Abstract. The Ice, Atmosphere, Arctic Ocean Observing System (IAOOS) field experiment took place from 2014 to 2019. Over this period, more than 20 instrumented buoys were deployed at the North Pole. Once locked into the ice, the buoys drifted for periods of a month to more than a year. Some of these buoys were equipped with 808 nm wavelength lidars which acquired a total of 1805 profiles over the course of the campaign. This IAOOS lidar dataset is exploited to establish a novel statistic of cloud cover and of the geometrical and optical characteristics of the lowest cloud layer. Cloud frequency is globally at 75%, and above 85% from May to October. Single layers are thickest in October/November and thinnest in the summer. Meanwhile, their optical depth is maximum in October. On the whole, the cloud cover is very low, with the great majority of first layer bases beneath 120 m. In the shoulder seasons, surface temperatures are markedly warmer when the IAOOS profile contains at least one low cloud than when it does not. This temperature difference is statistically insignificant in the summer months. Indeed, summer clouds have a shortwave cooling effect which can reach $-60 \, \mathrm{W \, m^{-2}}$ and balance out their longwave warming effect.

1 Introduction

The Arctic is a key region of climate change: it is warming about twice as fast as the middle latitudes. This phenomenon, called "Arctic amplification", is most commonly attributed to the ice-albedo feedback, which is due to areas of open ocean exposed by melting sea ice absorbing more solar radiation. However some models with fixed albedos also appear to show amplified warming in the Arctic, pointing to other mechanisms at work (Winton, 2006; Pithan and Mauritsen, 2014). Clouds are one of the main contributors to uncertainty in global climate models because cloud feedbacks and cloud-aerosol interactions are still poorly understood; however, clouds appear to be of particular importance in the Arctic (Tjernström et al., 2008), where they play a very important role in the climate system. Indeed, Arctic clouds are observed to influence the melting of sea ice (Kay and Gettelman, 2009) and may exert control on the ice-albedo feedback this way. However, these effects and processes are seasonally variable and not well represented by annual means (Kay and Gettelman, 2009).

Firstly, the cloud cover in the Arctic has a large seasonal variability: it is especially extensive in the summer and reaches a minimum in the winter (Curry et al., 1988, 1996). This result is well attested in the literature although values and trends tend to differ between studies and instruments. For example, during the Surface Heat Balance of the Arctic (SHEBA) campaign, winter cloud occurrence measured from a combined radar/lidar was 70%. It increased to over 80% in the summer months and reached

a 95% peak in September (Shupe et al., 2006). Using data from CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations), Zygmuntowska et al. (2012) find two peaks of 85% and 90% in May and October respectively, and a minimum in January-March around 70%, in good agreement with Shupe et al. (2006). However, in the same study, cloud fractions retrieved from the space-borne Advanced Very-High-Resolution Radiometer (AVHRR) instrument were < 60% for
30   the whole October-April period, and never rose above 80%.

Cloud microphysical characteristics and radiative impact are also seasonally-dependant. Winter clouds contain mostly ice and are therefore less emissive than summer liquid-containing clouds, although mixed-phased clouds maintain themselves throughout the year (Morrison et al., 2011). However, seasonal statistics of cloud optical depth (COD) over the Arctic ocean are scarce and uncertain: based on the AVHRR radiometer data for example, Wang and Key (2004) found a slight seasonal
35   variation in the cloud optical depth over the Arctic ocean, with a peak in May and October (> 6) and lower values (≈ 5) in the winter. It has been shown that cloud radiative forcing is positive (i.e., clouds warm the surface) for much of the year, except for a short period in late June to early July when the cloud shortwave forcing is larger than the longwave forcing (Intrieri et al., 2002a). Indeed, in contrast to winter, clouds impact the surface radiative budget in two competing ways in the summer. As in winter, they provide longwave warming; but they also have a shortwave cooling effect, by preventing solar radiation from
40   reaching the surface.

Large uncertainties remain about the characteristics of Arctic clouds and their surface impact, in part because more data and observations are needed (Kay et al., 2016). Ground-based measurements are sparse in the Arctic because of the harsh conditions and the lack of permanent settlements. The ground-based measurement stations of the International Arctic Systems for Observing the Atmosphere (IASOA) network (Uttal et al., 2016), for example Eureka (Nunavut, Canada) or Barrow (Alaska)
45   are necessarily coastal. Measurements on the sea-ice take the form of ship-based or airborne campaigns, covering only a narrow spatial and temporal window. The first such campaign was SHEBA, which covered a full year from October 1997 to October 1998. Although it yielded significant results (Stramler et al., 2011; Shupe et al., 2006), it is now more than 20 years old and not representative of the modern Arctic. Subsequent campaigns aimed at studying the Arctic's changing conditions such as the Arctic Summer Cloud Ocean Study (ASCOS) (Tjernström et al., 2014), the Arctic Clouds in Summer Experiment (ASCE)
50   (Sotiropoulou et al., 2016) or the Norwegian Young Sea Ice Experiment (N-ICE) (Walden et al.) covered one to six months, disproportionately in the summer. Most recently, the Multidisciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC) campaign is a one year-long study of the Arctic climate, with clouds as one of many research axes. The drift is due to end in September 2020.

