻¹) (Su et al., 2011).

3.4.3 Exploration of possible unknown daytime sources

According to the analyses in Sect. 1 and Sect. 3.4.2, the unknown sources are likely to be related to light. It was indeed found that the unknown sources have a good correlation with the parameters related to light. It was reported in previous studies that particulate nitrate photolysis is a source of HONO (Ye et al., 2017; Ye et al., 2016; Scharcko et al., 2014; Romer et al., 2018; McFall et al., 2018). We will discuss the possibility of HONO being produced by photolysis of particulate nitrate ($J(\text{NO}_3\text{-R}) \times \text{pNO}_3^-$) at this site in the next section. There was a logarithmic relationship showing good correlation between R_{unknown} (ppb·h⁻¹) and $J(\text{NO}_3\text{-R}) \times \text{pNO}_3^-$ ($\mu\text{g}\cdot\text{m}^{-3}\cdot\text{s}^{-1}$) in spring ($R^2 = 0.6348$), summer ($R^2 = 0.7266$), and autumn ($R^2 = 0.5041$) (Fig. 8). In conditions of relatively lower $J(\text{NO}_3\text{-R}) \times \text{pNO}_3^-$, R_{unknown} increased rapidly with increasing pNO_3^- concentration and its photolysis rate constant but reached a plateau after a critical value ($J(\text{NO}_3\text{-R}) \times \text{pNO}_3^- > 1 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{s}^{-1}$ in autumn, and $J(\text{NO}_3\text{-R}) \times \text{pNO}_3^- > 2 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{s}^{-1}$ in spring and summer). This indicated that in conditions that were relatively cleaner, the missing daytime source of HONO was limited by the pNO_3^- concentration and the photolysis rate constant. However, with severe haze or strong photolysis rate providing sufficient precursor or enough light to stimulate the reaction, the HONO production did not increase as $J(\text{NO}_3\text{-R}) \times \text{pNO}_3^-$ increased. It was found in a previous study (Scharcko et al., 2014) that NO_2 produced by NO_3^- photolysis in situ is more easily absorbed by acidic solutions than the original gaseous NO_2 . Therefore, we found the limiting factor for R_{unknown} to be the aerosol neutralization degree F in spring, summer, and autumn. Here, F was calculated from the equivalent concentrations of ammonium, sulfate, and nitrate (Wang et al., 2015) such that

$$F = [\text{NH}_4^+] / (2 \times [\text{SO}_4^{2-}] + [\text{NO}_3^-]). \quad (8)$$

Considering the acidity of aerosols, we found that R_{unknown} was limited when the aerosols were alkaline ($F > 1$). This field observation validates laboratory research on the release of HONO from photolysis of NO_3^- in acidic solutions (Scharcko et al., 2014).

We discuss whether photolysis of particulate nitrate is able to provide enough additional HONO by estimating the rate of HONO production by nitrate photolysis (Zhou et al., 2007; Li et al., 2012; Wang et al., 2017a) using

$$J_{\text{NO}_3^- \rightarrow \text{HONO}} = \frac{R_{\text{unknown}} \times H}{f \times [\text{NO}_3^-] \times v_{\text{NO}_3^-} \times t_d}, \quad (9)$$

where $J_{\text{NO}_3^- \rightarrow \text{HONO}}$ is the rate of photolysis of NO_3^- to form HONO, $v_{\text{NO}_3^-}$ is the dry deposition rate of NO_3^- during the period t_d , and f is the proportion of the surface exposed to the sun at midday. Here, we suppose that the surfaces involving NO_3^- were exposed to light by a factor $f = 1/4$, taking mixing height $H = 250 \text{ m}$, $v_{\text{NO}_3^-} = 5 \text{ cm}\cdot\text{s}^{-1}$ over $t_d = 24 \text{ h}$. We use the mean

value of $R_{\text{unknown}} = 2.36 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{h}^{-1}$ and $[\text{NO}_3^-] = 9.99 \mu\text{g}\cdot\text{m}^{-3}$ in spring; $R_{\text{unknown}} = 15.25 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{h}^{-1}$ and $[\text{NO}_3^-] = 2.44 \mu\text{g}\cdot\text{m}^{-3}$ in summer; and $R_{\text{unknown}} = 8.15 \mu\text{g}\cdot\text{m}^{-3}\cdot\text{h}^{-1}$ and $[\text{NO}_3^-] = 3.73 \mu\text{g}\cdot\text{m}^{-3}$ in autumn. The photolysis rates $J_{\text{NO}_3^- \rightarrow \text{HONO}}$ derived from Eq. (8) were $1.52 \times 10^{-5} \text{ s}^{-1}$, $4.02 \times 10^{-4} \text{ s}^{-1}$, and $1.40 \times 10^{-4} \text{ s}^{-1}$ for spring, summer, and autumn, respectively. These values are in the range 6.2×10^{-6} to 5.0×10^{-4} obtained in a previous study (Ye et al., 2017), which indicated that particulate nitrate photolysis was the main source in spring, summer, and autumn. The variability of $J_{\text{NO}_3^- \rightarrow \text{HONO}}$ may be caused by chemical composition, acidity, light-absorbing constituents, and the optical and other physical properties of aerosols.

3.5 Parameterization of HONO

Through an empirical parameterized formula, we can explore an accurate parameterization method for HONO, discuss the main control factors for the HONO concentration and its chemical behavior, and quantify its main sources and key kinetic parameters. As mentioned in Sect. 3.1, the HONO/ NO_x ratio is better than HONO/ NO_2 as an indicator of HONO generation. In another study (Elshorbany et al., 2012), data were collected from 15 field observations all over the world to establish the correlation between the HONO/ NO_x ratio and the HONO concentration in global models. Therefore, we applied this method in this study to parameterize the HONO concentration. As shown in Fig. 9, the HONO/ NO_x ratios in the four seasons were close to the calculated value (0.02). However, there were seasonal variations in the slope, showing a maximum in summer (2.60×10^{-2}), followed by autumn (2.06×10^{-2}), and a minimum in winter (1.59×10^{-2}). Except for in spring, HONO showed good correlation with NO_x , with R^2 values ranging from 0.8972 to 0.9621. Therefore, we used slopes of 2.60×10^{-2} , 2.06×10^{-2} , and 1.59×10^{-2} to parameterize the HONO concentrations in summer, autumn, and winter, respectively. As for spring, though only a weak correlation between HONO and NO_x was found, the majority of the HONO/ NO_x ratios fluctuated round a slope of 0.02 because concentrations of NO_x greater than 60 ppb only accounted for 8.83% of the data. Therefore, a slope of 0.02 was applied in spring to parameterize the HONO concentration.

As can be seen from Fig. 10, the estimated values are very close to the observed values in the nighttime in autumn. After sunrise and before noon, the values observed were higher than the estimated values, and this difference gradually increases. After noon and before sunset, the values observed were still higher than the values estimated, but the difference gradually decreases. This phenomenon was also found in the daytime in spring, summer and autumn, but not in winter. Compared with the daytime, the estimated values during the nighttime were closer to the observed values in both trend and value in all four seasons, which further demonstrates that nighttime HONO is mainly produced from the heterogeneous reaction of NO_2 on the ground and the surfaces of aerosols. Therefore, we should pay much more attention to simulation in the daytime. We distinguish two main sectors, nighttime and daytime, to analyze the factors affecting the HONO diurnal variation (Liu, 2017). Although $J(\text{HONO})\times\text{HONO}$ also correlated well with $J(\text{NO}_2)\times\text{NO}_2$ in all four seasons in this study and the linear fitting coefficients fluctuated around 0.01 in all four seasons (Fig. S2), bad simulation results during the daytime were found (Fig. S3) using

$$[\text{HONO}] = 0.01 \times [\text{NO}_2] \times J(\text{NO}_2) / J(\text{HONO}). \quad (10)$$

395 In contrast, excellent simulation results were found in a previous study using the same formula (Liu, 2017), which suggests that using the same simulation formula in different regions may obtain greatly varying results.

