Abstract. The size of aerosol particles has fundamental effects on their chemistry and radiative effects. We explore those effects using aerosol size and composition data in the lowermost stratosphere along with calculations of light scattering. In the size range between about 0.1 and 1.0 μm diameter (accumulation mode), there are at least two modes of particles in the lowermost stratosphere. The larger mode consists mostly of particles produced in the stratosphere and the smaller mode consists mostly of particles transported from the troposphere. The stratospheric mode is similar in the Northern and Southern hemispheres whereas the tropospheric mode is much more abundant in the Northern Hemisphere. The two modes have very different roles for radiative effects on climate and for heterogeneous chemistry. Because the larger particles are more efficient at scattering light, most of the radiative effect in the lowermost stratosphere is due to stratospheric particles. In contrast, the tropospheric particles can have more surface area, at least in the Northern Hemisphere. The surface area of tropospheric particles could have significant implications for heterogeneous chemistry because these particles, which are partially neutralized and contain organics, do not correspond to the surfaces used for laboratory studies of stratospheric heterogeneous chemistry. The purity of sulfuric acid particles in the stratospheric mode shows that there is limited production of secondary organic aerosol in the stratosphere, especially in the Southern Hemisphere. Out of eight sets of flights sampling the lowermost stratosphere (four seasons and two hemispheres) there were three with large injections of specific materials: volcanic, biomass burning, or dust. We then extend the analysis of size-dependent properties to particles considered for intentional climate modification. There is no single size that will simultaneously optimize the climate impact relative to the injected mass, infrared heating, potential for heterogeneous chemistry, and undesired changes in direct sunlight. In addition, light absorption in the far ultraviolet is identified as an issue requiring more study for both the existing and potentially modified stratosphere.

1 Introduction

30 Stratospheric particles have been studied for over 50 years (Junge and Manson, 1961; reviewed by Kremser et al., 2016). The stratospheric aerosol layer has a maximum in mixing ratio between about 20 and 25 km altitude. However, the larger air density

at lower altitudes means that the majority of the mass of stratospheric aerosol is in the lowermost stratosphere, below the maximum in mixing ratio (Yu et al., 2016).

35 Various trends have been reported for the background stratospheric aerosol at times not influenced by major volcanic eruptions. Deshler et al. (2006) concluded there was little long-term change in background stratospheric aerosol from 1971 to 2004. Hofmann et al. (2009) found an increasing trend after 2000, and Friberg et al. (2014) found an increasing trend from 1999 to 2008. There has been recognition that moderate volcanic eruptions frequently influence the stratospheric aerosol and true nonvolcanic “background” concentrations are not necessarily present just because there has been no Pinatubo-scale eruption
40 (Solomon et al., 1996, Vernier et al. 2011). Different altitudes may exhibit different trends (Khaykin et al., 2017). Moderate volcanic eruptions tend to mask trends in the non-volcanic background (Kremser et al., 2016). The data shown here reinforce the notion of modest but frequent perturbations to the lower stratosphere.

The overall circulation of air in the stratosphere, with rising air in the tropics and descending air in the extratropics, is mostly
45 fed by air entering at the tropical tropopause. The lowermost stratosphere is a region at middle and high latitudes between the local tropopause and slightly above the altitude of the tropical tropopause. Air in this lowermost stratosphere is affected by both downward motion in the extratropical stratosphere and adiabatic mixing with the troposphere (Holton et al., 1995). The tropospheric influence can extend as high as about 450 K potential temperature (Rosenlof et al., 1997). All of the data described here are in the lowermost stratosphere and show the influence of both air from higher in the stratosphere and air from the
50 troposphere.

The chemical composition of particles in the lower stratosphere has been measured by several techniques. Impactor samples collected from the CARIBIC platform have been quantitatively analyzed for N, O, S, K, Fe, and other elements (Nguyen and Martinsson, 2007; Friberg et al, 2014). The moles of oxygen were approximately four times sulfur plus about 0.2 times carbon,
55 indicating SO₄ in sulfate and sulfuric acid plus some contribution from oxygenated organics. Much of the detailed information on the chemical composition of aerosols in the lower stratosphere has come from the Particle Analysis by Laser Mass Spectrometry (PALMS) instrument (Murphy et al., 1998). These data show that most particles larger than about 110 nm fall into three distinct types: sulfuric acid with or without meteoric metals and mixed organic-sulfate particles from the troposphere (Murphy et al., 2014). Because the pure sulfuric acid particles do not contain biomass burning residues, they are not simply
60 tropospheric particles that have lost organics after entering the stratosphere (Murphy et al., 2007). Recent data from another single particle mass spectrometer have found comparable abundances of sulfuric acid particles with meteoric metals (Schneider et al. discussion).

We extend the previous results to show that the mixed organic-sulfate particles from the troposphere are generally smaller than
65 both types of sulfuric acid particles. We then show how this size difference has significant implications for light scattering and
heterogeneous chemistry.

2 Methods

70 This paper includes data in the lowermost stratosphere from the Atmospheric Tomography (ATom) mission with deployments
in four seasons during 2016 to 2018. Although the ATom mission was not specifically designed to sample the stratosphere, it
encountered stratospheric air in both the Northern and Southern Hemispheres during its regular vertical profiles. Stratospheric
air was encountered periodically at altitudes greater than 8 km and latitudes poleward of 30 degrees north or 40 degrees south
(Figure S1). Because the NASA DC8 aircraft has a ceiling of about 12 km, stratospheric air was always associated with low
75 tropopauses, sometimes in tropopause folds. We therefore use ozone rather than altitude as the primary definition of how far
into the stratosphere measurements were taken. Any high ozone below 6 km altitude was excluded.

Size distributions for accumulation-mode particles were measured using two modified commercial laser optical particle
spectrometers, an ultra-high sensitivity aerosol spectrometer (UHSAS; Droplet Measurement Technologies, Longmont, USA)
80 from 0.07 - 0.6 μm diameter and a laser aerosol spectrometer (LAS, TSI Inc., St. Paul, USA) from 0.6 to ~ 4.8 μm diameter
(Kupc et al., 2018; Brock et al., 2019). The diameters are based on calibration by ammonium sulfate particles. The size
resolution of the reported data is 20 bins per decade of particle size. Data are recorded at 1s intervals although averaging is
needed in the stratosphere to improve counting statistics for particles in the LAS size range (Brock et al., 2019).

