Atmospheric Chemistry and Physics Discussions

Abstract

Anthropogenic secondary organic aerosol (ASOA), formed from anthropogenic emissions of organic compounds, constitutes a substantial fraction of the mass of submicron aerosol in populated areas around the world and contributes to poor air quality and premature mortality. However, the precursor sources of ASOA are poorly understood, and there are large uncertainties in the health benefits that might accrue from reducing anthropogenic organic emissions. We show that the production of ASOA in 11 urban areas on three continents is strongly correlated with the anthropogenic reactivity of specific volatile organic compounds. The differences in ASOA production across different cities can be explained by differences in the emissions of aromatics and intermediate- and semi-volatile organic compounds, indicating the importance of controlling these ASOA precursors. With an improved modeling representation of ASOA driven by the observations, we attribute 340,000 $PM_{2.5}$ premature deaths per year to ASOA, which is over an order of magnitude higher than prior studies. A sensitivity case with a more recently proposed model for attributing mortality to $PM_{2.5}$ (the Global Exposure Mortality Model) results up to 900,000 deaths. A limitation of this study is the extrapolation from regions with detailed data to others where data is not available. Comprehensive air quality campaigns in the countries in South and Central America, Africa, South Asia, and the Middle East are needed for further progress in this area.

Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

1. Introduction

Poor air quality is one of the leading causes of premature mortality worldwide (Cohen et al., 2017; Landrigan et al., 2018). Roughly 95% of the world's population live in areas where $PM_{2.5}$ (fine particulate matter with diameter smaller than 2.5 μm) exceeds the World Health Organization's 10 μg m^{-3} annual average guideline (Shaddick et al., 2018). This is especially true for urban areas, where high population density is co-located with increased emissions of $PM_{2.5}$ and its gas-phase precursors from human activities. It is estimated that $PM_{2.5}$ leads to 3 to 4 million premature deaths per year, higher than the deaths associated with other air pollutants (Cohen et al., 2017). More recent analysis using concentration-response relationships derived from studies of populations exposure to high levels of ambient $PM_{2.5}$ suggest the global premature death burden could be up to twice this value (Burnett et al., 2018).

The average measured chemical composition of submicron PM (PM_1, which typically comprises most of $PM_{2.5}$ (Wang et al., 2015)) for various megacities, urban areas, and outflow regions around the world is shown in Fig. 1. A substantial fraction of urban PM_1 is organic aerosol (OA), which is composed of primary OA (POA, organic compounds emitted directly in the particle phase) and secondary OA (SOA, formed from chemical reactions of precursor organic gases). SOA is typically a factor of 2 to 3 higher than POA for these locations.

Understanding the gas-phase precursors of anthropogenic SOA (ASOA, defined as the SOA formed from anthropogenic volatile organic compounds (AVOC) (de Gouw et al., 2005; DeCarlo et al., 2010)) quantitatively is challenging (Hallquist et al., 2009). Though the enhancement of ASOA is largest in large cities, these precursors and production of ASOA should be important in any location impacted by anthropogenic emissions (e.g., Fig. 1). ASOA

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

comprises a wide range of condensable products generated by numerous chemical reactions involving AVOC precursors (Hallquist et al., 2009; Hayes et al., 2015; Shrivastava et al., 2017). These condensable products include intermediate volatile organic compounds (IVOCS, less volatile than traditional VOCs and often not measured or considered (Robinson et al., 2007; Hayes et al., 2015)) and semi volatile organic compounds (SVOCs, less volatile than IVOC and similarly not measured or considered).

The main categories of gas-phase precursors that dominate ASOA have been the subject of intensive research. Transportation-related emissions (e.g., tailpipe, evaporation, refueling) were assumed to be the major precursors of ASOA, which was supported by field studies (Parrish et al., 2009; Gentner et al., 2012; Warneke et al., 2012; Pollack et al., 2013). Yet, budget closure of observed ASOA mass concentrations could not be achieved with transportation-related VOCs (Ensberg et al., 2014). The contribution of urban-emitted biogenic precursors to SOA in urban areas is typically small, and rather, the contribution of biogenic SOA (BSOA) in urban areas is typically dominated by regionally advected SOA background (e.g., Hodzic et al., 2009, 2010a; Hayes et al., 2013; Janssen et al., 2017). BSOA is thought to dominate globally (Hallquist et al., 2009), but as shown in Fig. 1, the contribution of BSOA (1% to 20%) to urban concentrations, while often substantial, is typically smaller than that of ASOA (17% to 39%) (see Sect. 2). Recent studies have indicated that emissions from volatile chemical products (VCPs), defined as pesticides, coatings, inks, adhesives, personal care products, and cleaning agents (McDonald et al., 2018), as well as cooking emissions (Hayes et al., 2015), are important. While total amounts of ASOA precursors released in cities have dramatically declined (largely due to three-way catalytic converters in cars (Warneke et al., 2012; Pollack et al., 2013;

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

115 Zhao et al., 2017; Khare and Gentner, 2018)), VCPs have not declined as quickly (Khare and
116 Gentner, 2018; McDonald et al., 2018). Besides a few cities in the US (Coggon et al., 2018;
117 Khare and Gentner, 2018; McDonald et al., 2018), extensive VCP emission quantification has
118 not yet been published.

119 Due to the uncertainty on the ASOA precursors and on the amount of ASOA formed
120 from them, the number of premature deaths associated with urban organic emissions is largely
121 unknown. Currently, most studies have not included ASOA realistically (e.g., Lelieveld et al.,
122 2015; Silva et al., 2016; Ridley et al., 2018) in source apportionment calculations of the
123 premature deaths associated with long-term exposure of $PM_{2.5}$. These models represented total
124 OA as non-volatile POA and "traditional" ASOA precursors (transportation-based VOCs), which
125 largely under-predict ASOA (Ensberg et al., 2014; Hayes et al., 2015; Nault et al., 2018;
126 Schroder et al., 2018) given that the current understanding is that POA is volatile and contributes
127 to ASOA mass concentration (e.g., Grieshop et al., 2009; Lu et al., 2018). As PM_1 and SOA
128 mass are highest in urban areas (Fig. 1), also shown in Jimenez et al. (2009), it is necessary to
129 quantify the amount and identify the sources of ASOA to target future emission standards that
130 will optimally improve air quality and the associated health impacts. As these emissions are from
131 human activities, they will contribute to SOA mass outside urban regions and to potential health
132 impacts outside urban regions as well.

133 Here, we investigate the factors that control ASOA using 11 major urban, including
134 megacities, field studies (Fig. 1 and Table 1). The empirical relationships and numerical models
135 are then used to quantify the attribution of premature mortality to ASOA around the world, using
136 the observations to improve the modeled representation of ASOA. The results provide insight

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

into the importance of ASOA to global premature mortality due to $PM_{2.5}$ and further understanding the precursors and sources of ASOA in urban regions.

2. Methods

2.1 Ambient Observations

For values not previously reported in the literature (Table S4), observations taken between 11:00 – 16:00 local time were used to determine the slopes of SOA versus formaldehyde (HCHO) (Fig. S2), peroxy acetyl nitrate (PAN) (Fig. S3), and O_x ($O_x = O_3 + NO_2$) (Fig. S4). For CalNex, there was an approximate 48% difference between the two HCHO measurements (Fig. S1). Therefore, the average between the two measurements were used in this study, similar to what has been done in other studies for other gas-phase species (Bertram et al., 2007). All linear fits, unless otherwise noted, use the orthogonal distance regression fitting method (ODR).