In this context, many established statistics - e.g., Wang and Key (2004) - make use of satellite measurements, which have
55   large coverage but are flawed at high latitudes. Indeed, spectroradiometers (such as MODIS, or the AVHRR) may have difficulties in distinguishing clouds from the underlying sea-ice. Their performance also differs between the dark winter months and the summer (Zygmuntowska et al., 2012). All in all, there are large differences in measured values between instruments (Chan and Comiso, 2013). Satellite-based lidars such as the instrument aboard CALIPSO give more reliable measurements but are limited to 82°N because of the satellite flight path (Winker et al., 2009).

60   This paper presents results of the Ice, Atmosphere, Arctic Ocean Observing System (IAOOS) field experiment lidar measurements. This novel database offers a ground-based view of lower tropospheric clouds at very high latitudes (over 80°N) over a significant period of time - from 2014 to 2019 (Mariage, 2015). A small part of this dataset has already been analysed in Di Biagio et al. (2018) and Mariage et al. (2017). Here it is treated as a whole to extract a 5 year statistic of the Arctic cloud cover. First, the IAOOS field campaign and other relevant datasets are presented (Sect. 2). Then the treatment of the IAOOS

65   lidar data and the derivation of cloud characteristics are explained (Sect. 3). The obtained statistics of cloud frequency, and geometrical and optical properties are presented in Sect. 4.1 and the impact of the clouds on surface radiation and temperature is explored in Sect. 4.2 and 4.3.

2   Data used

2.1   The IAOOS field campaign: a 5 year study of the Arctic troposphere

70   #### 2.1.1   Deployed instruments

The IAOOS field experiment was led by Sorbonne University - through the LATMOS and LOCEAN laboratories - with the support of several structures, among which the French polar institute IPEV (Institut polaire français Paul-Emile Victor) and the technical division of the Institute for Earth Sciences and Astronomy (CNRS-INSU) from 2014 to 2019. The main campaign objective was to "collect real time observations of the ocean, ice, snow and atmosphere of the Arctic", offering a complementary

75   viewpoint to that of satellites (L2). In order to do this, several instruments were installed on an autonomous floating platform (or buoy). These buoys were then locked into the pack ice and left to drift with it for a duration of several months to a year. During that time period, the buoys were tracked by GPS and communicated the acquired data to the IPEV office in Brest (48°23′24″ N, 4°29′24″ W) every day.

The main instrument on the "atmosphere" side of the buoys was a micro lidar, which was was designed to study lower

80   troposphere and has a clear-sky range of around 4.4 km in the daytime, and 13.7 km at night, with a vertical resolution of 15 m (Mariage, 2015; Mariage et al., 2017). The wavelength was chosen in the near infrared (808 nm) in order to avoid disturbing the local fauna while maintaining a distinct molecular signal. This is similar to many commercial ceilometers (Mariage, 2015). However, it had to be custom made to resist the tough Arctic conditions. Indeed, several key components of a lidar are sensitive to ambient temperature variations, and the buoys' operating conditions in the pack ice could be up to 40°C colder than the lab

85   where it was calibrated. The lidar therefore had to be modified and isolated in order to keep it at a near constant temperature (Mariage, 2015). Furthermore, the tube containing the lidar emitter and receiver was topped with a window that, in operating conditions, was often covered by frost. This layer of frost attenuates the signal, and, in extreme cases, totally blinds the lidar. In order to overcome this problem a window heating system was put in place. The actual heating was limited to the 10-minute interval before the two- to four-time daily profile acquisition in order to avoid draining the battery too fast. Theoretically, this

90   ensured that the lidar window was clear during measurement. However, in practice, the frost prevented lidar measurements from mid-December to early March. The frost problem will be further detailed in Sect. 3.1.1.
Figure 1. Map of the IAOOS buoy tracks, 2014-2019 (this map only includes buoys which delivered the lidar data exploited in this article). The different colours correspond to the different buoys, with the year of launch indicated. The red circle corresponds to the 82°N latitude: north of this circle, no satellite lidar data is available.

The buoys were also equipped with temperature and pressure sensors for measuring outside conditions; and internal temperature and humidity sensors for monitoring the lidar system. On the underwater portion of the buoys, a float measured ocean temperature and salinity while an Ice Mass Balance system acquired temperature profiles of the snow, ice and liquid water layers - see Koenig et al. (2016).

2.1.2 Buoys and tracks

The first IAOOS platform was deployed in 2013. Since then, more than 20 buoys have drifted in the Arctic pack ice, and the last one was deployed in August 2019. However, not all buoys were equipped with lidars and not all deployed lidars operated successfully. In particular, the data transmission system of the 2016 buoys functioned poorly, and there are no exploitable lidar profiles from July 2015 to March 2017 (see Table 1). All in all, five buoys yielded usable lidar data, amounting to 1805 profiles covering the March to December months. A vast majority of the drift took place north of 82°N (red line, Fig. 1). Furthermore, apart from one buoy, all trajectories were confined to the Atlantic sector of the Arctic, reflecting the transpolar drift stream. Indeed, most buoys studied here were locked into the ice close to the North Pole.