As discussed in Sect. 3.4.3, nitrate photolysis is the main source of HONO in spring, summer, and autumn during the daytime, while the homogeneous gas-phase reaction of NO and OH is the major source of daytime HONO in winter. Therefore, we take the photolysis of nitrate into the spring, summer, and autumn calculations, but we use the reaction of NO and OH in the
400 calculations for winter. In this way, the daytime simulation results are significantly improved (Fig. 10). This further demonstrates that the apportionment of HONO sources is credible.

3.6 Comparison of contributions of HONO and O₃ to OH radicals

Comparing the OH radical production via photolysis of HONO and O₃, the effect of the high HONO concentrations in the daytime on the tropospheric oxidation capacity was evaluated (Ryan et al., 2018). Nitrous acid is considered to be a crucial
405 source of OH radicals (Lee et al., 2016). As shown in Eq. (11), OH production rates from O₃ photolysis ($P_{OH(O_3)}$) were calculated based on [O₃], $J(O^1D)$, and [H₂O] (Liu et al., 2019c). Only O(¹D) atoms produced by the O₃ photolysis at UV wavelengths less than 320 nm (Reaction (R5)) can combine with water to generate OH radicals (Reaction (R6)) in the atmosphere. The absolute water concentration was derived from temperature and RH. The reaction (R7) rates for N₂ is $3.1 \times 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ and for O₂ is $4.0 \times 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$. The net OH formation from HONO was estimated
410 by Eq. (12) (Su et al., 2008b; Sörgel et al., 2011; Li et al., 2018; Atkinson et al., 2004).

$$P_{OH(O_3)} = 2J(O^1D)[O_3]\phi_{OH}, \quad \phi_{OH} = k_6[H_2O]/(k_6[H_2O] + k_7[M]) \quad (11)$$

$$415 \quad P_{OH(HONO)} = J_{HONO}[HONO] - k_{OH+NO}[NO][OH] - k_{OH+HONO}[HONO][OH] \quad (12)$$

The diurnal patterns of $P(OH)$ are shown in Fig. 11. The formation rates of OH from O₃ photolysis peaked in midday at around 0.71 ppb·h⁻¹, 5.80 ppb·h⁻¹, 2.21 ppb·h⁻¹, and 0.48 ppb·h⁻¹ for spring, summer, autumn, and winter, respectively. The variation of $P_{OH(O_3)}$ is consistent with $J(O^1D)$ (Fig. S4), peaking in midday and in summer on a diurnal and a seasonal timescale, respectively. For summer and autumn, $P_{OH(HONO)}$ had a similar trend as $P_{OH(O_3)}$, peaking at around noon at the time of the
420 highest $J(HONO)$, but this was negligible at sunrise and sunset (Fig. S5). For spring and winter, however, $P_{OH(HONO)}$ reached a maximum in the morning rush hour caused by the combined influences of high HONO concentration and high $J(HONO)$. A similar result was also found in southwest Spain from mid-November to mid-December 2008 (Sörgel et al., 2011). These results show that HONO contributes considerably to the morning atmospheric oxidizing capacity of the suburban atmosphere of Xiamen. Although HONO concentrations (average: 0.66 ppb) are much lower than O₃ concentrations (average: 32.02 ppb)

425 during 07:00–16:00 LT, daytime HONO photolysis forms significantly more OH than daytime photolysis of O₃ in all four
seasons. Generally, the mean value of $P_{\text{OH}}(\text{HONO})$ from 07:00 to 16:00 LT was 4.31 ppb·h⁻¹, and the average $P_{\text{OH}}(\text{O}_3)$ was
1.14 ppb·h⁻¹. This indicates that HONO concentrations at 0.66 ppb during 07:00–16:00 LT increase the formation of OH
radicals by an order of magnitude, greatly increasing the local daytime tropospheric oxidative capacity. A similar result was
found in Melbourne, where the peak OH production rate reached 2 ppb·h⁻¹ from 0.4 ppb HONO (Ryan et al., 2018). The
430 important role of HONO in the production of OH promotes photochemical peroxyacetyl nitrate formation (Hu et al., 2020).

4. Conclusions

We conducted measurements of HONO in the atmosphere at an IUE supersite in a coastal city of southeastern China in August,
October, and December 2018 and March 2019, finding an average HONO concentration of 0.54 ± 0.47 ppb across the whole
observation period. Concentrations of HONO in spring and summer were higher than in winter and autumn, which was
435 consistent with seasonal variations in RH. Both higher HONO concentrations in the daytime and the HONO/NO_x ratio peaking
around noon suggested that additional, unknown sources of HONO might be related to light. It was found that the contribution
from vehicle exhaust emissions (1.64%) was higher than that found in most other studies due to the site being surrounded by
several expressways with a large number of passing diesel vehicles. The average nocturnal conversion rate of NO₂ to HONO
was 0.47% h⁻¹, which was within the range 0.29–2.40% h⁻¹ found by other studies. The HONO_{corr}/NO₂ ratio increased with
440 RH and the concentration of PM_{2.5} during the nighttime, which indicates that nocturnal heterogeneous reactions on the surfaces
of aerosols are the major source of HONO. However, dark heterogeneous formation (P_{hete}) was almost negligible in the daytime,
accounting for approximately 5.07% of known sources across the whole observation period. Observed values in the daytime
were up to 50 times higher than those calculated from the PSS, suggesting that there were a large number of daytime sources
of HONO. The highest proportion of all sources was $R_{\text{OH}+\text{NO}}$ in winter (56.15%), while R_{unknown} made up at the largest
445 proportion of all sources in summer (84.92%), autumn (80.29%), and spring (49.98%). It was found that there was a logarithmic
relationship between R_{unknown} and particulate nitrate photolysis, and the limiting factor was particulate acidity in spring, summer,
and autumn. The variation of HONO at night can be accurately simulated based on the HONO/NO_x ratio, while the main
sources should be considered for daytime simulation. Local tropospheric oxidation capacity was significantly increased by
HONO during 07:00–16:00, providing an OH radical source (4.31 ppb·h⁻¹) an order of magnitude greater than its concentration
450 (0.66 ppb).

Data availability.

Measurement data at the IUE station, including HONO data and relevant trace gases and aerosol data as well as meteorological
data, are available upon request from the corresponding author before the IUE database is open to the public.

Figure 1: Maps showing the position of Xiamen in China (left) and the position of the IUE supersite in Xiamen (right).

650 **Figure 2:** Diurnal variations in (a) HONO, (b) NO_x, (c) HONO/NO_x, and (d) $J(\text{NO}_2)$. The gray shading indicates nighttime (18:00–06:00, including 18:00).

Figure 3: Scatter plots of NO₂ versus HONO color coded by $J(\text{NO}_2)$. The three dashed lines represent 10%, 5%, and 1% ratios of HONO/NO₂. Daytime was 06:00–18:00 LT, including 06:00.

Figure 4: Scatter plots of nighttime HONO_{corr}/NO₂ ratios versus RH. The average top-five HONO_{corr}/NO₂ in every 5% RH interval are shown as orange squares, and the error bars show ± 1 SD.

655 **Figure 5:** The correlation between PM_{2.5} and HONO_{corr} (left) and the correlation between PM_{2.5} and HONO_{corr}/NO₂ (right). The squares depict PM_{2.5} $\geq 35 \mu\text{g}\cdot\text{m}^{-3}$; all scattered points are from the time when the ratio of HONO_{corr}/NO₂ reached a pseudo-steady state each night (03:00–06:00 LT).