For values in Table S4 through Table S8 not previously reported in the literature, the following procedure was applied to determine the emissions ratios, similar to the methods of Nault et al. (2018). An OH exposure ($OH_{exp} = [OH] \times \Delta t$), which is also the photochemical age (PA), was estimated by using the ratio of NO_x/NO_y (Eq. 1) or the ratio of m+p-xylene/ethylbenzene (Eq. 2). For the m+p-xylene/ethylbenzene, the emission ratio (Table S5) was determined by determining the average ratio during minimal photochemistry, similar to prior studies (de Gouw et al., 2017). This was done for only one study, TexAQS 2000. This method could be applied in that case as it was a ground campaign that operated both day and night; therefore, a ratio at night could be determined when there was minimal loss of both

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

VOCs. The average emission ratio for the other VOCs was determined using Eq. 3 after the OH_{exp} was calculated in Eq. 1 or Eq. 2. The rate constants used for determining OH_{exp} and emission ratios are found in Table S11.

$$OH_{exp} = [OH] \times t = \ln\left(\frac{\left(\frac{[NO_x]}{[NO_y]}\right)}{k_{OH+NO_2}}\right) \quad \text{Eq. 1}$$

$$OH_{exp} = [OH] \times t = -\frac{1}{k_{m+p-xylene} - k_{ethylbenzene}} \times \ln\left(\frac{[m+p-xylene]_t}{[ethylbenzene]_t} - \frac{[m+p-xylene]_0}{[ethylbenzene]_0}\right) \quad \text{Eq. 2}$$

$$\frac{[VOC(i)]}{[CO]}(0) = -\frac{[VOC(i)]}{[CO]}(t) \times \left(1 - \frac{1}{exp\left(-k_i \times [OH] \times t\right)}\right) \times k_i + \frac{[VOC(i)]}{[CO]}(t) \times k_i \quad \text{Eq. 3}$$

2.2 Error Analysis of Observations

The errors that will be discussed here are in reference to Fig. 5 and Fig. 6 and Table S4 either come from the 1σ uncertainty in the slopes (the SOA versus O_x, HCHO, or PAN values) or propagation of uncertainty in observations. For SOA, we estimate the 1σ uncertainty of ~15%, which is lower than the typical 1σ uncertainty of the AMS (Bahreini et al., 2009) due to the careful calibrations and excellent intercomparisons in the various campaigns (see Table 1 for references for the AMS comparisons). For ΔCO, the largest uncertainty is associated with the CO background (Hayes et al., 2013; Nault et al., 2018), and is estimated to be ~10% at 0.5 photochemical equivalent days (Hayes et al., 2013). The uncertainty in the emission ratios is ~10% (Wang et al., 2014; de Gouw et al., 2017); though, it may be higher for the values

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

calculated here (see above) due to the uncertainty in CO background, rate constants, and photochemical age. Therefore, for Fig. 5a, the uncertainty in the y-values is 18% and the uncertainty in the x-values is 10%. For Fig. 6, the uncertainty in the measurement is 21%.

Another potential source of uncertainty may stem from the fit of the data in Fig. 5a, as the data point from Seoul (KORUS-AQ) could be impacting the fit due to the difference in its value compared to the other locations. A sensitivity analysis, where one study was removed and a new fit was derived, was conducted to determine the impact of any one study on the fit reported in Fig. 5a (see Table S10). We find that though removing the Seoul data point increases the slope, the value is still within the uncertainty and statistically significant at the 95% confidence interval. Thus, the data from Seoul does not change the results and conclusions reported in this study.

2.3 Emission Inventories for Various Urban Areas around the World

All BTEX (benzene, toluene, ethylbenze, and xylenes) and non-BTEX aromatic emissions are shown in Table S5 (BTEX) or Table S8 (non-BTEX aromatics) and are described above. The emission ratios are derived from ambient measurements utilizing photochemical aging techniques (Nault et al., 2018).

Details of the emission inventories for cities in the US, for Beijing, and for London/UK used here to estimate the IVOC:BTEX emission ratio (Fig. 2) and thus the IVOC emissions can be found in SI Sect. 1 through 3. Briefly, emissions for the US are based on McDonald et al. (2018), for China on the Multi-resolution Emission Inventory for China (MEIC) (Zhang et al., 2009; Zheng et al., 2014, 2018; Liu et al., 2015; Li et al., 2017, 2019), and for the UK on the

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

National Atmospheric Emissions Inventory (NAEI) (EMEP/EEA, 2016). The IVOC:BTEX emission ratio from inventories are multiplied with the observed BTEX measured in urban air to estimate IVOCs emitted in each region (Table S5), including North America, Europe, and Asia. This ensures IVOC emissions used in our calculations properly reflect differences in mixtures of emission sources (e.g., mobile sources versus VCPs) that vary by continent for each field campaign. Additionally, we rely on inventories for estimating atmospheric abundances of IVOCs because it has been challenging to measure the full range of IVOC precursors that are emitted into urban air (Zhao et al., 2014, 2017; Lu et al., 2018). In particular, many of the IVOCs emitted from VCPs are oxygenated, which are challenging to measure using traditional gas chromatography-mass spectrometry (GC-MS) techniques. Oxygenated IVOCs may not elute completely through a non-polar column, and are likely underestimated (Zhao et al., 2014). The bottom-up IVOC:BTEX ratios for the US, Beijing, and UK are described in greater detail in SI Sect. S1 through S3. IVOC emissions are classified based on their vapor pressure (effective saturation concentration: $0.3 < C^* < 3 \times 10^6$ μg m^{-3}), with the vapor pressure estimated by the SIMPOL.1 model (Pankow and Asher, 2008). Unspeciated mass has been suggested as important SOA precursors from gasoline and diesel engines, and parameterized by n-tridecane and n-pentadecane, respectively (Jathar et al., 2014). For VCPs, the volatility distribution of VOCs is in-between that of gasoline and diesel fuel. Therefore, n-tetradecane was suggested as a surrogate for unspeciated mass of VCPs by McDonald et al. (2018).

Similar to IVOCs, the ability to measure the full range of SVOCs emitted into urban air is challenging. Therefore, we estimate SVOC emission ratios relative to POA mass concentrations (Table S9), as described by Ma et al. (2017). For the hydrocarbon-like portion, we used the

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

volatility distribution from Worton et al. (2014) to estimate SVOC, as this is associated with fossil fuel emissions from transportation (Zhang et al., 2005). For the other POA, we used the volatility distribution from Robinson et al. (2007), as this POA is typically cooking primary aerosol.

Fig. 3 shows the calculated emission ratio versus saturation concentration (c*) for the cities with emission inventories. The saturation concentration for SVOC was determined as part of the estimation procedure discussed above. For IVOC, the emission ratios for the different sources (gasoline, diesel, other fossil fuel sources, and VCP emissions) were split into the volatility bins, as in McDonald et al. (2018). Finally, for BTEX and non-BTEX aromatics, and other VOC emission ratios (see Fig. 3 for references for the other VOC emission ratios), CRC (Rumble, 2019) or SIMPOL.1 (Pankow and Asher, 2008) (for estimating vapor pressures not in CRC) was used to estimate the saturation concentrations.