Buoy	Start date	End date	Nb of exploitable profiles
B02	13/04/2013	02/12/2014	462
B12	26/04/2015	05/06/2015	73
B24	06/04/2017	20/11/2017	322
B25	15/08/2017	28/10/2018	429
B27	19/04/2018	17/03/2019	519

Table 1. Start and end date of the buoy lidar data acquisition and number of exploitable profiles. Note that buoy B07 also yielded some profiles (Di Biagio et al., 2018) which are not treated here.

2.2 Other data

2.2.1 N-ICE

Four IAOOS buoys were deployed during the Norwegian Young Sea Ice Experiment (N-ICE) campaign, which took place from January to June 2015 aboard the R/V Lance research vessel (Walden et al.). The buoys drifted in the sea-ice close to the research vessel. The goal of this field campaign was to investigate thin, first-year sea-ice and its interactions with the rest of the Arctic system; instruments deployed included an MicroPulse Lidar (MPL) to determine cloud phase and a four component radiometer. Radiosondes were also launched twice-daily, yielding profiles of relative humidity, temperature and wind speed. The radiative flux and meteorological data from the second period (April to June) of this campaign were in this study as a complement to the IAOOS data (see Sect. 4.2.1 and 4.3).

2.2.2 ERA5

ERA5 is the new reanalysis from the European Center for Medium-Range Weather Forecast, replacing ERA-Interim. ERA5 provides hourly or four times daily estimates of many weather variables on a 0.25°x0.25° grid and with 137 vertical levels. It is made available online with a three month delay (L1). Here we interpolated the ERA5 values on the IAOOS positions using bilinear interpolation in space (and linear interpolation in time) during the N-ICE drift period. This allowed us to compare the radiative flux values measured during N-ICE with the ERA5 reanalyses (see Sect. 4.2.1).

3 Methodology of the IAOOS lidar data treatment

120 ### 3.1 Overcoming Arctic-specific challenges

3.1.1 Lidar window frost

Several problems are associated with the autonomous drift of a lidar in harsh Arctic conditions, as outlined in Sect. 2.1. In particular, the cold conditions cause frost to form on the lidar window, because the installed window heating system could not operate the whole time in order to preserve batteries. This caused the signal to be attenuated and therefore the system constant

125 C - which is the ratio of the raw signal in photon numbers to the actual signal - to diminish.

Because it is crucial to know the system constant value in order to extract geophysical information from the raw lidar signal, this effect had to be corrected. The correction method was put in place by Mariage (2015). First a "frost index", γ is defined:

$$\gamma = \frac{P_0}{P}$$

where P is the lidar window reflection peak, and P_0 the minimal value taken by P over the course of a drift. P_0 is therefore assumed to be the value of the reflection peak when the window is entirely frost-free. γ then ranges from approximately 1 when

130 the window is frost free to very low values ($< 5 \cdot 10^{-2}$) when the window is totally opaque. In fact, this frost index becomes a proxy for the window transmittance.

Under the assumption that aerosol load is very low in the high Arctic, C can be calculated from cloud-free profiles. Its values are then compared to the frost index. As could be expected, $\frac{1}{C}$ diminishes with γ: that is, the signal is dampened when the window is covered with frost. An empirical fit of $\frac{1}{C}$ as a function of γ can then be established (Mariage, 2015). This allows us

135 to deduce the value of C for each profile from the value of γ. The fitting coefficients were determined independently for each buoy when possible, since the frost index depends on P_0, which is buoy specific.

It should be noted however that when the frost is too thick, no usable signal is recoverable. This means that there were no exploitable lidar profiles in late December to early March.

3.1.2 Receiver saturation due to reflective low clouds

140 The detectors used in the IAOOS lidar are avalanche photodiodes, and can reach saturation. This means that if they are exposed to a signal which is too intense, the photon count goes down. If the saturation is very intense, the photon count can even reach zero (Exc, 2018). Following saturation, the photon number count then slowly increases back up to its normal background value. Saturation is not usually an issue in most lidar operation situations; however during the Arctic summer, background noise levels are high due to shortwave radiation and the reflective sea ice and the signal reflected by the very low cloud cover is often enough

145 to saturate the detector. This problem was observed from the very first deployment of the IAOOS buoys (Mariage, 2015). It translates visually into a lidar signal which dips below background noise levels at a certain altitude, and then slowly increases back to the background. Over the whole IAOOS period, approximately 30% of profiles were concerned by this phenomenon.