Figure 6: Average diurnal variations of HONO concentrations observed (solid markers/lines) and HONO_{PSS} calculated by Eq. (1) (hollow markers and dashed lines).

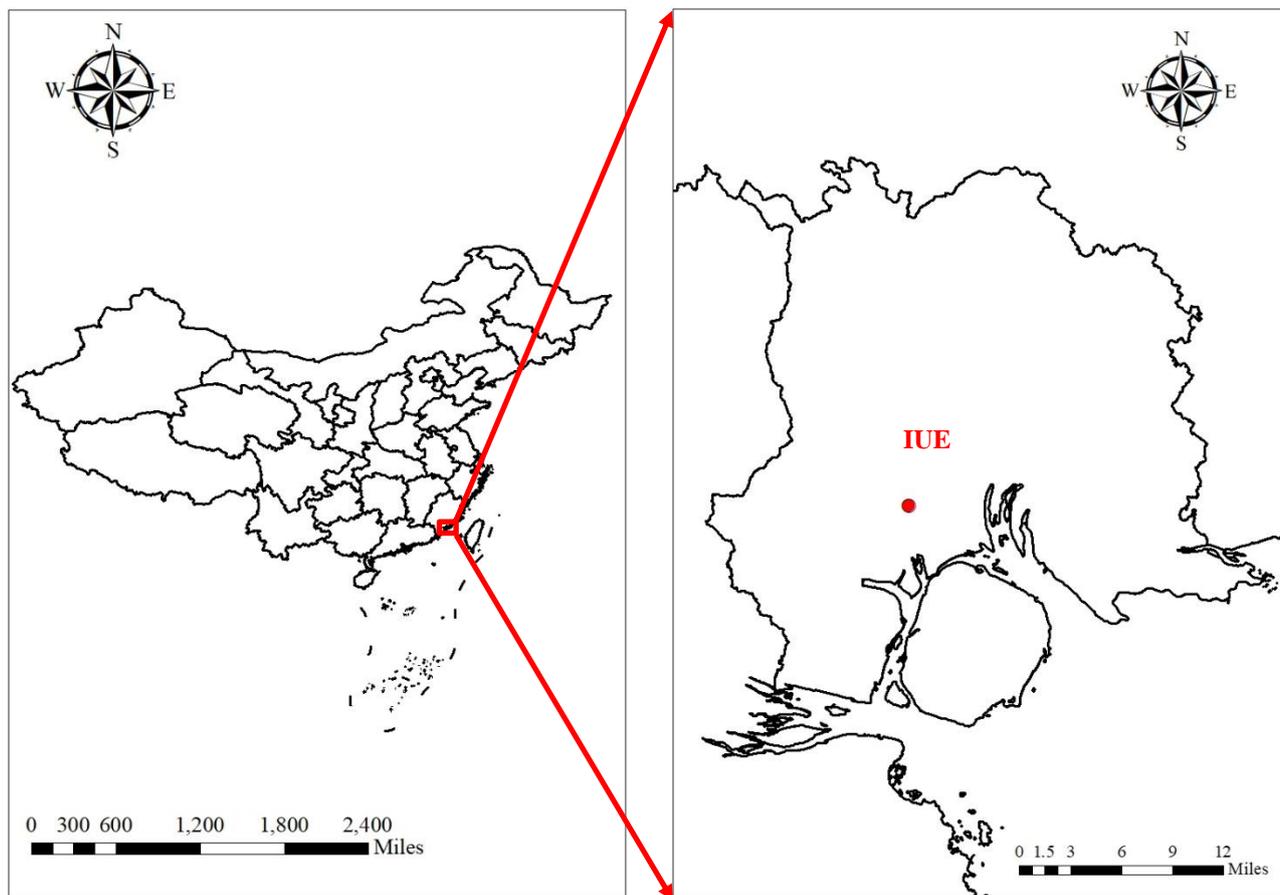

660 **Figure 7:** Average diurnal variations of each source (>0) and sink (<0) of HONO in the four seasons.

Figure 8: Relationships between the photolysis of particulate nitrate and R_{unknown} , colored by F in spring, summer, and autumn.

Figure 9: The ratio of HONO/NO_x in the four seasons (correlation between the average of NO_x per 10 ppb interval and the average value of HONO).

665 **Figure 10:** The diurnal variations in the measured values of HONO (black squares), the estimated values of HONO using the parameterized formula (red circles), and the estimated values of HONO using the parameterized formula combined with the main daytime sources (green triangles).

Figure 11: Comparison of OH formation by photolysis of HONO and O₃ in the four seasons.

670 **Figure 1:** Maps showing the position of Xiamen in China (left) and the position of the IUE supersite in Xiamen (right).