2.4 ASOA Budget Analysis of Ambient Observations

To calculate the ASOA budget, we used the observed BTEX (Table S5) and non-BTEX aromatic (Table S8) emission ratios, the emission inventories for IVOC (see above), and estimated SVOCs from the primary OA emissions (see above). The methods to calculate ASOA from emissions have been described in detail elsewhere (Hayes et al., 2015; Ma et al., 2017; Schroder et al., 2018), and are briefly described here. All calculations described were conducted with the KinSim v4.02 chemical kinetics simulator (Peng and Jimenez, 2019) within Igor Pro 7 (Lake Oswego, Oregon), and are summarized in Fig. S5. A typical average particle diameter for urban environments of ~200 nm (Seinfeld and Pandis, 2006) is used to estimate the

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

condensational sink term for the partitioning of gas-to-particle, although condensation is always fast compared to the experiment timescales. Further, we assume an average 250 g mol^{-1} molar mass for OA and an average SOA density of 1.4 g cm^{-3} (Vaden et al., 2011; Kuwata et al., 2012). Finally, all models are initialized with the campaign specific OA background (typically ~2 µg sm^{-3}) and POA (Table S9) for partitioning of gases to the particle phase, and ran at the average temperature for the campaign.

For the modeled VOCs (BTEX and non-BTEX aromatics), each species undergoes temperature-dependent OH oxidation (Table S11), forming four SVOCs that partition between gas- and particle-phase, using updated SOA yields that account for wall loss (Ma et al., 2017). For IVOCs, the emission weighted SOA yields and rate constants from the "Zhao" option (Zhao et al., 2014) of Ma et al. (2017) are used, and the products are apportioned into three SVOC bins and one low-volatility organic compound (LVOC) bin (Fig. S5). Finally, SVOCs undergo photooxidation at a rate of 4×10^{-11} cm^3 $molecules^{-1}$ s^{-1} (Dzepina et al., 2009; Hodzic et al., 2010b; Tsimpidi et al., 2010; Hodzic and Jimenez, 2011; Hayes et al., 2015; Ma et al., 2017; Schroder et al., 2018), producing one product per oxidation step, with yields from Robinson et al. (2007) for cooking and other SVOCs and yields from Worton et al. (2014) for fossil fuel related SVOCs, as recommended by Ma et al. (2017). The products from SVOC and IVOC oxidation are allowed to further oxidize, as highlighted in Fig. S5 and described in prior studies (Hayes et al., 2015; Ma et al., 2017; Schroder et al., 2018). Generally, each product reacts at a rate of 4×10^{-11} cm^3 $molecules^{-1}$ s^{-1} to produce some product at one volatility bin lower, adding one oxygen to the compound for each oxidation (Dzepina et al., 2009; Tsimpidi et al., 2010; Hodzic and Jimenez, 2011; Hayes et al., 2015; Ma et al., 2017; Schroder et al., 2018). An update includes

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

fragmentation for a fraction of the molecules that are oxidized, as described in Schroder et al. (2018) and Koo et al. (2014). As shown in Fig. S5, fragmentation of the compound occurs as it is oxidized and goes down one volatility bin. For further oxidation of SVOCs from the oxidation of primary IVOCs, one oxygen is added and 0.25 carbon is removed per step, leading to an increase in mass of 1.03 (instead of 1.07) per oxidation step (Koo et al., 2014; Schroder et al., 2018). For further oxidation of products from primary SVOC emissions, one oxygen is added and 0.5 carbon is removed per step, leading to an increase in mass of 0.99 (instead of 1.07) per oxidation step (Koo et al., 2014; Nault et al., 2018).

2.5 GEOS-Chem Modeling

The model used in this study, for ASOA apportionment (Fig. 1), for apportionment of ASOA to total PM2.5 for premature mortality calculations (Worldwide Premature Deaths Due to ASOA), and for sensitivity analysis for ASOA production and emissions on premature mortality calculations, is the GEOS-Chem v12.0.0 global chemical transport model (Bey et al., 2001; The International GEOS-Chem User Community, 2018) to calculate global concentrations of $PM_{2.5}$ and ASOA at 2°×2.5° horizontal resolution. Goddard Earth Observing System – Forward Processing (GEOS-FP) assimilated data from the NASA Global Modeling and Assimilation Office (GMAO) were used for input meteorological fields. The model was run for 2013 to 2018 to take into account interannual variability of meteorological impacts onto $PM_{2.5}$ (therefore, averaging $PM_{2.5}$ over variations in meteorology). However, the HTAPv2 emission inventory, which was used for anthropogenic emissions (Janssens-Maenhout et al., 2015), was kept constant for the 5 years. GEOS-Chem simulates gas and aerosol chemistry with ~700 chemical reactions.

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

GEOS-Chem calculates the following $PM_{2.5}$ species: sulfate, ammonium, nitrate (Park et al., 2006); black carbon and POA (Park et al., 2005); SOA (Pye and Seinfeld, 2010; Marais et al., 2016); sea salt (accumulation mode only (Jaeglé et al., 2011)); and, dust (Duncan Fairlie et al., 2007).

2.5.1 Biogenic SOA

For monoterpene and sesquiterpene SOAs, we used the default complex SOA scheme (without semi-volatile POA) using the two-product model framework (Pye and Seinfeld, 2010). This scheme calculates initial oxidation of VOCs with OH, O_3, and NO_3, and resulting products are assigned to four different gas-phase semi-volatile species (TSOA0–3) based on volatilities (c^* = 0.1, 1, 10, 100 μg m^{-3}). Aerosol and gas species fractions are calculated online using the partitioning theory, and all are removed by dry and wet deposition processes.

For isoprene SOA, we used the explicit isoprene chemistry developed by Marais et al. (2016). All the isoprene-derived gas-phase products, including isoprene peroxy radical, ISOPOOH, IEPOX, glyoxal, and methylglyoxal, are explicitly simulated. Irreversible heterogeneous uptake of precursors to aqueous aerosols are further calculated using online aerosol pH and surface area.

GEOS-Chem was used to estimate the relative fractions of the measured SOA in our studies between anthropogenic and biogenic (isoprene and monoterpene) sources (Fig. 1). Extensive research has been conducted to evaluate and improve the models performance in predicting BSOA, as summarized in Table S3. Though these evaluations mainly occurred in the southeast US, a recent study has also included more global observations to compare with

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

GEOS-Chem (Pai et al., 2020). Generally, GEOS-Chem appears to overestimate biogenically derived SOA; however, the model predicted SOA is typically within the uncertainty of the AMS (Table S3). The overestimation, though, would suggest that the fraction of urban SOA may be under-predicted by this method, whereas the BSOA may be over-predicted. Therefore, in urban regions, the amount of SOA from biogenic sources may be lower, especially after the rapid SOA enhancements (within 12 to 24 equivalent photochemical hours that have been observed around the world (Nault et al., 2018)). Typically the BSOA is present as a regional background and subtracted for the analyses used in this work, which focus on strong urban plumes on top of that background (Hayes et al., 2013, 2015).

2.5.2 Default GEOS-Chem Sensitivity to ASOA Simulations

For the sensitivity calculation using the "traditional" ASOA precursors, we used the two-product model framework (Pye and Seinfeld, 2010). Benzene, toluene, and xylene are oxidized with OH and converted to peroxy radicals. These peroxy radicals react with HO_2 or NO, resulting in non-volatile ASOA (HO_2 pathway, ASOAN species in GEOS-Chem) or semi-volatile ASOA tracers (NO pathway, ASOA1-3 in GEOS-Chem). As is the case for monoterpene and sesquiterpene SOA above, GEOS-Chem calculates online partitioning and dry/wet deposition processes for semi-volatile ASOA tracers. Other conditions including mortality calculation are kept the same as the base simulation above.