Atmospheric
Chemistry
and Physics
Discussions

A saturated profile may contain some geophysical data above the saturation altitude; therefore, it was important to correct this effect. We hypothesised that the saturated signal S_{sat} resulted from the convolution of the "true" signal S with a saturation

150   impulse response function (IRF):

$$S_{sat}(z) = S(z) * IRF(z)$$

The goal was therefore to deduce S from the measured profile, i.e. S_{sat}. A deconvolution algorithm was therefore put into place (Richardson, 1972; Refaat et al., 2008). The deconvolution process recovered useful signal from the saturated profiles in about a third of cases. In the remaining two-thirds, the "true" signal was only background noise. This represented an appreciable gain in data for the IAOOS campaign.

155   ## 3.2 Derivation of cloud characteristics from raw lidar data

The lidar profile treatment program is a simplified version of the CALIPSO treatment algorithm described by Winker et al. (2009).

3.2.1 Attenuated scattering ratio calculation

The first step involves calculating the attenuated scattering ratio:

160    $$SR_{att} = \frac{(S - B) \cdot z^2}{C \cdot O(z) \cdot \beta_m(z) T_m(z)^2} = (1 + \frac{\beta_p(z)}{\beta_m(z)}) \cdot T_p(z)^2 \tag{1}$$

where

- S is the raw signal

- B the background noise (calculated as the mean of the raw signal above 20 km, where there is no geophysical signal due to attenuation)

165   - z the altitude above the lidar, which is at sea level

- C is the system constant, which varies with the lidar window frost as described above

- $O(z)$ is the overlap factor between the lidar source and receiver: this factor is determined for each buoy as the average ratio of the raw signal to the calculated Rayleigh signal for very clear, cloudless days. The overlap creates a minimum height underneath which the signal cannot be resolved: a sort of lidar "blind zone".

170   The Rayleigh (molecular) backscatter and transmission are calculated according to Bucholtz (1995), using vertical temperature and pressure profiles from ERA5 reanalyses.

Atmospheric
Chemistry
and Physics
Discussions

3.2.2 Cloud detection

Clouds are then detected by applying a threshold to SR_{att}, since in the absence of particulate attenuation the attenuated scattering ratio will be equal to 1 ($\beta_p = 0$, $T_p^2 = 1$). The initial threshold, S_t, is set to 1.1 at $z = 0$ and increases with altitude in order to take into account that noise increases on the vertical (Winker and Vaughan, 1994).

The base of a feature is detected when seven consecutive points are above the threshold. The top is detected either when SR_{att} has fallen beneath the threshold and has stopped decreasing (a condition inspired by Winker and Vaughan (1994)) or when the signal is below the noise level. The noise level is defined as $2\sigma z^2$, where σ is the standard deviation of the raw signal above 20 km. Assuming gaussian noise, 95% of pure noise fluctuations are therefore beneath this level.

Above the features, SR_{att} will again be constant but equal to $T_f^2(z_{top})$, where z_{top} is the top altitude of the features and T_f its transmission, because of the particle attenuation. This means that new features above this feature will be missed unless the threshold is modified to take the feature attenuation into account. Therefore, above a feature, the threshold is updated to $T_f^2 \cdot S_t$.

Once detected, a feature is determined to be a cloud if its spread, defined as the ratio of maximum feature SR_{att} to average below-feature SR_{att}, is greater than 100 (or 20 for higher-altitude layers for which average below-feature SR_{att} is strongly impacted by noise).

3.2.3 Calculation of optical depth and lidar ratio

When the lidar beam goes through the cloud layer and reaches the particle-free air on the other side, the cloud transmission can be directly calculated as the ratio of the mean SR_{att} above and below the cloud layer over a minimum of 20 points (or 300 m).

However, this was rarely the case during IAOOS, especially in the summer when the noise level is high. Over the whole IAOOS campaign, only 14% of all features were transparent to the lidar. In all other cases, T_c^2 was calculated from the integrated attenuated backscatter (IAB), assuming a constant lidar - or backscatter-to-extinction - ratio S_c within the cloud layer:

$$IAB = \int_{z_0}^{z_1} \beta_p(z) \cdot e^{-2\int_{z_0}^z \eta\alpha_p(z')dz'} dz = \frac{1}{2\eta S_c}(1 - T_c^2) \qquad (2)$$

with z_0 and z_1 the bottom and top of the cloud, and η the multiple scattering coefficient (Platt, 1973). The IAB can then be calculated from the attenuated scattering ratio and molecular backscatter (Winker et al., 2009) :

$$IAB \approx \int_{z_0}^{z_1} SR_{att}(z) \cdot \beta_m(z)dz$$
$$-\frac{1}{2}(z_1 - z_0) \cdot (\beta_m(z_0)SR_{att}(z_0) + \beta_m(z_1)SR_{att}(z_1)) \qquad (3)$$

The (relatively few) cases where the cloud layer transmission could be independently calculated were used to derive values of the multiple-scattering lidar ratio $S^* = \eta S_c$ by inverting Eq. (2).