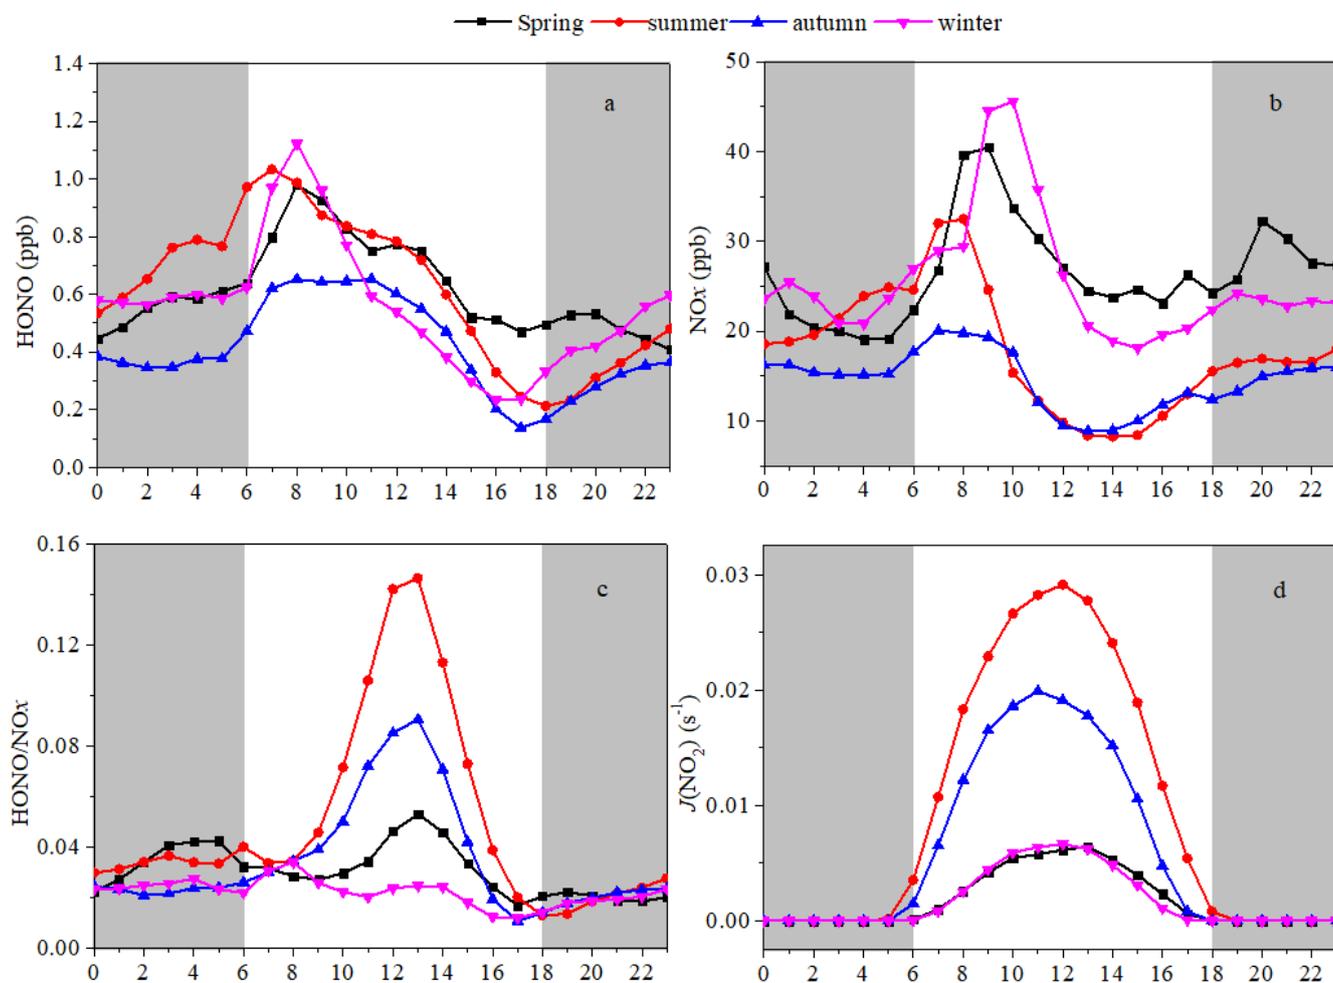

Figure 2: Diurnal variations in (a) HONO, (b) NO_x, (c) HONO/NO_x, and (d) $J(\text{NO}_2)$. The gray shading indicates nighttime (18:00–06:00, including 18:00).