2.6 Estimation of Premature Mortality Attribution

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

Premature deaths were calculated for five disease categories: ischemic heart disease (IHD), stroke, chronic obstructive pulmonary disease (COPD), acute lower respiratory illness (ALRI), and lung cancer (LC). We calculated premature mortality for the population aged more than 30 years, using Eq. 4.

$$Premature\ Death = Pop \times y_0 \times \frac{RR-1}{RR} \quad \text{Eq. 4}$$

Mortality rate, y_0, varies according to the particular disease category and geographic region, which is available from Global Burden of Disease (GBD) Study 2015 database (IHME, 2016). Population (Pop) was obtained from Columbia University Center for International Earth Science Information Network (CIESIN) for 2010 (CIESIN, 2017). Relative risk, RR, can be calculated as shown in Eq. 5.

$$RR = 1 + \alpha \times \left(1 - exp\left(\beta \times \left(PM_{2.5} - PM_{2.5,Threshold}\right)^{\rho}\right)\right) \quad \text{Eq. 5}$$

α, β, and ρ values depend on disease category and are calculated from Burnett et al. (2014) (see Table S12 and associated file). If the $PM_{2.5}$ concentrations are below the $PM_{2.5}$ threshold value (Table S12), premature deaths were computed as zero. However, there could be some health impacts at concentrations below the $PM_{2.5}$ threshold values (Krewski et al., 2009); following the methods of the GBD studies, these can be viewed as lower bounds on estimates of premature deaths.

We performed an additional sensitivity analysis using the Global Exposure Mortality Model (GEMM) (Burnett et al., 2018). For the GEMM analysis, we also used age stratified population data from GWPv3. Premature death is calculated the same as shown in Eq. 4; however, the relative risk differs. For the GEMM model, the relative risk can be calculated as shown in Eq. 6.

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

$$RR = exp(\theta \times \lambda) \text{ with } \lambda = \frac{\log\left(1+\frac{z}{\alpha}\right)}{\left(1+\exp\left(\frac{(\hat{\mu}-z)}{\pi}\right)\right)} \quad \text{Eq. 6}$$

Here z = max(0,$PM_{2.5}$-$PM_{2.5,Threshold}$); θ, π, $\hat{\mu}$, α, and $PM_{2.5,Threshold}$ depends on disease category and are from Burnett et al. (2018). Similar to the Eq. 5, if the concentrations are below the threshold (2.4 μg m^{-3}, Burnett et al. (2018)), then premature deaths are computed as zero; however, the GEMM has a lower threshold than the GBD method.

For GBD, we do not consider age-specific mortality rates or risks. For GEMM, we calculate age-specific health impacts with age-specific parameters in the exposure response function (Table S13). We combine the age-specific results of the exposure-response function with age distributed population data from GPW (CIESIN, 2017) and a national mortality rate across all ages to assess age-specific mortality.

We calculated total premature deaths using annual average total $PM_{2.5}$ concentrations derived from satellite-based estimates at the resolution of 0.1°×0.1° from van Donkelaar et al. (2016) . Application of the remote-sensing based $PM_{2.5}$ at the 0.1°×0.1° resolution rather than direct use of the GEOS-Chem model concentrations at the 2°×2.5° resolution helps reduce uncertainties in the quantification of $PM_{2.5}$ exposure inherent in coarser estimates (Punger and West, 2013). We also calculated deaths by subtracting from this amount the total annual average ASOA concentrations derived from GEOS-Chem (Fig. S9). To reduce uncertainties related to spatial gradients and total concentration magnitudes in our GEOS-Chem simulations of $PM_{2.5}$, our modeled ASOA was calculated as the fraction of ASOA to total $PM_{2.5}$ in GEOS-Chem, multiplied by the satellite-based PM2.5 concentrations (Eq. 7).

$$ASOA_{sat} = (ASOA_{mod}/PM_{2.5,mod}) \times PM_{2.5,sat} \quad \text{Eq. 7}$$

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

374 Finally, this process for estimating $PM_{2.5}$ health impacts considers only $PM_{2.5}$ mass concentration
375 and does not distinguish toxicity by composition, consistent with the current US EPA position
376 expressed in Sacks et al. (2019).
377
378 **3. Observations of ASOA Production across Three Continents**
379 **3.1 Observational Constraints of ASOA Production across Three Continents**
380 Measurements during intensive field campaigns in large urban areas better constrain
381 concentrations and atmospheric formation of ASOA because the scale of ASOA enhancement is
382 large compared to SOA from regional background. Generally, ASOA increased with the amount
383 of urban precursor VOCs and with atmospheric PA (de Gouw et al., 2005; de Gouw and Jimenez,
384 2009; DeCarlo et al., 2010; Hayes et al., 2013; Nault et al., 2018; Schroder et al., 2018; Shah et
385 al., 2018). In addition, ASOA correlates strongly with gas-phase secondary photochemical
386 species, including O_x, HCHO, and PAN (Herndon et al., 2008; Wood et al., 2010; Hayes et al.,
387 2013; Zhang et al., 2015; Nault et al., 2018; Liao et al., 2019) (Table S4; Fig. S2 to Fig. S4),
388 which are indicators of photochemical processing of emissions.
389 However, as initially discussed by Nault et al. (2018) and shown in Fig. 4, there is large
390 variability in these various metrics across the urban areas evaluated here. To the best of the
391 authors' knowledge, this variability has not been explored and its physical meaning has not been
392 interpreted. As shown in Fig. 4, though, the trends in $\Delta SOA/\Delta CO$ are similar to the trends in the
393 slopes of SOA versus O_x, PAN, or HCHO. For example, Seoul is the highest for nearly all
394 metrics, and is approximately a factor of 6 higher than the urban area, Houston, that generally

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

showed the lowest photochemical metrics. This suggests that the variability is related to a physical factor, including emissions and chemistry.

The VOC concentration, together with how quickly the emitted VOCs react ($\Sigma k_i \times [VOC]_i$, i.e., the hydroxyl radical, or OH, reactivity of VOCs), where k is the OH rate coefficient for each VOC, are a determining parameter for ASOA formation over urban spatial scales (Eq. 8). ASOA formation is normalized here to the excess CO mixing ratio (ΔCO) to account for the effects of meteorology, dilution, and non-urban background levels, and allow for easier comparison between different studies:

$$\frac{\Delta \mathrm{ASOA}}{\Delta \mathrm{CO}} \propto [\mathrm{OH}] \times \Delta t \times \left(\sum_i k_i \times \left[\frac{\mathrm{VOC}}{\mathrm{CO}} \right]_i \times \mathrm{Y_i} \right) \quad \text{Eq. 8}$$

where Y is the aerosol yield for each compound (mass of SOA formed per unit mass of precursor reacted), and [OH]×Δt is the PA.

BTEX are one group of known ASOA precursors (Gentner et al., 2012; Hayes et al., 2013), and their emission ratio (to CO) was determined for all campaigns (Table S5). BTEX can thus provide insight into ASOA production. Fig. 5a shows that the variation in ASOA (at PA = 0.5 equivalent days) is highly correlated with the emission reactivity ratio of BTEX (R_{BTEX}, $\sum_i [\mathrm{VOC}/\mathrm{CO}]_i$) across all the studies. However, BTEX alone cannot account for much of the ASOA formation (see budget closure discussion below), and instead, BTEX may be better thought of as both partial contributors and also as indicators for the co-emission of other (unmeasured) organic precursors that are also efficient at forming ASOA.