85 Particle composition was measured with the Particle Analysis by Laser Mass Spectrometry (PALMS) instrument (Thomson
et al., 2000; Froyd et al. 2019). A pressure-controlled aerodynamic focusing inlet brings particles into a vacuum where they
cross two continuous laser beams. The transit time between the beams measures the aerodynamic diameter of each particle.
The aerodynamic diameters are under vacuum conditions with most particles much smaller than the mean free path at the inlet
exhaust; however transition flow corrections are considered. Transit times were calibrated to known particle sizes before and
90 after every field deployment. A 193 nm pulse from an excimer laser is triggered when a particle arrives at the second laser
beam. Either positive or negative ions are analyzed with a time-of-flight mass spectrometer. The polarity was switched every
few minutes. Most of the data shown here are from positive ion spectra. Negative ion spectra do not distinguish sulfuric acid
with and without meteoric metals because the metal ions only appear in the positive ion spectra.

95 The optical size distributions are combined with the PALMS single-particle composition data for particles larger than 100 nm
to create size distributions that are resolved by composition. This requires converting the PALMS aerodynamic diameters to
correspond to the optical diameters (Froyd et al., 2019). The composition-resolved size distributions presented here use wider

size bins than the native optical particle counter resolution but narrower size bins than the standard ATom products (Froyd et al., 2019). The narrower bins are possible because of improved statistics after averaging over all of the data within a specific band of ozone and latitude, even if those data were not contiguous in time.

For the purpose of this study particles are classified into four basic categories: sulfuric acid with and without meteoric metals, mixed organic-sulfate particles, and other particles including dust. Example spectra are shown in Murphy et al. (2014). When appropriate further distinctions can be made, such as separating biomass burning particles from other mixed organic-sulfate particles.

Calculations of light scattered back to outer space are made for an optically thin layer uniformly spread over a sunlit hemisphere as described in Murphy (2009), except that these calculations use an atmospheric transmittance appropriate for approximately 11 km altitude (Arvesen, 1969). Changing the solar spectrum over the entire range from top-of-atmosphere to surface gives qualitatively similar results. At the low relative humidities in the stratosphere, water uptake is less important for optical properties than it is in the troposphere. The mean relative humidity for the ATom data at ozone > 250 ppbv was less than 10%.

A sectional aerosol model (CARMA) coupled with the NSF/DOE Community Earth System Model (CESM) is used in the study to simulate the composition and size distributions of stratospheric aerosols (Yu et al., 2015; Toon et al., 1988). CESM-CARMA tracks two external-mixed groups of aerosols. The first group consists of pure sulfate particles (formed through nucleation and condensation of water vapor and sulfuric acid) with 20 size bins ranging from 0.4 nm to 2.6 μm in diameter; the second group consists of internal mixed aerosols (containing condensed sulfate, organics, black carbon, salt and dust) with 20 size bins from 0.1 μm to 17 μm . The model is run at a horizontal resolution of 1.9° (latitude) x 2.5° (longitude). It has 56 vertical layers from the surface to 1.8 hPa with a vertical resolution of ~1 km near tropopause.

3 Composition-resolved size distributions in the stratosphere

Figure 1 shows the composition-resolved size distributions measured in the lowermost stratosphere for the four ATom deployments, separated by the Northern and Southern Hemisphere. The data are for ozone between 250 and 400 ppbv. This range of ozone is chosen to be definitely in stratospheric air and to include data from both hemispheres on all four deployments. On each panel the thick black line is the size distribution from the optical particle counters. At each size the fraction of particle types from PALMS is shaded. A number of features in Figure 1 are worthy of comment.

The volume distributions show a peak near 400 nm diameter and another peak, or at least a shoulder, near 180 or 200 nm. These sizes are both within what is considered the accumulation mode. The composition reveals why there are two modes.

Indeed, without the composition it would be difficult to be sure that there were two separate modes. For example, the Wyoming particle counters used on stratospheric balloon flights (Deshler et al., 2003) do not clearly resolve the modes.

135 The 400-nm mode is from sulfuric acid particles produced in the stratosphere, especially those with meteoric metals. The size
of these meteoric-sulfuric particles is extremely consistent through both hemisphere and the four deployments (Table 1). The
primary source of sulfuric acid in the stratosphere, oxidation of carbonyl sulfide, is similar in the two hemispheres. The
meteoric-sulfuric particles also have a narrow size distribution, with a typical geometric standard deviation of about 1.4 when
fit with a log-normal distribution. This is consistent with condensational growth, which tends to lead to narrow size
distributions. Sulfuric acid particles without meteoric material have more diverse sizes except for the volcanically influenced
140 ATom1 Southern Hemisphere, when the sulfuric acid particles had a narrow size distribution very similar to the meteoric-
sulfuric particles.

The smaller mode near 200 nm is from mixed organic-sulfate particles that have mixed into the stratosphere. The mass spectra
of particles in the smaller mode are essentially identical to those of particles in the upper troposphere. Comparing the Northern
and Southern Hemispheres in Figure 1, the concentration of the smaller mode is larger in the Northern Hemisphere. The upper
145 troposphere in the Southern Hemisphere has generally lower aerosol concentrations, so mixing in a given amount of
tropospheric air will bring in fewer particles than the same amount of mixing in the Northern Hemisphere.