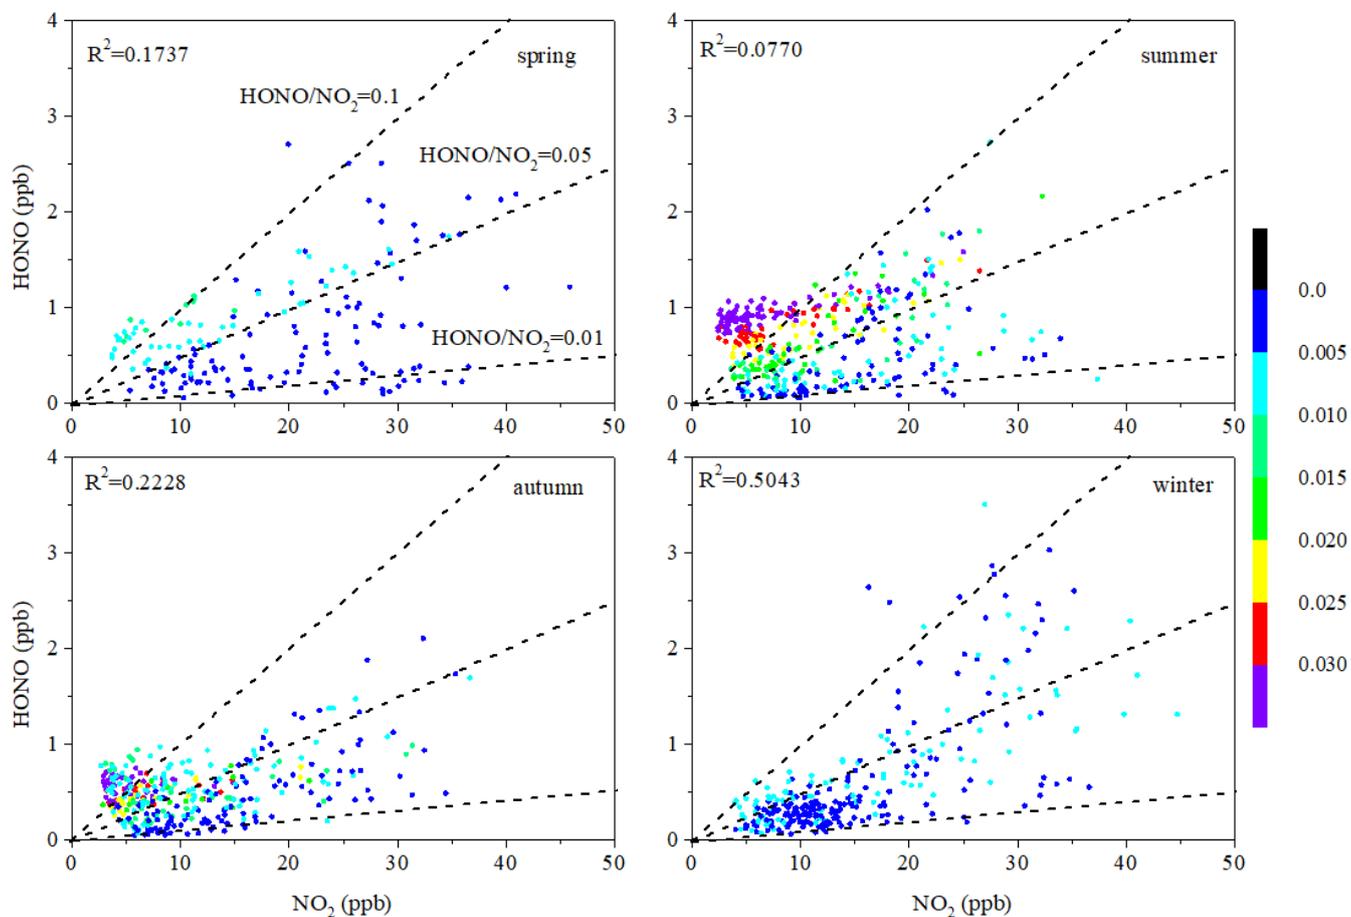

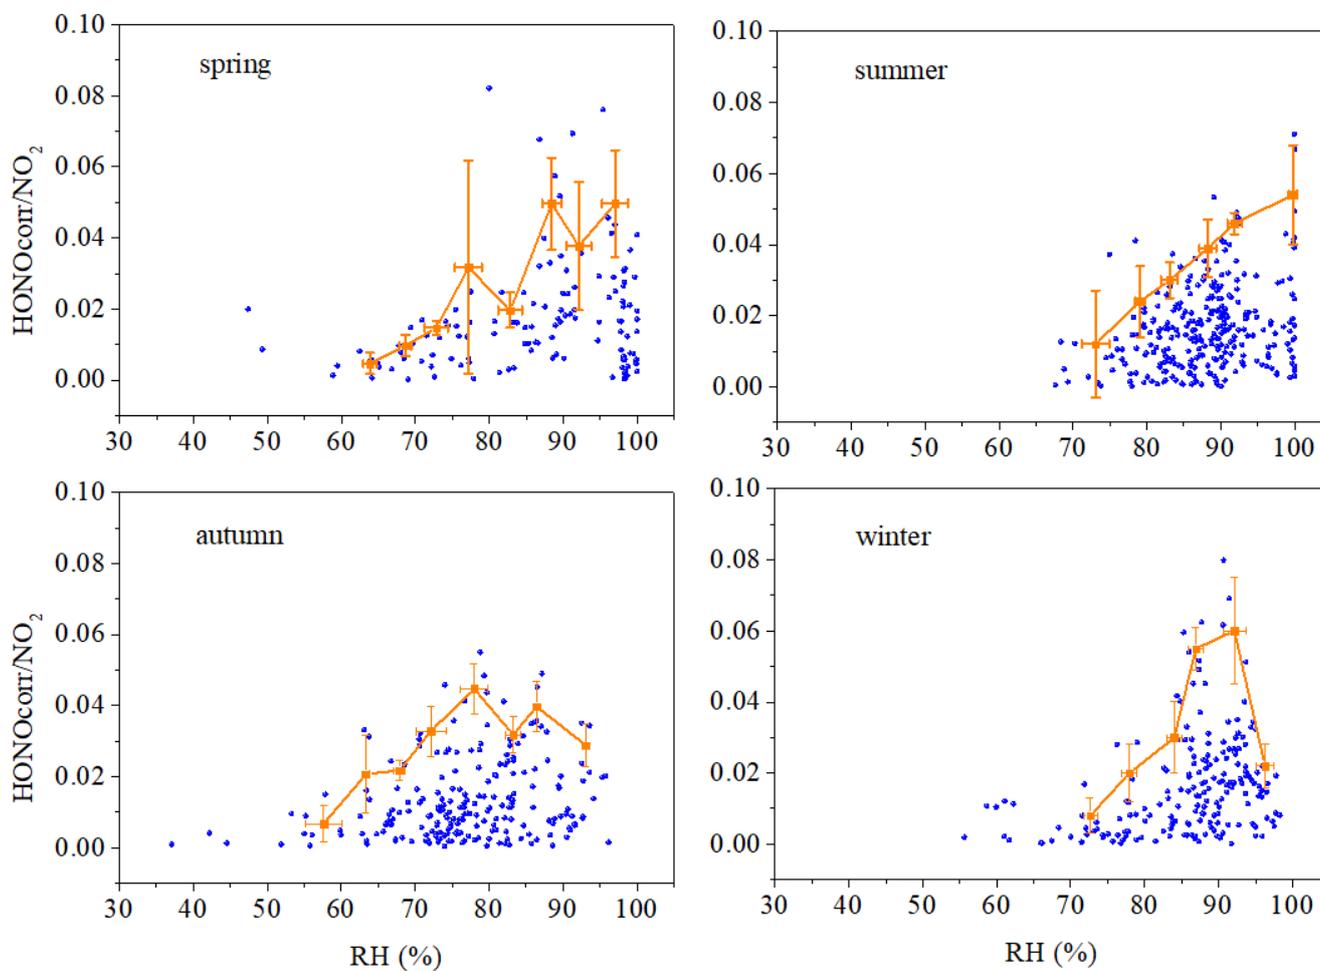

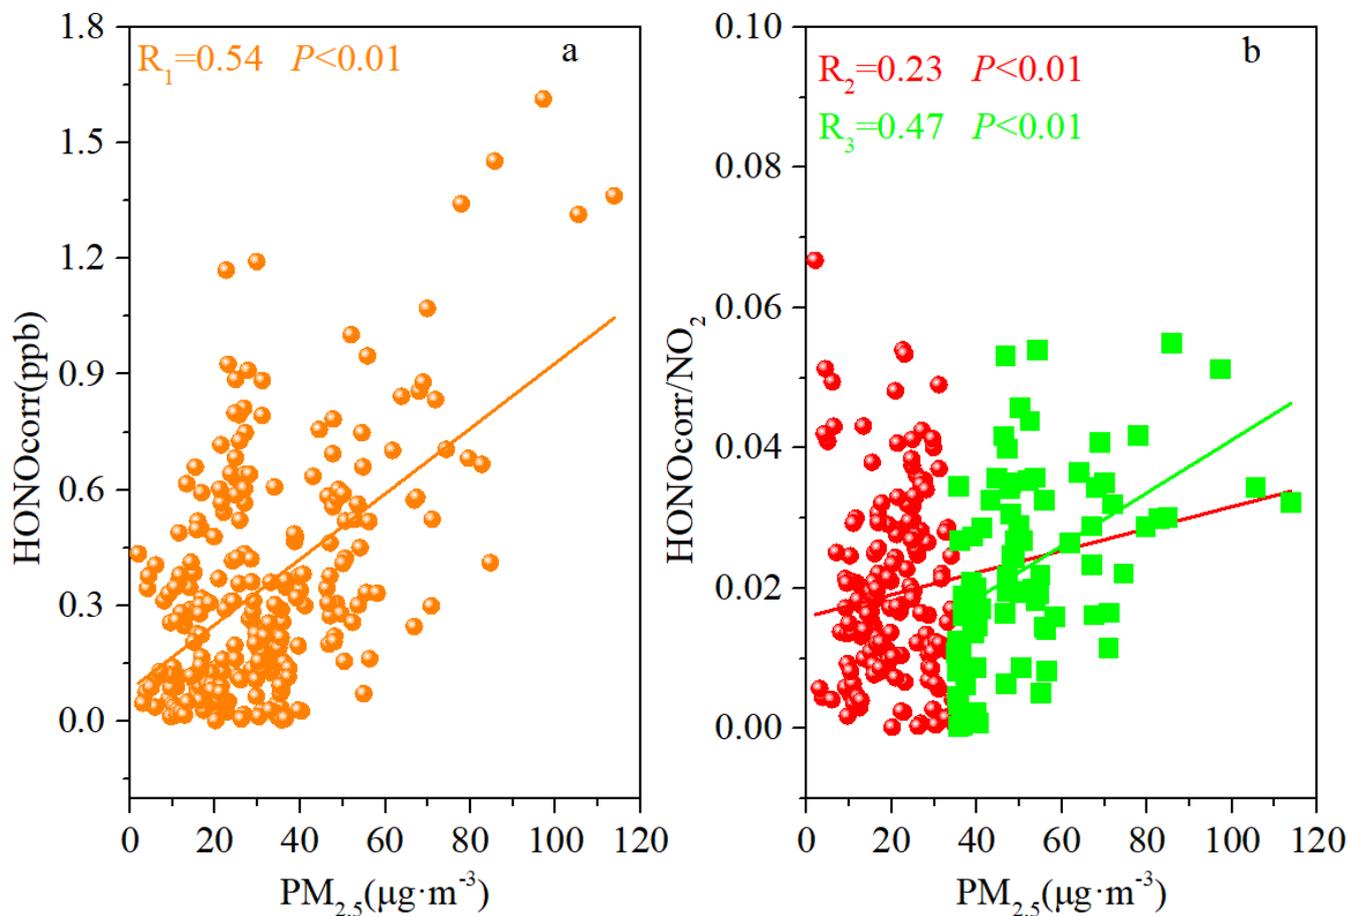

Figure 3: Scatter plots of NO₂ versus HONO color coded by $J(\text{NO}_2)$. The three dashed lines represent 10%, 5%, and 1% ratios of HONO/NO₂. Daytime was 06:00–18:00 LT, including 06:00.

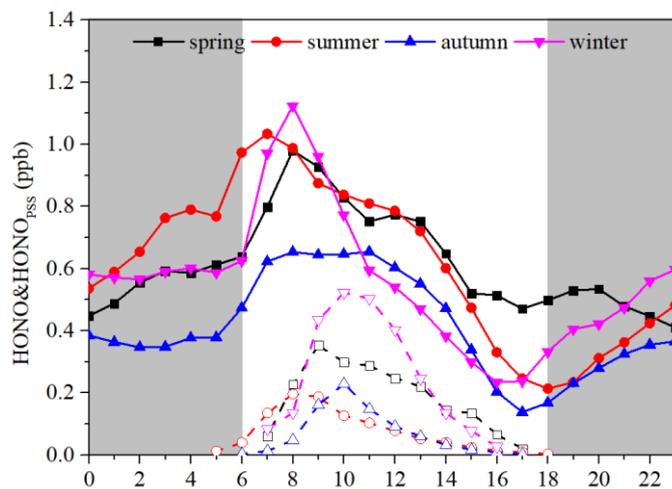

680

Figure 4: Scatter plots of nighttime HONO_{corr}/NO₂ ratios versus RH. The average top-five HONO_{corr}/NO₂ in every 5% RH interval are shown as orange squares, and the error bars show ±1 SD.