For both Rayleigh- and IAB-derived T_c, the cloud optical depth τ_c can then be deduced:

$$T_c = e^{-\eta \cdot \tau_c} \qquad (4)$$

Atmospheric
Chemistry
and Physics
Discussions

200   The multiple-scattering coefficient η was assumed constant and equal to 0.8, based on previous analyses of the IAOOS data (Mariage et al., 2017; Di Biagio et al., 2018).

3.2.4   Uncertainty and limits of the method

Equation (2) implies that as $T_c^2 \to 0$, $IAB \to \frac{1}{2\eta S_c}$. This means that for optically thick clouds, a small error on the value of IAB or S_c risks propagating to a large error on COD. The error is also asymmetrical: an overestimation of IAB or S_c yields

205   a much worse result on COD than an underestimation of these same quantities. In practice, if the lidar ratio of a cloud of true optical depth 1.5 is underestimated by 10%, the measured optical depth will be ≈ 1.1. On the other hand, if it is overestimated by the same amount, the measured optical depth will be ≈ 2.2. In some cases, overestimation of lidar ratio or IAB can even lead to negative T_c^2 values, which is non-physical and doesn't allow for the calculation of optical depth. In practice, therefore, this method is appropriate mainly for optically thinner cloud layers. We will refer to "low-IAB" cloud layers, for which the

210   method does not lead to non-physical results (i.e., the cloud layer is thin enough that this method works well). This accounts for 42% of all features. We will call "high-IAB" cloud layers those for which calculated T_c^2 is negative. These mathematically correspond to clouds with higher IAB, and therefore higher COD, than low-IAB cases. The inclusion of these high-IAB COD values in the statistic will be discussed in Sect. 4.1.3.

Although uncertain in other respects, this COD calculation method has the advantage of being only faintly impacted by

215   background noise levels. On the other hand, noise levels can have a strong impact on the cloud top determination. Tests with simulated lidar signals indicate that cloud top determination error reaches up to 150 m for typical summer noise levels and optically thicker clouds ($\tau_c \approx 2.5$). This error is much lower for low noise levels, such as are found in the high Arctic during the polar night (October - March). This difference must be kept in mind when interpreting seasonal variation of cloud geometrical thickness (Sect. 4.1.2).

220   ## 4   Results & discussion

4.1   Seasonal variability of Arctic low clouds and their impact on surface temperatures

4.1.1   Frequency of cloud presence

IAOOS data confirms that low clouds (i.e., with a base under 2 km) are very frequent in the Arctic, especially in the summer. Global low cloud frequency from March to December, defined as the average of monthly ratios of profiles containing at least

225   one cloud with base lower than 2 km to all profiles, is 75%. This value is coherent with previous statistics of cloud fraction above 80°N derived from satellites, for example Wang and Key (2004) and Curry et al. (1996), which usually give a global annual cloud cover of around $60 - 70\%$, with a maximum in summer and a minimum in November - April.

Observed seasonal variation of cloud fraction can differ strongly between satellites (Wang and Key, 2004; Zygmuntowska et al., 2012). Chan and Comiso (2013) found large disagreements between MODIS and CALIOP in the Arctic, for example,

230   especially over sea-ice and during the polar night. This is because MODIS finds it difficult to differentiate between the surface
Figure 2. Monthly variation of low cloud frequency, defined as the number of profiles that contain at least one cloud layer with base lower than 2 km divided by the total number of profiles for the month, for five IAOOS buoys. The dashed line represents the total monthly cloud frequency over all IAOOS profiles. It is only calculated for months with more than 30 profiles in total.

and the clouds when relying only on IR channels. On the other hand, Blanchard et al. (2014) shows that there is good general agreement and similar trends in cloud fraction over Eureka (Nunavut, Canada) between CALIOP, MODIS, CloudSat and the IIR instrument aboard CALIPSO, with a global maximum in September - November and a minimum in March - May. However, discrepancies between passive and active instruments remain (Blanchard et al., 2014). Ground-based measurements play a key

235 part in quantifying seasonal cloud cover variability in the Arctic, although they are often sensitive primarily to lower-level clouds. Averaging ship and ice-camp data above 80°N, Hahn et al. (1995) found that cloud cover was globally stable around 60% in winter, increasing to 80% from April to June, and decreasing again from September to November. A maximum of 85% was reached in August/September. The combined lidar-radar measurements at SHEBA give slightly higher values of 70% in winter and 90% in summer, with an earlier transition (February to April) and a peak in September (Intrieri et al., 2002b). The

240 IAOOS data shows a similar trend, with generally higher cloud cover values. From May to October, clouds are present over 85% of the time (Fig. 2), decreasing to 60% in April and November, which appear to be the transition months. In contrast to the previous ground-based climatologies outlined above, there are two peaks at more than 90% in the monthly cloud frequency, although they differ little from the summer baseline. The first is in June, although there is strong variability between years and buoys in this month (see below). The second peak, which is very consistent for every year and buoy, is in October. This is

245 reminiscent of the results of Zygmuntowska et al. (2012), from CALIPSO data, which show a peak in cloud occurrence above 90% in October.