O_x, PAN, and HCHO are produced from the oxidation of a much wider set of VOC precursors (including small alkenes, which do not appreciably produce SOA when oxidized).

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

These alkenes have similar reaction rate constants with OH as the most reactive BTEX compounds (Table S11); however, their emissions and concentration can be higher than BTEX (Table S7). Thus, alkenes would dominate R_{Total}, leading to O_x, HCHO, and PAN being produced more rapidly than ASOA (Fig. 5b–d). When R_{BTEX} becomes more important for R_{Total}, the emitted VOCs are more efficient in producing ASOA. Thus, the ratio of ASOA to gas-phase photochemical products shows a strong correlation with R_{BTEX}/R_{Total} (Fig. 5b–d).

3.2 Budget Closure of ASOA for 4 Urban Areas on 3 Continents Indicates Reasonable Understanding of ASOA Sources

We show that BTEX alone cannot explain the observed ASOA budget for urban areas around the world. Fig. 6a shows that approximately 25±6% of the observed ASOA originates from the photooxidation of BTEX. Therefore, other precursors must account for most of the ASOA produced.

Because alkanes, alkenes, and oxygenated compounds with carbon numbers less than 6 are not significant ASOA precursors, we focus on emissions and sources of BTEX, other mono-aromatics, IVOCs, and SVOCs. These three classes of VOCs, aromatics, IVOCs, and SVOCs, have been suggested to be significant ASOA precursors in urban atmospheres (Robinson et al., 2007; Hayes et al., 2015; Ma et al., 2017; McDonald et al., 2018; Nault et al., 2018; Schroder et al., 2018; Shah et al., 2018), originating from both fossil fuel and VCP emissions.

Using the best available emission inventories from cities on three continents (EMEP/EEA, 2016; McDonald et al., 2018; Li et al., 2019) and observations, we quantify the

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

emissions of BTEX, other mono-aromatics, IVOCs, and SVOCs for both fossil fuel (e.g., gasoline, diesel, kerosene, etc.), VCPs (e.g., coatings, inks, adhesives, personal care products, and cleaning agents), and cooking sources (Fig. 2 and Fig. 3). This builds off the work of McDonald et al. (2018) for urban regions on three different continents. Combining these inventories and observations for the various locations provide the following insights about the potential ASOA precursors not easily measured or quantified in urban environments (e.g., Zhao et al., 2014; Lu et al., 2018): (1) aromatics from fossil fuel accounts for 14-40% (mean 22%) of the total BTEX and IVOC emissions for the five urban areas investigated in-depth (Fig. 2), agreeing with prior studies that have shown that the observed ASOA cannot be reconciled by the observations or emission inventory of aromatics from fossil fuels (e.g., Ensberg et al., 2014; Hayes et al., 2015). (2) BTEX from both fossil fuels and VCPs account for 25-95% (mean 43%) of BTEX and IVOC emissions (Fig. 2). China has the lowest contribution of IVOCs, potentially due to differences in chemical make-up of the solvents used daily (Li et al., 2019), but more research is needed to investigate the differences in IVOCs:BTEX from Beijing versus US and UK emission inventories. Nonetheless, this shows the importance of IVOCs for both emissions and ASOA precursors. (3) IVOCs are generally equal to, if not greater than, the emissions of BTEX in 4 of the 5 urban areas investigated here (Fig. 2). (4) Overall, VCPs account for a large fraction of the BTEX and IVOC emissions for all five cities. (5) Finally, SVOCs account for 27-88% (mean 53%) of VOCs generally considered ASOA precursors (VOCs with volatility saturation concentrations $\leq 10^7$ μg m^{-3}) (Fig. 3). Beijing has the highest contribution of SVOCs to ASOA precursors due to the use of solid fuels and cooking emissions (Hu et al., 2016). Also, this indicates the large contribution of a class of VOCs difficult to measure (Robinson et al.,

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

460 2007) that are an important ASOA precursor (e.g., Hayes et al., 2015), showing further emphasis
461 should be placed in quantifying the emissions of this class of compounds.

462 These results provide an ability to further investigate the mass balance of predicted and
463 observed ASOA for these urban locations (Fig. 6). The inclusion of IVOCs, other aromatics not
464 including BTEX, and SVOCs leads to the ability to explain, on average, 85±12% of the observed
465 ASOA for these urban locations around the world (Fig. 6a). Further, VCP contribution to ASOA
466 is important for all these urban locations, accounting or, on average, 37±3% of the observed
467 ASOA (Fig. 6b).

468 This bottom-up mass budget analysis provides important insights to further explain the
469 correlation observed in Fig. 5. First, IVOCs are generally co-emitted from similar sources as
470 BTEX for the urban areas investigated in-depth (Fig. 2). The oxidation of these co-emitted
471 species leads to the ASOA production observed across the urban areas around the world. Second,
472 S/IVOCs generally have similar rate constants as toluene and xylenes ($\geq 1\times10^{-11}$ cm^3 $molec.^{-1}$ s^{-1})
473 (Zhao et al., 2014, 2017), the compounds that contribute the most to R_{BTEX}, explaining the rapid
474 ASOA production that has been observed in various studies (de Gouw and Jimenez, 2009;
475 DeCarlo et al., 2010; Hayes et al., 2013; Hu et al., 2013, 2016; Nault et al., 2018; Schroder et al.,
476 2018) and correlation (Fig. 5). Finally, the contribution of VCPs and fossil fuel sources to ASOA
477 is similar across the cities, expanding upon and further supporting the conclusion of McDonald
478 et al. (2018) in the importance of identifying and understanding VCP emissions in order to
479 explain ASOA.

480

481 **4. Improved Urban SIMPLE Model Using Multi-Cities to Constrain**

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

4.1 Updates to the SIMPLE Model

With the combination of the new dataset, which expands across urban areas on three continents, the SIMPLE parameterization for ASOA (Hodzic and Jimenez, 2011) is updated in the standard GEOS-Chem model to reproduce observed ASOA in Fig. 5a. The parameterization operates as represented by Eq. 9.

$$\text{Emissions} \rightarrow \text{SOAP} \xrightarrow{k \times [OH]} \text{ASOA} \qquad \text{Eq. 9}$$

SOAP represents the lumped precursors of ASOA, k is the reaction rate coefficient with OH (1.25×10^{-11} cm^3 $molecules^{-1}$ s^{-1}), and [OH] is the OH concentration in molecules cm^{-3}.

SOAP emissions were calculated based on the relationship between ΔSOA/ΔCO and $R_{aromatics}$/ΔCO in Fig. 5a. First, we calculated $R_{aromatics}$/ΔCO (Eq. 10) for each grid cell and time step as follows:

$$\frac{R_{aromatics}}{\Delta CO} = \frac{E_B \times k_B + E_T \times k_T + E_X \times k_X}{E_{CO}} \qquad \text{Eq. 10}$$

Where E and k stand for the emission rate and reaction rate coefficient with OH, respectively, for benzene (B), toluene (T), and xylenes (X). Ethylbenzene was not included in this calculation because its emission was not available in HTAPv2 emission inventory. However, ethylbenzene contributed a minor fraction of the mixing ratio (~ 7%, Table S5) and reactivity (~6%) of the total BTEX across the campaigns. Reaction rate constants used in this study were 1.22×10^{-12}, 5.63×10^{-12}, and 1.72×10^{-11} cm^3 $molec.^{-1}$ s^{-1} for benzene, toluene, and xylene, respectively (Atkinson and Arey, 2003; Atkinson et al., 2006).