Of the eight cases in Figure 1, three have much higher aerosol concentrations than the others, for three very different reasons.
150 The ATom1 Southern Hemisphere had a large and very narrow mode of pure sulfuric acid particles. These were most likely
produced from SO₂ injected into the stratosphere by the Calbuco eruption in April 2015, about 16 months before the
measurements. The ATom3 Northern Hemisphere had a large tropospheric organic-sulfate contribution. More detailed
composition shows that these included a large fraction of biomass burning particles. A separate paper is in preparation about
this event. The ATom4 Northern Hemisphere had both a large contribution from organic-sulfate particles and a remarkable
155 amount of dust at and above the tropopause. Concentrations at the tropopause often reached several micrograms per standard
cubic meter. The dust was very widespread: it was measured over both the north Atlantic and Pacific Oceans over more than
40 degrees of latitude. This may be Asian dust and pollution carried to high altitude in an event similar to that described by
Huang et al. (2008). The ATom4 and Huang et al. events were both in May. A separate paper is also planned about this dust
event.

160 Figure 2 shows the CESM/CARMA model results for the ATom2 flights for the same 250-400 ppbv range of ozone as the
data in Figure 1. ATom2 is chosen because neither hemisphere was perturbed by volcanic sulfate, biomass burning, or dust.
The model reproduces the tropospheric mode well in the Northern Hemisphere but overestimates it in the Southern
Hemisphere. The model reproduces the total volume of stratospheric particles well in both hemispheres but the modeled

165 diameter of these particles is too small. A possible reason is that the model does not include meteoric smoke particles on which
sulfuric acid can condense. That is, the model treats both the meteoric-sulfuric and sulfuric acid particles observed by PALMS
as a single type. Figure S2 compares the Northern Hemisphere ATom data to Wilson et al. (2008). Consistent with the ATom
observations, the tropospheric particle mode at about 200 nm is in some cases distinct from the larger stratospheric mode.

170 Figure 3 shows composition-resolved size distributions further into the stratosphere with ozone between 500 and 850 ppbv.
Only the Northern Hemisphere during ATom2 and ATom4 had significant amounts of PALMS data in this ozone range. For
ATom2, the primary difference at higher ozone was more meteoric-sulfuric particles, a result also found by Schneider et al.
(discussion). The large mixing event of dust and other tropospheric particles during ATom2 barely affected “altitudes” of more
than 500 ppbv ozone.

175

4 Vertical profiles

The shaded regions in Figure 1 can be integrated over all sizes to give the volume associated with each type of particle, then
multiplied by a density to give the mass. Figure 4 shows vertical profiles of the mass concentrations for the meteoric sulfuric
180 particles and organic-sulfate particles. As expected for their sources, the concentration of meteoric-sulfuric particles increases
with altitude and the concentration of organic-sulfate particles decreases with altitude. The concentration of the meteoric-
sulfuric particles is fairly consistent between hemispheres and deployments. In contrast, the concentration of organic-sulfate
particles was larger in the Northern Hemisphere than the Southern Hemisphere and varied considerably between deployments.
It is worth noting that the highest concentration of tropospheric particles in each hemisphere, ATom3 for the Southern
185 Hemisphere and ATom4 for the Northern Hemisphere, were both local springtime.

Figure 5 shows the ratio of the C^+ peak, an indicator of organic content, to two peaks indicative of sulfate or sulfuric acid. The
top axis gives an approximate mass fraction of organics adapted from calibrations described by Froyd et al. (2019). The vertical
axis of ozone serves as a measure of distance into the stratosphere. That the stratospheric and tropospheric particle
190 compositions remain distinct implies that there is very limited redistribution of semi-volatile organics between particles. Like
most upper tropospheric particles, the organic-sulfate particles contain on average about 40 to 80 organic material by mass.
There is little variation with ozone, indicating a long lifetime for the organic material as well as little uptake of sulfuric acid.
The latter is consistent with most of the sulfuric acid coming from carbonyl sulfide above 20 km rather than SO_2 near the
tropopause (Kremser et al., 2016; Rollins et al., 2017).

195

There is some limited uptake of organics onto the stratospheric particles, although the maximum organic concentration is still
much less than for tropospheric particles. Meteoric-sulfuric particles definitely formed in the stratosphere, so any significant

organic content indicates net uptake of organics. Their organic content grows as the particles descend to the lowermost stratosphere and the upper troposphere.

200

The meteoric-sulfuric particles contain much less than 1% organic mass at altitudes with ozone greater than 500 ppbv and as much as 2 to 4% near the tropopause in the Northern Hemisphere. Such limited formation of secondary organic mass in the lowermost stratosphere is consistent with previous PALMS measurements (Murphy et al., 2007).

205 A new finding from ATom is that there is a very distinct and consistent difference between the hemispheres in the small amount of organic content that does form in the meteoric-sulfuric acid particles. Since the particles start from similar formation processes much higher in the stratosphere, we conclude that there is more condensable or reactive organic vapor in the Northern Hemisphere lower stratosphere. This could be either gas phase species mixed from the troposphere or semi-volatile organics transferring from organic-sulfate particles.

210

Adding a few percent mass to the meteoric-sulfuric particles represents a very small amount of organic vapor. Without knowing uptake coefficients the amount of vapor cannot be determined uniquely, but a representative calculation is that one or two pptv of an organic gas-phase species with molecular weight of about 100 daltons that reacts with sulfuric acid on every collision would add few percent mass to a 450 nm particle in a few months. The same order of magnitude can be obtained by noting
215 from Figure 4 that at 200 ppbv ozone there is about 100 ng standard m⁻³ of meteoric sulfuric particles. 1% by mass of these particles corresponds to about a part per trillion by mass of air. We conclude that an order of magnitude for highly condensable organic vapor in the lowermost stratosphere is a few parts per trillion in the Northern Hemisphere and less in the Southern Hemisphere. A less reactive or condensable organic molecule could be present at a correspondingly higher concentration.

220 **5 Radiative and chemical implications**

The different sizes of the sulfuric acid and organic-sulfate particles lead to substantial differences in their radiative and chemical effects. Important properties are the amount of infrared heating, the amount of light scattered, implications for photolysis, the surface area available for heterogeneous chemistry, and the mass sedimentation rate.

225

A key part of the radiative implications is the efficiency of light scattering as a function of particle size. Figure 6 shows the mass scattering efficiency as a function of particle size averaged over the solar spectrum and a sunlit Earth. Calculations are for a real refractive index of 1.45 and minimal absorption. Atmospheric extinction is determined by the solid total scattering curve. Much of the light scattered by particles continues downward to the Earth and so does not directly affect climate.