IAOOS cloud frequency has the greatest interannual variability in spring to early summer (April to June), and appears most consistent in September - October. In 2014, the B02 buoy observed a very sharp spring transition in cloud frequency: from 40% in April to more than 90% in May and June (blue circles, Fig. 2). On the other hand, this transition was much more gradual

250 in 2017 (buoy B24, orange diamonds: the June cloud frequency is less than 80%). This is not an effect of spatial variability as both B02 and B24 were drifting in the Atlantic sector of the Arctic (Fig. 1).

It has been observed from satellite data that the Atlantic sector is the cloudiest part of the Arctic Ocean (Liu et al., 2012; Wang and Key, 2004). This is linked to the low pressure systems and the storm tracks arriving from the northern Atlantic

10

Month	N_p (#)	$\frac{N_{ml}}{N_{profiles}}$ (%)	First cloud base (%)			
			$<$ 120m	$120-$ 500m	500m -2km	$2-$ 5km

Oct	98	13	98	2	0	0
Nov	54	2	93	3	3	0
Dec	44	0	93	7	0	0

Table 2. Cloud multiple layer and base characteristics for all profiles from March to December. N_p is the total number of lidar profiles for each month, and N_{ml} is the number of profiles containing multilayered clouds. The last four columns represent the % of first layer cloud bases in each altitude range. The 120 m cutoff corresponds to the minimum altitude at which the lidar overlap factor can be corrected for all buoys. Cloud bases above 5 km, which correspond to "high-level" clouds in many reanalyses such as ERA5, are not included because the lidar range in perfectly clear daytime conditions is only 4.4 km (Sect. 2.1).

Ocean. This is not supported by the IAOOS data: there is little difference in cloud frequency between buoy B25, which drifted
255 to the Laptev sea from summer to autumn 2018, and buoy B27, which at that time was drifting in the Atlantic sector. However, the IAOOS dataset lacks spatial coverage for a robust determination of the ocean-wide variability of cloud cover.

The results above pertain to the low cloud cover, i.e. clouds with a base underneath 2 km. Clouds with a base between $2-5$ km are much rarer in the IAOOS dataset, occurring only 3% of the time from March to December, with a peak at 8% in July. However, as the lidar signal is often dampened by the first cloud layers, IAOOS statistics of cloud cover above 2 km are 260 expected to be biased low.

4.1.2 Cloud geometrical properties

Multi-layer clouds were detected 7% of the time by the IAOOS lidar over the course of the campaign. This value is small compared to previous observations: for example, Liu et al. (2012) find that multi-layer clouds are present 20% of the time year-round, with very low seasonal variation. These results are drawn from satellite observations and Liu et al. (2012) note that 265 they are also underestimated. Ground-based measurements generally attest to frequent multilayering in the summertime, with layers separated by several hundred meters (Curry et al., 1988, 1996). SHEBA measurements even show that multi-layer clouds exceeded single-layer clouds in June and July 1998, and occurred on average 45% of the time over the whole experiment period
Figure 3. Monthly evolution of first layer cloud geometrical thickness (in km), for five IAOOS buoys. The markers represent the median value, and the whiskers indicate the 25th and 75th percentiles. The open circles represent individual cloud thickness values where the lidar signal sees through the cloud layer, i.e. the cloud top is clearly detected. The median, 25th and 75th percentiles are only calculated when more than 15 data points are available.

(Intrieri et al., 2002b). IAOOS measurements also attest to a higher frequency of multiple layered clouds in summer: they occur more than 10% of the time July - October, and only 4% of the time in April and May (Table 2). November, December and March

270 multilayered cloud occurrence is non-significant. IAOOS measurements strongly underestimate frequency of multilayered clouds due to the fact that the lowest cloud layer entirely attenuates the lidar signal in most profiles. Furthermore, cloud layers separated by less than 300 m were counted as one in the IAOOS data treatment in order to have a better estimation of cloud transmission (Sect. 3.2.3). However, the robust measurement of the geometry of the first cloud layer derived from IAOOS measurements base is a useful statistic. Indeed, the base of the lowest cloud layer is expected to have the strongest impact on

275 surface radiative fluxes as compared to higher cloud layers. Hereafter, all cloud statistics refer to single cloud layers; in most cases, the lowest.

It is clear from the IAOOS database that Arctic clouds are extremely low, with little seasonal variability. From April to December, at least 85% of first layer clouds have a base below 120 m, which is the minimum altitude at which the lidar overlap factor can be corrected for all buoys (Table 2). The median base altitude is therefore at 120 m in nearly every month. In March,

280 only 57% of cloud bases are below 120 m. Another 29% of first layer cloud bases are between 120 and 500 m, which still corresponds to low level, likely boundary layer clouds (note however the low number of profiles in this month). This is in line with the results of previous measurements campaigns. During ASCOS, which took place in August 2008, the lowest cloud base distribution peaked beneath 100 m (Tjernstrom et al., 2012). Median first cloud base from SHEBA measurements (Shupe et al., 2007) was also less than 120 m for all months except March (179 m) and April (209 m). Nevertheless, higher-altitude

285 first cloud layers were more frequent than during IAOOS, especially in spring to early summer (Intrieri et al., 2002b).