685 **Figure 5:** The correlation between $\text{PM}_{2.5}$ and $\text{HONO}_{\text{corr}}$ (left) and the correlation between $\text{PM}_{2.5}$ and $\text{HONO}_{\text{corr}}/\text{NO}_2$ (right). The squares depict $\text{PM}_{2.5} \geq 35 \mu\text{g}\cdot\text{m}^{-3}$; all scattered points are from the time when the ratio of $\text{HONO}_{\text{corr}}/\text{NO}_2$ reached a pseudo-steady state each night (03:00–06:00 LT).

690 **Figure 6:** Average diurnal variations of HONO concentrations observed (solid markers/lines) and HONO_{PSS} calculated by Eq. (1) (hollow markers and dashed lines).

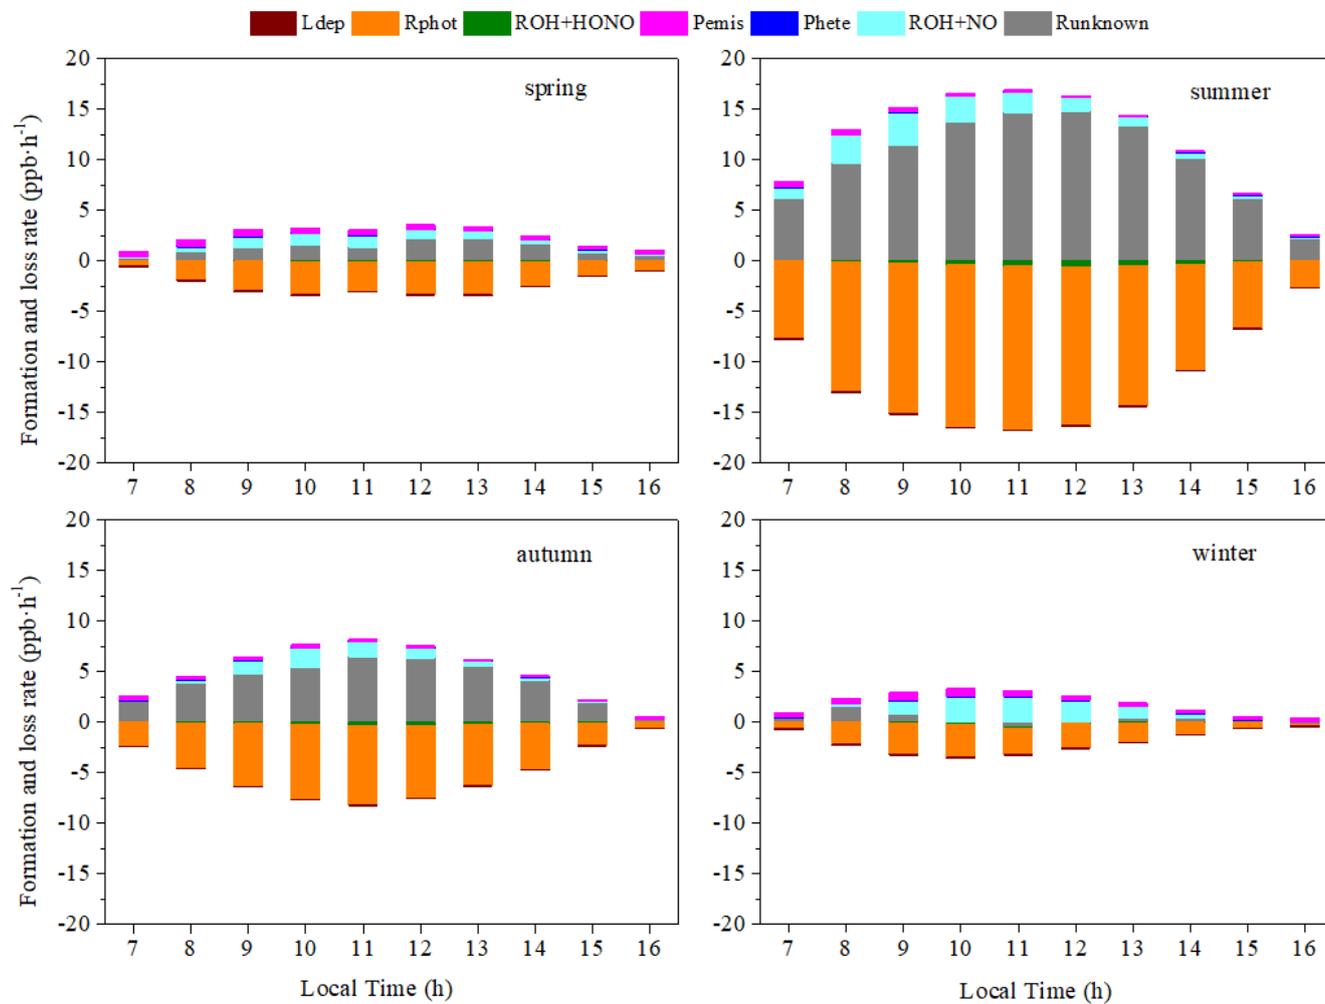

Figure 7: Average diurnal variations of each source (>0) and sink (<0) of HONO in the four seasons.