230 Separating out the light scattered to outer space (dashed curve) gives a maximum that is slightly broader and shifted to smaller sizes than light extinction. Over much of the size range of particles that scatter light efficiently, only about 1/5 of the light that

is scattered goes to outer space; the remainder becomes diffuse light. This is a reason for the large increases in diffuse light (with decreases in direct sunlight) after volcanic eruptions (Murphy, 2009).

235 The top panel of Figure 7 replots the chemically resolved size distribution for ATom2 in the Northern Hemisphere. This was
chosen as an example because it is similar to several other locations and seasons such as ATom1 Northern Hemisphere and
ATom3 Southern Hemisphere. There was more sampling time in the ATom2 Northern Hemisphere stratosphere so the particle
statistics are better, with about 10,000 particles. In Figure 7 the two sulfuric acid particle categories have been combined. Of
the particles larger than 0.1 μm diameter, about 39% of the volume was organic-sulfate particles from the troposphere and
240 61% sulfuric acid particles from the stratosphere (including both those with and without meteoric metals). The percentage
contribution to each parameter in Figure 7 by stratospheric aerosol will be somewhat larger at ambient conditions because
sulfuric acid has some water uptake even at <10% relative humidity. Ambient sulfuric acid particles may have roughly 5 to
15% larger diameters than measured in the warm aircraft cabin.

245 5.1 Infrared heating

An important property for stratospheric particles is their absorption and emission of infrared radiation. Infrared properties are
more important for stratospheric aerosol than very low-altitude aerosol because the latter are close to the surface temperature
and so absorb and emit similar amounts of energy.

250 Infrared absorption by stratospheric particles is important for two reasons. First, it heats the stratosphere around the particles.
Changes in circulation due to infrared heating were responsible for significant changes in ozone after the Pinatubo eruption
(Labitzke and McCormick, 1992; Pitari and Rizzi, 1993). The heating-induced changes in ozone were as large or larger than
those due to heterogeneous chemistry. There are additional feedbacks on the circulation after changes in infrared heating due
255 to changes in ozone and water vapor (Visoni et al., 2017). Infrared heating is largest in the lower stratosphere where the
temperature contrast with the surface is greatest (Lacis, 2015).

Second, infrared absorption by stratospheric particles offsets some or even all of the shortwave cooling of the Earth. For
sulfuric acid particles similar to those after the Pinatubo eruption, longwave heating offset roughly 25% of the shortwave
260 cooling (Hansen et al., 2005). This increases to about 50% for large injection rates because larger particles (>0.6 μm) become
increasingly less efficient at scattering sunlight to outer space (Figure 6) compared to their volume (Niemeier and Timmreck,
2015). Alumina with the size distribution from rocket emissions was calculated to cause net warming (Ross and Sheaffer,
2014).

265 For wavelengths much larger than the particles, absorption and emission are approximately proportional to total particle
volume (and the material) and do not depend on particle size (van de Hulst, 1981). Therefore, net thermal infrared heating is
insensitive to the size of particles and will approximately follow the volume distribution in the top panel of Figure 7. For
ATom2, most of the volume distribution was composed of particles of stratospheric origin, but that was not always the case
(Figure 1). The infrared effects of the tropospheric particles found in the lower stratosphere are hard to assess. Longwave
270 radiative heating depends not only on the strength of the absorption bands but also on their overlap with atmospheric windows
in the infrared spectrum. The presence of a significant fraction of organic material has unknown implications for infrared
heating.

5.2 Scattering of visible light

275

The middle panel in Figure 7 shows the size distribution weighted by the amount of sunlight scattered to outer space, which is
relevant for shortwave climate effects. Weighting the size distribution by the light extinction would shift the peak just slightly
further to larger particles. Because of their size, the sulfuric acid particles contribute a greater fraction of the light scattering
than their mass fraction. In fact, comparing Figures 1 and 6, the most abundant size of the sulfuric acid particles in the lower
280 stratosphere was close to the maximum in light scattering to outer space per unit mass. The ATom mission was during a time
with small volcanic influence. In contrast, particles shortly after the Pinatubo eruption had volume mean diameters greater
than $0.7\ \mu\text{m}$ (Wilson et al., 2008; Figure S2), large enough that their mass scattering efficiency decreased.

5.3 Heterogeneous chemistry

285

Particle size can affect heterogeneous chemistry. Reactions with sulfuric acid particles that are important to stratospheric
chemistry span the range from reactions that occur in the interior of liquid particles and hence are proportional to volume to
reactions that occur on the surface and hence are proportional to surface area (Hanson et al., 1994). Heterogeneous chemistry
can be especially important within or at the edge of the polar vortex (Solomon et al., 2015; Stone et al., 2017).

290

The bottom panel of Figure 7 shows the size distribution weighted by surface area rather than volume. For these conditions
surface reactions are closely proportional to surface area; gas-phase diffusion is a minor correction. For the case shown in
Figure 7, the organic-sulfate particles from the troposphere are about half of the surface area in the lowermost stratosphere.
This is significant because whereas stratospheric heterogeneous chemistry on sulfuric acid has been extensively studied, little
295 is known about the same reactions on organic-sulfate particles.

The organic-sulfate particles differ from the sulfuric acid particles in important ways. Most obviously, they contain a high
proportion of organics that may participate in new chemistry with halogen radicals. Iodine in particular may react with organic

aerosols (Murphy and Thomson, 2000; Pechtl et al., 2007). Although not fully neutralized, the organic-sulfate particles are not
300 nearly as acidic as the relatively pure sulfuric acid particles. This can be determined from acid cluster peaks in the PALMS
mass spectra. Some chlorine activation reactions that lead to ozone destruction are acid-catalyzed (Burley and Johnston, 1992)
and therefore may be slower on partially neutralized particles. The organic-sulfate particles also contain less water – sulfuric
acid is extremely hygroscopic compared to other species at the low relative humidities in the stratosphere. The availability of
condensed water for heterogeneous reactions could be further reduced if the organic-sulfate particles are glassy at the low
305 temperatures and humidity in the stratosphere (Krieger et al., 2012; Price et al., 2014).