On the other hand, Fig. 3 highlights a significant difference in measurements of single-layer cloud geometrical thickness between summer (May to September) and the shoulder months (April, October/November). The median cloud thickness from June to August ranges between 360 and 390 m, whereas it is nearly 750 m in October and March, and more than 1 km in November. As explained in Sect. 3.2.3, it is expected that summer cloud thickness would be underestimated by up to 150 m

290 due to higher noise levels in this period. However, this is too small an error to explain the different median values observed
between summer and spring/autumn. Furthermore, these values and trends are coherent with previous studies of single-layer
clouds at Barrow and Eureka. For example, the average thickness of single-layer clouds at Barrow from June to August 2000
was 320 m while the September average was 550 m (Dong and Mace, 2003). Over the 2005 to 2008 period the average
single-layer mixed-phase cloud thickness at Eureka varied from 200 m to 700 m with maxima in autumn and minima in spring

295 (de Boer et al., 2009). Total thickness of all clouds, single-layered or not, may however be much larger. During SHEBA, median
total cloud thickness from radar data was above 1 km in every month, with peaks at around 3 km in April and October (Shupe
et al., 2007). These values are from 3 (March/April) to 7 (July/August) times larger than the IAOOS monthly median values.

4.1.3 Cloud optical properties

As noted in Sect. 3.2.3, cloud layers for which both IAB and T_c^2 are determined independently can be used to calculate the

300 multiple-scattering lidar ratio S^*. In total, there were 222 such cloud layers during the IAOOS period, covering the March to
December period. They are shown in Fig. 4a, along with the median and the 25th and 75th percentiles for each month. The
global median is 17.5 sr, with 90% of values falling in the $7 - 38$ sr range. Although the spread is quite large, these results are
consistent with cloud lidar ratio values found in the literature. For example O'Connor et al. (2004) found that S^* values ranged
between 14.5 and 16.5 sr for low water clouds; for ice or mixed-phase clouds, the range was $5 - 40$ sr, very similar to IAOOS

305 results.

The seasonal variation of S^* is statistically significant: the median S^* for the summer months (JJA) was 23 sr versus 15.5 sr in
the autumn (SON). The Mann-Whitney U is 4953.5, with $n_1 = 67$, $n_2 = 98$, yielding a p-value of $< 10^{-5}$ (Mann and Whitney,
1947). There are two possible causes for the observed variability in $S^* = \eta S_c$: changes in the multiple scattering coefficient η
or S_c. η decreases with cloud temperature (Garnier et al., 2015) while S_c depends on cloud microphysical properties, among

310 which cloud droplet effective radius and phase. In the absence of additional measurements, it is difficult to determine which
one has the largest impact here, as well as the ultimate physical cause of variation. For example, the very high values observed
in March might be due to the higher occurrence of ice particles in clouds during this period, but could also be suggestive of
Arctic haze. Indeed, Lubin and Vogelmann (2006) found evidence that the cloud droplet effective radius is lower, and S_c is
therefore higher, when aerosol condensation nuclei concentrations are high in the Arctic, independent of other seasonal or

315 temperature effect. In any case, the monthly median values were then used to calculate COD (Sect. 3.2.3).

The average single-layer COD during IAOOS excluding high-IAB cases was 0.9, with values ranging from 0.3 to 2.1. These
values are small when compared to previous satellite and ground based studies in the Arctic. But as noted in Sect. 3.2.4,
the retrieval method used for calculating COD from the IAOOS lidar data when the signal is fully attenuated is not suited to
optically thick clouds: the rough upper bound of COD which can be measured through this method is 2. As almost 20% of cloud

320 layers observed during the campaign were high-IAB, this likely has a non-negligible impact on results. Furthermore, contrarily
to satellite data, IAOOS values are single-layer, not whole column, COD. The contribution of the first layer to total column
COD is discussed in Sect. 4.3. It is therefore understandable that previous studies gave larger COD values. For example, Curry
et al. (1996) cites a range of $2 - 24$ with an average of 8 in summer. Wang and Key (2004) also finds that monthly mean COD
Figure 4. Panel a: monthly variations of lidar ratio values over the IAOOS campaigns. The open circles represent the measurements. The filled markers represent the monthly medians, with the whiskers indicating the 25th and 75th percentiles. Panel b: monthly evolution of single-layer COD, for five IAOOS buoys. Open circles represent the Rayleigh-derived cloud optical depths. Crosses correspond to the low-IAB COD values (Sect. 3.2.4) Filled markers represent the monthly medians, when high-IAB cases are excluded (circles) or included (squares). These medians are calculated when more than 15 data points are available.

(from 1982 - 1999) varied from 4 to 6 in the AVHRR data over the Arctic Ocean. From ground-based lidar measurements at
325   SHEBA, Turner (2005) shows that 63% of clouds were single-layer with an optical depth < 6, and that optically thin clouds
tended to be predominantly composed of ice.