695

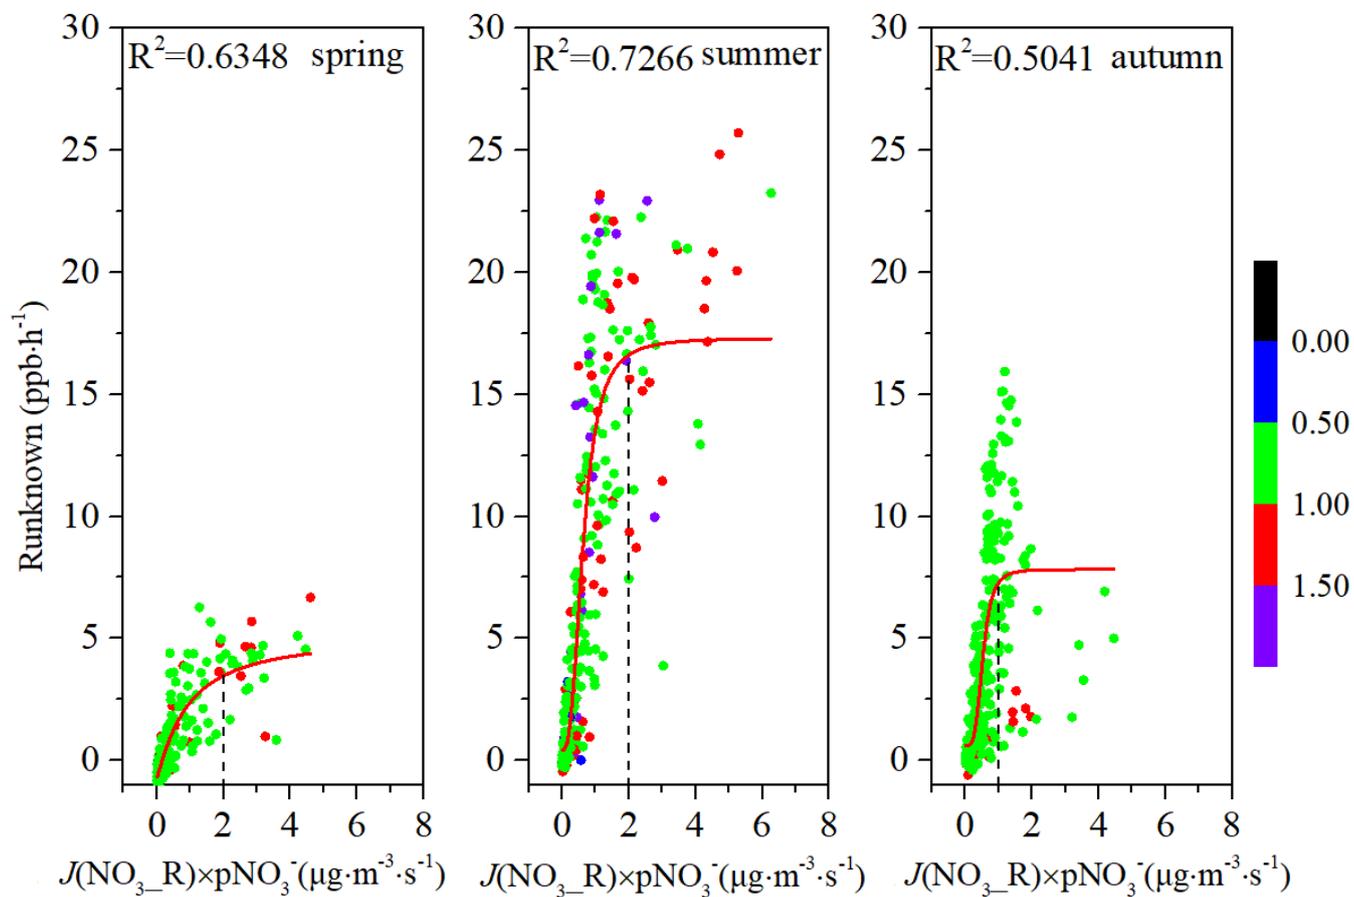

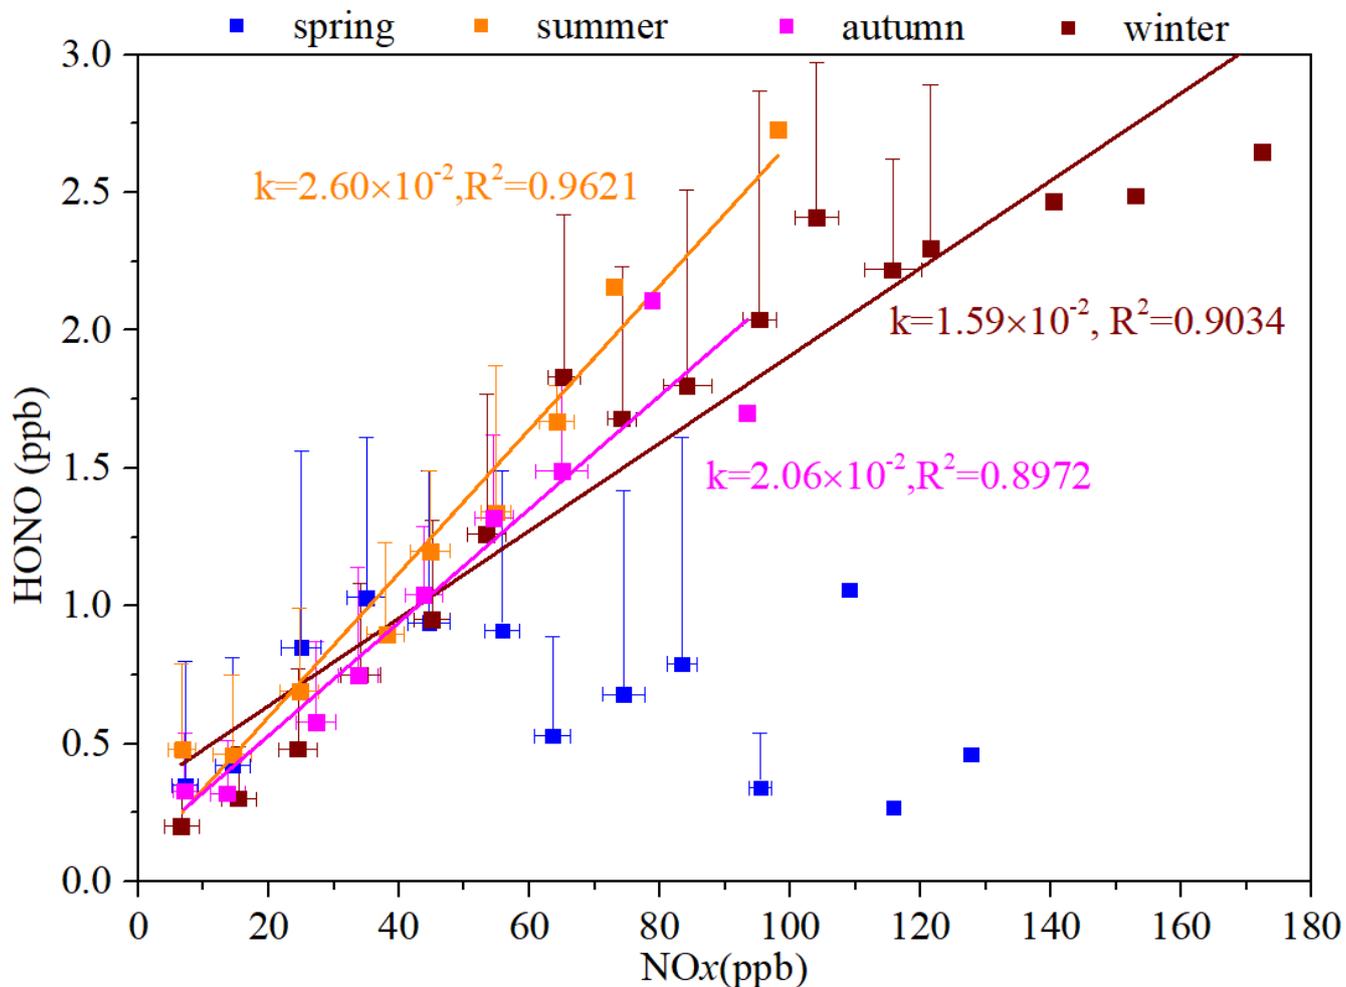

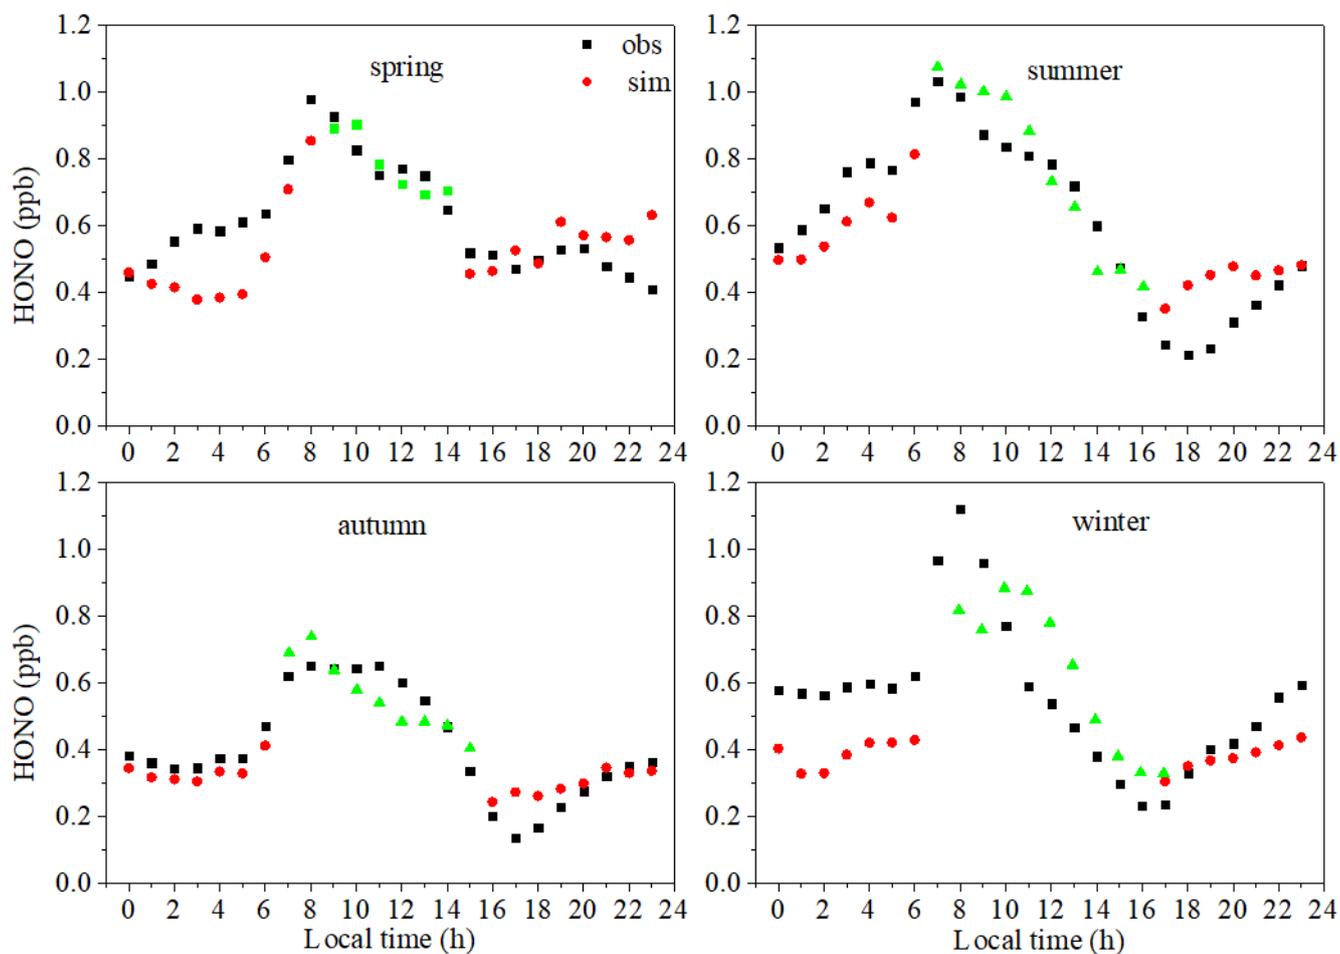

Figure 8: Relationships between the photolysis of particulate nitrate and R_{unknown} , colored by F in spring, summer, and autumn.

700 Figure 9: The ratio of HONO/NO_x in the four seasons (correlation between the average of NO_x per 10 ppb interval and the average value of HONO).

705 **Figure 10:** The diurnal variations in the measured values of HONO (black squares), the estimated values of HONO using the parameterized formula (red circles), and