5.4 Sedimentation

Sedimentation is a key process in the stratospheric aerosol budget (Wilson et al., 2008). It is more important than in the
310 stratosphere than it is near ground level partly because particles fall faster at lower air density. A bigger reason sedimentation
is important in the stratosphere is the relevant time scale: a fall speed of a kilometer per month would be unimportant in the
lower troposphere but can control the residence time of a particle in the stratosphere. Particles larger than about 1 μm diameter
have sedimentation rates greater than 10 km yr^{-1} in the lower stratosphere. On Figure 7, the sedimentation flux as a function
of size would be slightly more skewed to large diameters than the light scattering panel. For the case shown in Figure 7 the
315 sulfuric acid particles have roughly twice the volume of the organic-sulfate particles. Their source strength must be somewhere
between about twice as large as the tropospheric particles (if loss is controlled by bulk air motion) and three times as large (if
loss is controlled by sedimentation).

5.5 Ultraviolet scattering and absorption

320 Absorption and scattering of ultraviolet light are distinct from that of visible light because of the impact on photolysis rates.
Light scattering by stratospheric aerosol changes the path length of light in the stratosphere, which in turn changes photolysis
rates (Huang and Massie, 1997; Pitari et al., 2015). The calculations are complex because Rayleigh scattering in the ultraviolet
leads to strong effects from multiple scattering (Bian and Prather, 2002), especially at twilight or if a scattering aerosol layer
325 is located above gas-phase absorption (Davies et al., 1993; Anderson et al., 1995). In addition, the long path lengths magnify
the importance of any absorption of ultraviolet light by aerosols.

The scattering of ultraviolet light peaks at smaller particle sizes than for sunlight. This means that the smaller tropospheric-
organic particles contribute substantially to the scattering of ultraviolet light. The relative contributions to scattering of light
330 at $< 240 \text{ nm}$ are fairly similar to the surface area panel in Figure 7 except that sizes smaller about 80 nm and larger about 600
nm contribute less to UV scattering than they do to surface area.

One important wavelength band is 200 to 242 nm, where photolysis of O₂ is responsible for formation of ozone and photolysis of N₂O produces odd nitrogen (NO_y). (Brasseur and Solomon, 1986). For purely scattering particles, changes in photolysis in
335 this wavelength range are reduced by large cancellations in direct and diffuse light (Michelangeli et al., 1989). Light scattering by the El Chichon volcanic cloud was estimated to reduce O₂ photolysis by about 10% (Michelangeli et al., 1989). The overall effect of scattering seems to be to reduce ozone formation (Pitari et al., 2015).

Unlike pure scattering particles, absorbing particles would not have a similar partial cancellation between direct and diffuse
340 sunlight. Huang and Massie (1997) examined the effect of substituting ash, with visible and UV absorption, for non-absorbing sulfuric acid in a simple model of photolysis after a volcanic eruption. There are competing effects on the ozone column because both J_{O2} and J_{O3} are reduced by UV absorption, with one reducing and the other increasing ozone (Pitari and Rizzi, 1993). The individual effects were several percent of the ozone column with the net impact difficult to assess because their simple model did not include NO_x or halogen chemistry. The imaginary refractive index of the organic-sulfate particles at
345 wavelengths below 242 nm is not known but could easily be large enough to lead to significant absorption compared to scattering.

6 Relevance to volcanic or intentional aerosol injection

350 Sulfur dioxide is periodically injected into the stratosphere by major volcanic eruptions, leading to an increase in sulfuric acid aerosol. One such example is visible in the ATom1 Southern Hemisphere panel in Figure 1. There have also been numerous proposals for, and studies of, injecting material into the stratosphere for the purpose of solar radiation management (National Research Council, 2015). Regardless of the desirability of such actions, some of the calculations presented above on the optical properties and potential for heterogeneous chemistry have implications for added material whether it be from volcanoes or
355 deliberate intervention.

6.1 Complex controls on particle size

The previous sections demonstrate that particle size is important for many of the properties relevant to climate and chemical
360 effects. In the real world, one cannot instantly fill a box with monodisperse particles of a chosen size, the way one might in a model. It is important to understand what controls the size distribution of particles in the stratosphere and how will it change with additional aerosol or precursors such as sulfur dioxide. The mean diameter in the stratosphere is not a single number but varies with the aerosol loading, altitude, and latitude (English et al., 2012).

365 The size of particles in the unperturbed or perturbed stratosphere can be understood in two complementary ways. The first way, a top-down approach, says that for a given mass of stratospheric aerosol, the more particles there are, the smaller they

must be. The second way, a bottom-up approach, considers how the size of each particle is set by a balance of growth and removal processes in the stratosphere.

370 For the top-down approach, one must consider at least three sources of particle number in the stratosphere. Particles come
down from the mesosphere, up from the troposphere, and new particles can form in the stratosphere (Murphy et al., 2014). The
375 meteoric source of particles to the stratosphere is mostly “smoke” consisting of material that evaporated from ablating
meteoroids and condensed into new particles high in the atmosphere. Much of this material descends near the winter poles
(Bardeen et al., 2008). Second, tropospheric particles provide an important source of stratospheric particles below 20 km
altitude (Yu et al., 2016). The fate of tropospheric particles entering the stratosphere is poorly represented in most models.
New particle formation is also important for the stratosphere. The pure sulfuric acid category in Figure 1 is probably from
380 growth of particles formed in (or at the edge of) the stratosphere. One formation region is near the tropical tropopause with
upward transport into the stratosphere (Brock et al., 1995; English et al., 2011). There is probably also formation of new
sulfuric acid particles higher in the stratosphere over the winter poles (Wilson et al., 1989), although this must be distinguished
from meteoric smoke descending in the same regions (Curtius et al., 2005).