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

Second, E_{SOAP}/E_{CO} can be obtained from the result of Eq. 11, using slope and intercept in Fig. 5a, with a correction factor (F) to consider additional SOA production after 0.5 PA equivalent days, since Fig. 5a shows the comparison at 0.5 PA equivalent days.

$$\frac{E_{SOAP}}{E_{CO}} = \left(Slope \times \frac{R_{Aromatics}}{\Delta CO} + Intercept \right) \times F \quad \text{Eq. 11}$$

Where slope is 24.8 and intercept is –1.7 from Fig. 5a. F (Eq. 12) can be calculated as follows:

$$F = \frac{ASOA_{t=\infty}}{ASOA_{t=0.5d}} = \frac{SOAP_{t=0}}{SOAP_{t=0} \times (1 - exp(-k \times \Delta t \times [OH]))}, \Delta t = 43200\ s \quad \text{Eq. 12}$$

F was calculated as 1.8 by using [OH] = 1.5×10^6 molecules cm^{-3}, which was used in the definition of 0.5 PA equivalent days for Fig. 5a.

Finally, E_{SOAP} can be computed by multiplying CO emissions (E_{CO}) for every grid point and time step in GEOS-Chem by the E_{SOAP}/E_{CO} ratio.

4.2 Results of Updated SIMPLE Model

The SIMPLE model was originally designed and tested against the observations collected around Mexico City (Hodzic and Jimenez, 2011). It was then tested against observations collected in Los Angeles (Hayes et al., 2015; Ma et al., 2017). As both data sets have nearly identical ΔSOA/ΔCO and R_{BTEX} (Fig. 4 and Fig. 5), it is not surprising that the SIMPLE model did well in predicting the observed ΔSOA/ΔCO for these two urban regions with consistent parameters. Though the SIMPLE model generally performed better than more explicit models, it generally had lower skill in predicting the observed ASOA in urban regions outside of Mexico City and Los Angeles (Shah et al., 2019; Pai et al., 2020).

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

This may stem from the original SIMPLE model with constant parameters missing the ability to change the amount and reactivity of the emissions, which are different for the various urban regions, versus the ASOA precursors being emitted proportionally to only CO (Hodzic and Jimenez, 2011; Hayes et al., 2015). For example, in the HTAP emissions inventory, the CO emissions for Seoul, Los Angeles, and Mexico City are all similar (Fig. S6); thus, the original SIMPLE model would suggest similar ΔSOA/ΔCO for all three urban locations. However, as shown in Fig. 4 and Fig. 5, the ΔSOA/ΔCO is different by nearly a factor of 2. The inclusion of the emissions and reactivity, where R_{BTEX} for Seoul is approximately a factor of 2.5 higher than Los Angeles and Seoul, into the improved SIMPLE model better accounts for the variability in SOA production, as shown in Fig. 5. Thus, the inclusion and use of this improved SIMPLE model refines the simplified representation of ASOA in chemical transport models and/or box models.

5. Preliminary Evaluation of Worldwide Premature Deaths Due to ASOA with Updated SIMPLE Parameterization

The improved SIMPLE parameterization is used along with GEOS-Chem to provide an accurate estimation of ASOA formation in urban areas worldwide and provide an ability to obtain realistic simulations of ASOA based on measurement data. We use this model to quantify the attribution of $PM_{2.5}$ ASOA to premature deaths. Analysis up to this point has been for PM_1; however, both the chemical transport model and epidemiological studies utilize $PM_{2.5}$. For ASOA, this will not impact the discussion and results here because the mass of OA (typically 80–90%) is dominated by PM_1 (e.g., Bae et al., 2006; Seinfeld and Pandis, 2006), and ASOA is

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

543 formed mostly through condensation of oxidized species, which favors partitioning onto smaller
544 particles (Seinfeld and Pandis, 2006).

545 The procedure for this analysis is described in Fig. 7 and Sect. 2.5 and 2.6. Briefly, we
546 combine high-resolution satellite-based $PM_{2.5}$ estimates (for exposure) and a chemical transport
547 model (GEOS-Chem, for fractional composition) to estimate ASOA concentrations and various
548 sensitivity analysis (van Donkelaar et al., 2015). We calculated ~3.3 million premature deaths
549 (using the Integrated Exposure-Response, IER, function) are due to long-term exposure of
550 ambient $PM_{2.5}$ (Fig. S7, Table S14), consistent with recent literature (Cohen et al., 2017).

551 The attribution of ASOA $PM_{2.5}$ premature deaths can be calculated one of two ways: (a)
552 marginal method (Silva et al., 2016) or (b) attributable fraction method (Anenberg et al., 2019).
553 For method (a), it is assumed that a fraction of the ASOA is removed, keeping the rest of the
554 $PM_{2.5}$ components approximately constant, and the change in deaths is calculated from the deaths
555 associated with the total concentration less the deaths calculated using the reduced total $PM_{2.5}$
556 concentrations. For method (b), the health impact is attributed to each $PM_{2.5}$ component by
557 multiplying the total deaths by the fractional contribution of each component to total $PM_{2.5}$. For
558 method (a), the deaths attributed to ASOA are ~340,000 people per year (Fig. 8); whereas, for
559 method (b), the deaths are ~370,000 people per year. Both of these are based on the IER response
560 function (Cohen et al., 2017).

561 Additional recent work (Burnett et al., 2018) has suggested less reduction in the
562 premature deaths versus $PM_{2.5}$ concentration relationship at higher $PM_{2.5}$ concentrations, and
563 lower concentration limits for the threshold below which this relationship is negligible, both of
564 which lead to much higher estimates of $PM_{2.5}$ associated premature deaths. This is generally

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

565 termed the Global Exposure Mortality Model (GEMM). Using the two attribution methods
566 described above (a and b), the ASOA $PM_{2.5}$ premature deaths are estimated to be ~640,000
567 (method a) and ~900,000 (method b) (Fig. S7 and Fig. S10 and Table S15).

568 Compared to prior studies using chemical transport models to estimate premature deaths
569 associated with ASOA (e.g., Silva et al., 2016; Ridley et al., 2018), which assumed non-volatile
570 POA and "traditional" ASOA precursors, the attribution of premature mortality due to ASOA is
571 over an order of magnitude higher in this study (Fig. 9). This occurs using either the IER and
572 GEMM approach for estimating premature mortality (Fig. 9). For regions with larger populations
573 and more $PM_{2.5}$ pollution, the attribution is between a factor of 40 to 80 higher. This stems from
574 the non-volatile POA and "traditional" ASOA precursors over-estimating POA and
575 under-estimating ASOA compared to observations (Schroder et al., 2018). These offsetting
576 errors will lead to model predicted total OA similar to observations (Ridley et al., 2018; Schroder
577 et al., 2018), yet different conclusions on whether POA versus SOA is more important for
578 reducing $PM_{2.5}$ associated premature mortality. Using a model constrained to atmospheric
579 observations (Fig. 5 and Fig. 6, see Sect. 4) leads to a more accurate estimation of the
580 contribution of ASOA to $PM_{2.5}$ associated premature mortality that has not been possible in prior
581 studies. We note that ozone concentrations change little as we change the ASOA simulation (see
582 Sect. S4 in the SI and Fig. S12).