the estimated values of HONO using the parameterized formula combined with the main daytime sources (green triangles).

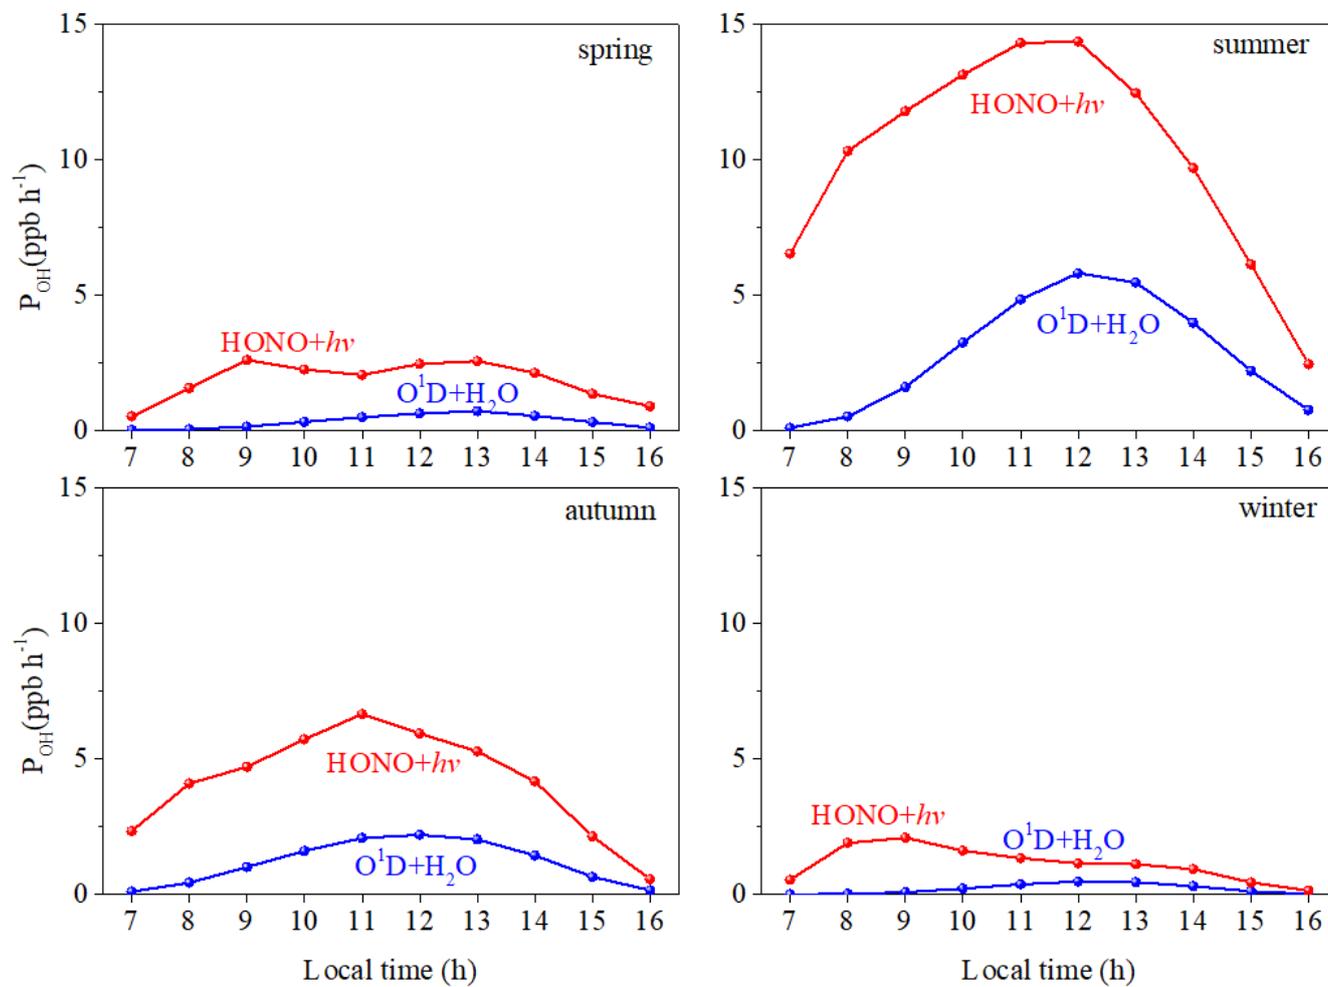

Figure 11: Comparison of OH formation by photolysis of HONO and O_3 in the four seasons.

Note: Night (18:00-6:00, including 18:00, local time); Day (6:00-18:00, including 6:00, local time)

NO_x=NO₂ (IBBCEAS)+NO (Thermal 42i). IBBCEAS measure both HONO and NO₂. The NO₂ concentration is always overestimated by the Thermo Fisher 42i.

Table 2. Emission ratios of fresh vehicle plumes $\Delta\text{HONO}/\Delta\text{NO}_x$.