Adding sulfuric acid or its precursors will have complex effects on new particle formation, with more vapor to condense but
also more surface area sink. In contrast, injected solid particles would provide a surface sink for background sulfuric acid from
oxidation of carbonyl sulfide, likely reducing new particle formation. This implies that injected solid particles would probably
385 change the size of the natural sulfuric acid particles in the stratosphere. Sufficiently small injected solid particles might reach
high altitudes where existing sulfuric acid particles have evaporated (Weisenstein et al., 2015; Jones et al., 2016). There could
be unknown effects if they were later entrained in descending air in the winter polar regions.

The bottom-up approach considers how the size of stratospheric particles is determined by a balance of growth and removal
390 processes. Particles grow by coagulation and by condensation of sulfuric acid and other species. Coagulation in the unperturbed
stratosphere is slow except for special situations such as shortly after new particle formation (Brock et al., 1995; Hamill et al.,
1997). Coagulation increases non-linearly with aerosol concentration so it becomes more significant after volcanic eruptions
(Pinto et al., 1989) or large injection scenarios (Weisenstein et al., 2015). In these cases, coagulation helps drive the extra mass
primarily to larger particles rather than more numerous particles (Heckendorn et al., 2009; Niemeier and Timmreck, 2015).
395 Both sedimentation and downward motion are important removal processes (Wilson et al., 2008).

One implication of having multiple sources of particles in the stratosphere is that there is no single response to injected material.
It is only in the last few years that stratospheric models have incorporated multiple sources of particles along with detailed
microphysics (Pitari et al. 2014; Yu et al., 2016; Mills et al., 2017). There is still considerable uncertainty in quantitatively

400 understanding the size of particles in the current stratosphere, let alone after a perturbation. Figure 2 demonstrates that a
detailed microphysics model of the stratosphere did not grow the sulfuric acid particles to large enough sizes.

6.2 Impacts on the stratosphere as a function of size

405 The preceding section suggests that the ultimate size of particles is not something that can simply be chosen when injecting
aerosol particles or their precursors; instead it is also strongly influenced by subsequent particle formation and growth
processes in the stratosphere. Even solid particles may coagulate or grow by condensation of sulfuric acid and not retain their
original size. Despite this, it is of interest to examine the impact of particle size on the relative magnitude of effects. Figure 8
shows an estimate of net cooling compared to particle volume, surface area, and sedimentation rate.

410

The shortwave effect is modified to include longwave effects by adapting a calculation in Lacis et al. (1992), who showed that
heating exceeded shortwave cooling for several different types of particles when their diameters were more than about 4 μm .
Since infrared absorption is almost independent of size, an approximate net cooling was estimated by subtracting a constant
from the calculated shortwave scattering to space (Figure 6) such that the net was zero at 4 μm diameter. Subtracting this
415 amount is only approximate but the patterns in Figure 8 are not sensitive to the exact crossing point. The relative sedimentation
curve in Figure 8 also varies slightly with altitude but again the patterns are similar.

The size that has the least infrared absorption for a given amount of shortwave climate impact is about 0.5 μm diameter (filled
circles). Larger or smaller particles will be less effective at cooling the Earth and will cause more stratospheric circulation
420 changes for a given amount of cooling. Sufficiently large ($> 4 \mu\text{m}$) or small ($< 0.1 \mu\text{m}$) particles cause net heating of the Earth
(Lacis et al., 1992). Even for the optimal size, the infrared heating due to deliberate injections of sulfuric acid or its precursors
into the stratosphere would cause significant changes in circulation (Aquila et al., 2014).

The potential for increased heterogeneous chemistry would be reduced by using larger particles with less surface area. Particles
425 with a diameter of about 1 μm have the largest cooling effect for a given surface area (open circles). These larger particles,
however, have high sedimentation rates (downward triangles) and limited stratospheric lifetimes. For a given climate impact,
the mass flux due to sedimentation is minimized by particles with a diameter of about 300 nm. The least diffuse light is created
by the smallest particles (Figure 6). The exact sizes of the various maxima depend on the refractive index and density. However,
the patterns of which variables are maximized at larger or smaller sizes will be similar.

430

7 Discussion

435 The title of Solomon et al. (2011) includes the phrase “the persistently variable ‘background’ stratospheric aerosol”. The ATom data presented here add new meaning to that phrase. Out of eight samplings of the lowermost stratosphere, three exhibited much higher aerosol concentrations for three different reasons: a volcanic eruption, biomass burning aerosol, and transport of dust and other near-surface particles. None of these events were targeted during the flights. Such variations in the stratospheric aerosol layer are important for both heterogeneous chemistry (Solomon et al., 1996) and climate (Solomon et al., 2011).

440 There are important differences in the aerosol in the lower stratosphere between the Northern and Southern Hemispheres. A smaller amount of tropospheric aerosol in the Southern Hemisphere stratosphere indicates that the tropospheric particles are mixing into the lower stratosphere within each hemisphere rather than entering in rising air in the tropics and splitting into the two hemispheres. Sulfuric acid particles in the Southern Hemisphere also acquire less organic content. This suggests that there are lower concentrations of gas-phase organics in the Southern Hemisphere. One of several possible formation routes is that small organic compounds such as acetone and formaldehyde can react with concentrated sulfuric acid to form polymers that stay in the aerosol (Iraci and Tolbert, 1997; Williams et al., 2010). Other routes would be if low-volatility organic molecules were formed in the gas phase or evaporated from the tropospheric particles and recondensed on the sulfuric acid particles. Even in the Northern Hemisphere, only low part-per-trillion range concentrations of gas-phase organics are required to explain the very small amounts of organics taken up by the sulfuric acid particles.

450 The data here add support to the concept of Yu et al. (2016) that tropospheric particles comprise a significant fraction of the aerosol in the lowermost stratosphere. Such tropospheric particles offer a route for anthropogenic influence on the stratosphere. The Yu et al. model also correctly predicts that tropospheric particles are smaller than sulfuric acid particles formed in the stratosphere (Figure 2).

455 Absorption of ultraviolet light means that impurities should be considered when assessing deliberately added materials. For example, absorption appropriate for optical-quality sapphire should probably not be used when evaluating proposals to add industrial quantities of alumina to the stratosphere. Even part-per-million impurities in alumina increase absorption in the ultraviolet (Innocenzi et al., 1990). Compared to many materials, sulfuric acid has extremely low absorption in the ultraviolet (Noziere and Esteve, 2005; Dykema et al., 2016).