583 A limitation in this study is the lack of sufficient measurements in South and Southeast
584 Asia, Eastern Europe, Africa, and South America (Fig. 1), though these areas account for 44% of
585 the predicted reduction in premature mortality for the world (Table S14). However, as
586 highlighted in Table S16, these regions likely still consume both transportation fuels and VCPs,

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

587 although in lower per capita amounts than more industrialized countries. This consumption is
588 expected to lead to the same types of emissions as for the cities studied here, though more field
589 measurements are needed to validate global inventories of VOCs and resulting oxidation
590 products in the developing world. Transportation emissions of VOCs are expected to be more
591 dominant in the developing world due to higher VOC emission factors associated with inefficient
592 combustion engines, such as two-stroke scooters (Platt et al., 2014) and auto-rickshaws (e.g.,
593 Goel and Guttikunda, 2015). Also, unlike many of the cities studied here, solid fuels are used for
594 residential heating and cooking, which impact the outdoor air quality as well (Hu et al., 2013,
595 2016; Lacey et al., 2017; Stewart et al., 2020), and which also lead to SOA (Heringa et al.,
596 2011). Recently, emission factors from Abidjan, Côte d'Ivoire, a developing urban area, showed
597 the dominance of emissions from transportation and solid fuel burning, with BTEX being an
598 important fraction of the total emissions, and that all the emissions were efficient in producing
599 ASOA (Dominutti et al., 2019). Further, investigation of emissions in New Delhi region of India
600 demonstrated the importance of both transportation and solid fuel emissions (Stewart et al.,
601 2020; Wang et al., 2020) while model comparisons with observations show an underestimation
602 of OA compared to observations due to a combination of emissions and OA representation (Jena
603 et al., 2020). Despite emission source differences, SOA is still an important component of $PM_{2.5}$
604 (e.g., Singh et al., 2019) and thus will impact air quality and premature mortality in developing
605 regions. Admittedly, though, our estimates will be less accurate for these regions.
606

607 **6. Conclusions**

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

In summary, ASOA is an important, though inadequately constrained component of air pollution in megacities and urban areas around the world. This stems from the complexity associated with the numerous precursor emission sources, chemical reactions, and oxidation products that lead to observed ASOA concentrations. We have shown here that the variability in observed ASOA across urban areas is correlated with R_{BTEX}, a marker for the co-emissions of IVOC from both transportation and VCP emissions. Global simulations indicate ASOA contributes to a substantial fraction of the premature mortality associated with $PM_{2.5}$. Reductions of the ASOA precursors will reduce the premature deaths associated with $PM_{2.5}$, indicating the importance of identifying and reducing exposure to sources of ASOA. These sources include emissions that are both traditional (transportation) as well as non-traditional emissions of emerging importance (VCPs) to ambient $PM_{2.5}$ concentrations in cities around the world. Further investigation of speciated IVOCs and SVOCs for urban areas around the world along with SOA mass concentration and other photochemical products (e.g., O_x, PAN, and HCHO) for other urban areas, especially in South Asia, throughout Africa, and throughout South America, would provide further constraints to improve the SIMPLE model and our understanding of the emission sources and chemistry that leads to the observed SOA and its impact on premature mortality.

Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

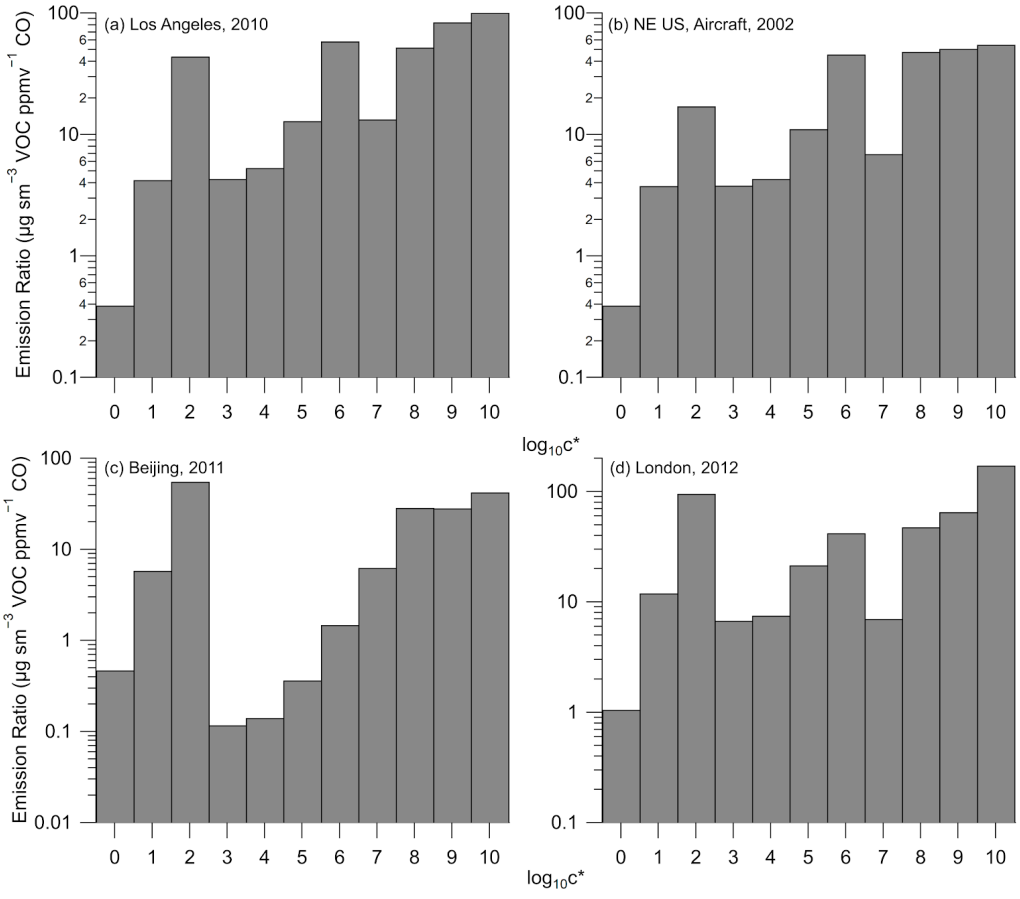
682

683



684 **Figure 3**. Emission ratio versus saturation concentration ($\log_{10}$(c*)) for (a) Los Angeles, (b) NE
685 US, aircraft, (c) Beijing, and (d) London. The emission ratios for VOCs ($\log_{10}$(c*) ≥ 7) were
686 taken from de Gouw et al. (2017) and Ma et al. (2017) for Los Angeles, Warneke et al. (2007) for
687 NE US, aircraft, and Wang et al. (2014) for Beijing while the VOC emission ratio for London is
688 from Table S6 to Table S8. For VOCs between $\log_{10}$(c*) of 3 and 6 (IVOCs), the volatility
689 distribution from McDonald et al. (2018), along with the ratio of IVOC to BTEX from Figure
690 SI-6 and the emission ratio of BTEX (Table S6), were used to determine the emission ratio
691 versus saturation concentration. Finally, for VOCs between $\log_{10}$(c*) 0 and 2 (SVOCs), the
692 volatility distributions from Robinson et al. (2007) for non-fossil fuel POA and from Worton et
693 al. (2014) for fossil fuel POA were used to convert the normalized POA mass concentration
694 (Table S9) to VOC emission ratios. Note, the emission ratio versus saturation concentration for
695 New York City, 2015, was similar to (b), as the emissions were similar (Fig. 2) and the BTEX for
696 New York City is the same as NE US (Table S5).