460 The broad distribution of particle sizes in the unperturbed stratosphere is the superposition of several narrower distributions. Single particle types, particularly meteoric-sulfuric acid particles, can have narrow size distributions (lognormal standard deviation ~ 1.4).

465 Multiple formation mechanisms for stratospheric particles imply that the size of particles after a volcanic or intentional injection may be difficult to predict. Yet an accurate prediction of size is important: The diameter must be known to perhaps

25% to accurately estimate tradeoffs between climate impact and side effects (Figure 8). A state-of-the-art microphysical bin model underestimates the size of stratospheric sulfuric acid particles, indicating that we do not fully understand what controls the size of particles in the stratosphere. The size difference has significant impacts on properties: the modeled particles have about 65% of the climate impact per unit mass as the observations, 160% of the surface area, and sediment about 60% as fast.

There is no single diameter that produces the largest shortwave climate impact with the fewest side effects (Figure 8). To the extent that one could control the size of particles after an intentional injection, any chosen size involves tradeoffs. Particles smaller than about 0.6 μm diameter have more surface area for possible heterogeneous chemistry. Particles larger than about 0.4 μm require more injected mass and produce more diffuse light. For a given amount of scattered sunlight, either sufficiently large or small particles have more infrared absorption and hence more impacts on stratospheric circulation. Most of the mass of particles after the Mt. Pinatubo eruption was larger than 0.6 μm diameter (Brock et al., 1993; Wilson et al. 2008), a size range with relatively little surface area compared to their climate impact. The heterogeneous chemistry observed after Mt. Pinatubo may therefore underestimate what might happen with intentionally added material.

Data availability and author contributions

Data are available at <https://daac.ornl.gov/ATOM/campaign/>, <https://espo.nasa.gov/atom/content/ATom>, and <https://www.esrl.noaa.gov/csl/projects/atom/data/MurphyACP2020/>. DMM wrote the manuscript with assistance from all other authors. DMM, KDF, CAB, AK, GPS, and CJW made aerosol measurements and analysed the data. IB and CRT made ozone measurements and analysed the data. PY performed model calculations. Authors declare no competing interests.

485

Acknowledgements

T. Ryerson helped provide ozone measurements. J. C. Wilson provided data from his 2008 paper. These measurements were supported by NOAA internal climate funding and also in part by NASA award NNH15AB12I. The ATom mission as a whole was supported by NASA's Earth System Science Pathfinder Program EVS-2 funding. A. Kupe was supported by the Austrian Science Fund's Erwin Schrodinger Fellowship J-3613References

765

Figure 1. Composition resolved size distributions from the lower stratosphere during the Atmospheric Tomography (ATom) mission. The size distributions from optical particle counter measurements are apportioned at each size into classes of particles based on the PALMS single particle composition data. The smallest few size bins sometimes had too few particles with PALMS mass spectra to apportion the composition. Sizes in all figures are geometric diameter at low relative humidity and concentrations are per standard cm^3 . Fine structure in some total volume distributions at $0.6 \mu\text{m}$ and larger may be artifacts due to Mie resonances in the optical particle counter; minima near 0.2 or $0.3 \mu\text{m}$ are robust.

770

Figure 2. A comparison of the CARMA bin microphysics aerosol model in the CESM climate model with observed size distributions during ATom2. Total particle volumes are proportional to areas under each curve.

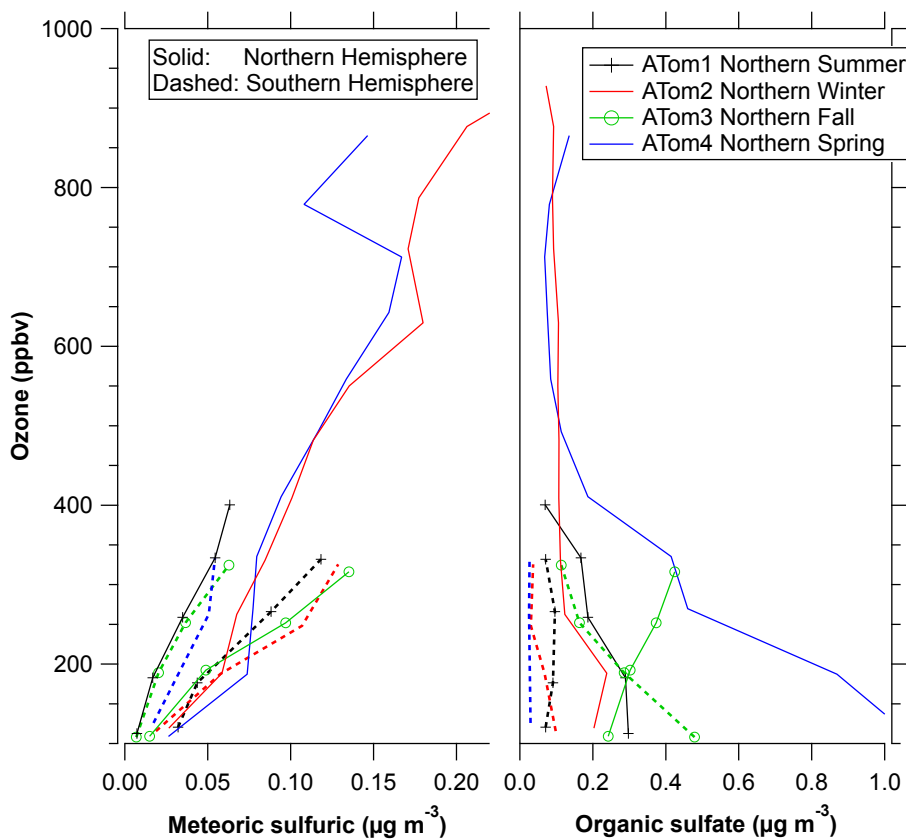

775

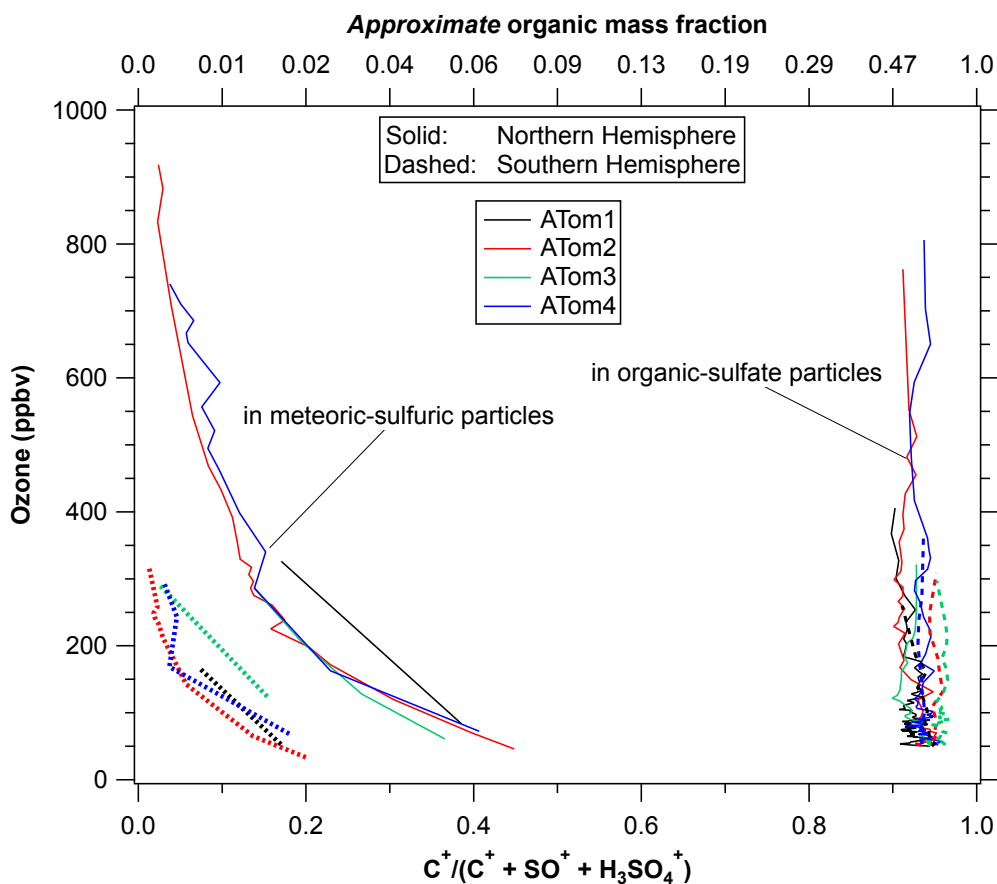

Figure 3. Composition-resolved size distributions for the times when data are available for ozone greater than 500 ppbv, all in the Northern Hemisphere. The dashed curves are to facilitate comparison with Figure 1.

780

785 **Figure 4.** Profiles of the mass concentration of two types of particles in the lower stratosphere, using ozone as a surrogate for a vertical coordinate. Sulfuric acid particles with meteoric metals have a high-altitude source whereas organic-sulfate particles originate in the troposphere. The organic-sulfate particles are more abundant in the Northern Hemisphere than they are in the Southern Hemisphere.

790 **Figure 5.** The organic content of two types of stratospheric particles using ozone as a surrogate for altitude. Shown are the relative areas of the C^+ peak in the mass spectra relative to two peaks indicative of sulfate. The top axis is an approximate mass fraction. The organic-sulfate particles are about 40 to 70% organic by mass, consistent with a tropospheric source. The sulfuric acid particles have near-zero organic content well into the stratosphere, increasing up to a few percent by mass near the tropopause. There was a strong difference in the organic content of the sulfuric acid particles between the hemispheres. Each point is the average of about 200 mass spectra.

795

800 **Figure 6.** The mass scattering efficiency of particles with a refractive index similar to sulfuric acid. Shown are the total scattered light, the light scattered away from the Earth to space, and their ratio. Larger particles have more forward scattering and therefore a smaller fraction scattered to space. The lowest curve shows the climate impact after an approximate correction for warming due to infrared absorption. Particles smaller than about 0.1 μm or larger than about 4 μm warm the Earth (Lacis et al., 1992). Tropospheric particles containing ammonium sulfate or organic material with higher refractive indices would shift the curves to slightly larger diameters.

805

Figure 7. The composition-resolved size distribution from Figure 1 for the ATom2 Northern Hemisphere weighted by volume, light scattered to outer space, and surface area. The two sulfuric acid categories (with and without meteoric metals) have been combined. Percentages refer to sizes above 0.1 μm only. Figure S3 shows the percentage contributions of various particle types to these processes for other deployments. Scaling to net thermal infrared heating gives nearly identical relative contributions as volume in the top panel. Scaling to sedimentation rate gives a similar shape to the middle panel.

810

815 **Figure 8. Calculated net cooling per unit volume, surface area, and sedimentation velocity. Calculations of sunlight reflected to outer space are for a single size aerosol averaged over the solar spectrum and zenith angles characteristic of the sunlit Earth. The wavelength averaging eliminates the oscillations from Mie scattering. Each curve is normalized so the maximum point is unity. For example, 1 μm diameter particles have about 10 times the net cooling per unit surface area than do particles with about 0.2 μm diameter.**

825

Table 1. Total volumes and volumes and log-normal fit parameters for individual types of particles. Lognormal fits were performed for particle volume so the fit diameter is for the volume distribution. The volumes and fits are for the size range 0.1 to 1.7 μm diameter except as noted (first column). Data are for 250–400 ppbv ozone except the last two rows are for 500–850 ppbv. Volumes are per standard cm³. Fits are to the equation $V = a \cdot \exp(-(\ln D - \ln D_{fit})^2 / (2\sigma^2))$ where D is the diameter and a is a scaling factor. Each fit is for a specific component. Fits were not attempted for “other” particles (mostly dust) because they did not generally show a defined mode. Italics indicate a poor fit to a lognormal shape.