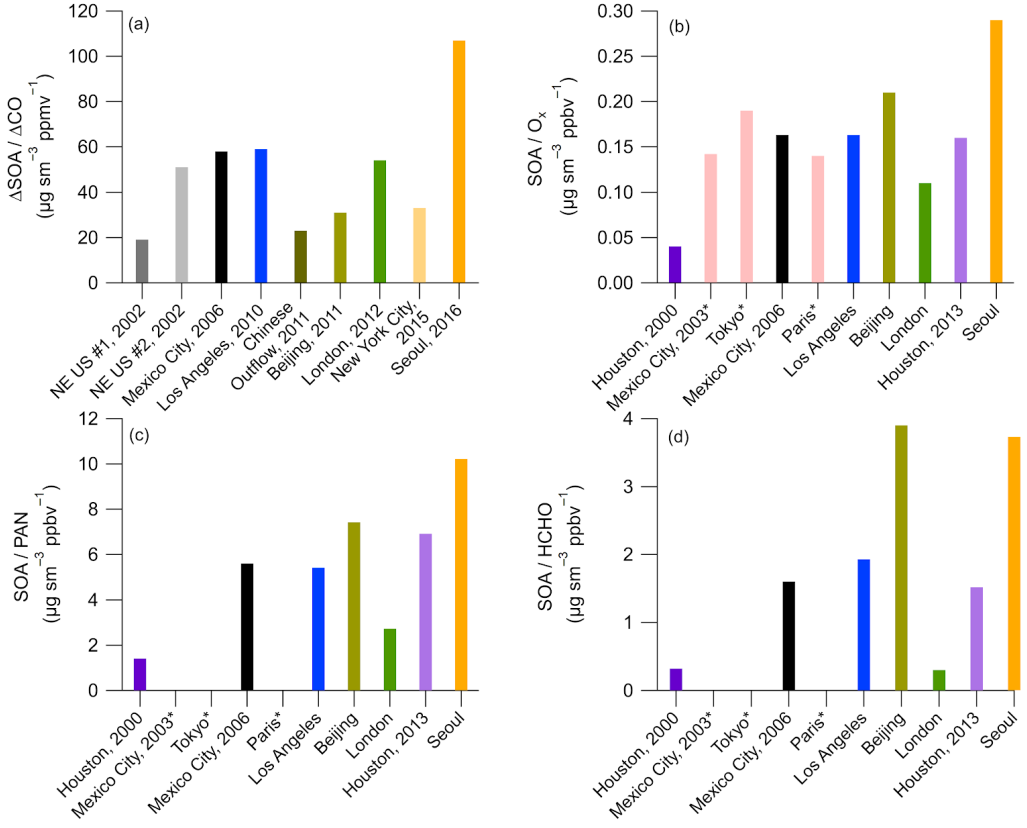

Figure 4. (a) A comparison of the ΔSOA/ΔCO for the urban campaigns on three continents. Comparison of (b) SOA/Ox, (c) SOA/HCHO, and (d) SOA/PAN slopes for the urban areas (Table S4). For (b) through (d), cities marked with * have no HCHO, PAN, or hydrocarbon data.

https://doi.org/10.5194/acp-2020-914
Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

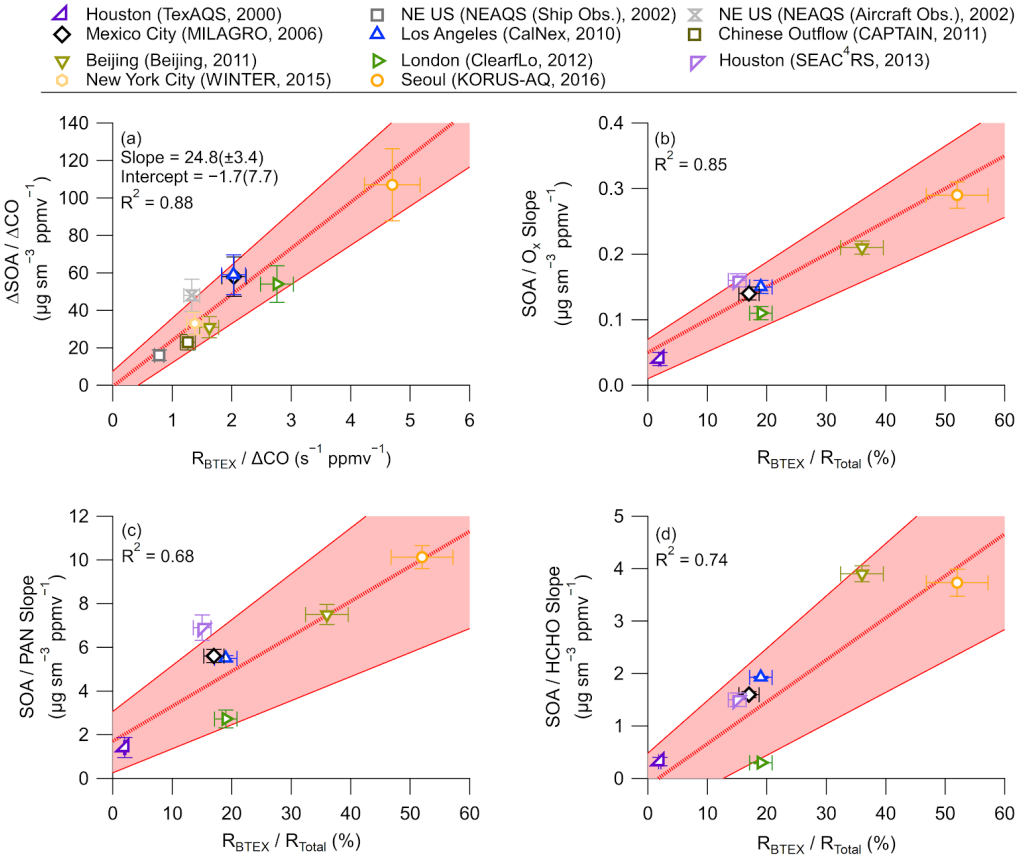

Figure 5. (a) Scatter plot of background and dilution corrected ASOA concentrations (ΔASOA/ΔCO at PA = 0.5 equivalent days) versus BTEX emission reactivity ratio (R_{BTEX}= $\sum_i [VOC/CO]_i$) for multiple major field campaigns on three continents. Comparison of ASOA versus (b) Ox, (c) PAN, and (d) HCHO slopes versus the ratio of the BTEX/Total emission reactivity, where total is the OH reactivity for the emissions of BTEX + C¬2-3 alkenes + C2-6 alkanes (Table S5 through Table S7), for the campaigns studied here. For all figures, red shading is the ±1σ uncertainty of the slope, and the bars are ±1σ uncertainty of the data (see Sect. 2.2).

Preprint. Discussion started: 11 November 2020

Atmospheric Chemistry and Physics Discussions

716

717 **Figure 7**. Flowchart describing how observed ASOA production was used to calculate ASOA in
718 GEOS-Chem, and how the satellite-based $PM_{2.5}$ estimates and GEOS-Chem $PM_{2.5}$ speciation was
719 used to estimate the premature mortality and attribution of premature mortality by ASOA. See
720 Sect. 2 for further information about the details in the figure. SIMPLE is described in Eq. 9 and
721 by Hodzic and Jimenez (2011) and Hayes et al. (2015). The one of two methods mentioned
722 include either the Integrated Exposure-Response (IER) (Burnett et al., 2014) with Global Burden
723 of Disease (GBD) dataset (IHME, 2016) or the new Global Exposure Mortality Model (GEMM)
724 (Burnett et al., 2018) methods. For both IER and GEMM, the marginal method (Silva et al.,
725 2016) or attributable fraction method (Anenberg et al., 2019) are used.