Single-layer COD appears to vary seasonally (Fig. 4b). Excluding high-IAB cases, the monthly median COD appears to be
almost constant from April to September, and largest in October - November (filled circles). However, this is in part because
of the low noise levels in these months as compared to the summer. In March and October - December, i.e. the months with
330   no sunlight, more than 50% of cloud layers were transparent to the lidar. This proportion is less than 10% in May to July.
The COD can therefore be directly calculated for optically thick clouds from late September - March but not in other months.
This is visible in Fig. 4b: in late September/October, there is a sudden apparition of directly-calculated COD values (open
circles) greater than 2. The IAB method, which is an alternative to the direct method of calculating COD when the signal is
fully attenuated by the cloud, is mainly suited to optically thin clouds (Fig. 4, grey crosses). This creates bias between summer
335   months, for which the COD calculation is limited by noise levels to optically thin clouds, and October - December, during
which higher COD values can be calculated.

To overcome this problem, the COD of high-IAB cloud layers was set to 2. This value was chosen as it is the 95th percentile
of CODs calculated for low-IAB layers, and high-IAB cloud layers are globally expected to have higher COD than low-IAB

Month	Number of pro-files	Cloud fraction (%)	Median temperature (°C)		
			Cloudy	Cloudless	Δ
Mar	28	46	-23.2	-29.9	6.8
Apr	94	59	-17.7	-21.2	3.5
May	359	88	-9.9	-13.6	3.7
Jun	330	92	-1.5	-1.5	0
Jul	342	85	-0.1	-0.5	0.4
Aug	205	85	-0.9	-1.1	0.2
Sep	251	89	- 3.7	-6	2.3
Oct	98	92	-6.6	-14.6	8.
Nov	54	56	-16.7	-25	8.4
Dec	44	32	-27.9	-28.5	0.6

Cloudless profiles contain no clouds. Δ is the difference between cloudy and cloudless profile median temperatures.

layerS. The monthly median COD was then calculated including these high-IAB cases (Fig. 4, filled squares). This correction

340 is not quantitatively robust as the value of 2 is arbitrarily chosen, not calculated. However, it is helpful for examining the seasonal trend. It creates a significant difference in June and July, the months in which the percentage of high-IAB cloud layers is the highest. With this correction, the median monthly COD exhibits two peaks (June and October) and a minima in April. The October peak is however still the annual maximum.

Previous satellite measurements have exhibited a pattern of higher COD in the shoulder seasons, for instance May and

345 October for the AVHRR data (Wang and Key, 2004) over the Arctic Ocean. IAOOS measurements confirm that there is a peak in single-layer COD in October, and possibly in June.

4.1.4 Impact of clouds on surface temperatures

IAOOS lidar profiles can be split into two groups: those that contain a low cloud with a base < 2 km and those that don't. The temperatures measured by the buoy meteorological station during each lidar profile acquisition can be compared to estimate

350 the effect of the presence of clouds on surface temperatures.

The 2 m temperature distributions of cloudy and cloudless profiles differ significantly in October-November and March-April (Table 3). The Mann-Whitney test p-value is less than 0.05 ($< 10^{-4}$ for November) and the common language effect size is more than 70% ($> 80\%$ for October and November). For all of these these months, the 2 m temperature is much lower

for cloudless than for cloudy profiles. Indeed, the difference between the medians is of $8°C$ for the autumn months and around
355 $4 - 7°C$ in the spring (Table 3). This difference is probably not due solely to radiative processes, as cloudy situations in the
Arctic winter are also associated with the passage of storms, which bring warm, moist air with them. However, as seen in Sect.
4.1.3, IAOOS-measured CODs are larger in October/November than April. Since emissivity increases with optical depth, this
supports a larger surface warming in autumn than in spring.

The months with the lowest median temperature difference between cloudy and cloudless profiles are June, July and August.
360 In fact, the temperature distributions are statistically indistinguishable in these months from the relatively few measurements
we have access to here. In particular, there is no month in which cloudless profiles are warmer than cloudy profiles, even though
clouds are known to exert negative radiative forcing from late June to early July. The reasons for this are explored in Sect. 4.3
by investigating the summer radiative balance.

4.2 Radiative modes in the Arctic

365 ### 4.2.1 Identification of two summer radiative modes from IAOOS and N-ICE data

The 2 m temperature difference between cloudy and cloudless profiles exposed in Sect. 4.1.4 is consistent with previous stud-
ies. Indeed, it is now well attested that the Arctic climate exhibits two distinct states during the winter, which are distinguished
through the surface net longwave flux (netLW) values. The bimodality of netLW was first observed during the SHEBA mea-
surement campaign over the January-February 1998 period (Stramler et al., 2011) and has since been confirmed Arctic-wide
370 by satellite observations (Cesana et al., 2012). The "radiatively clear" mode (netLW < -30 W m^{-2}) is associated with strong
radiative cooling, high pressures and low temperatures. Clouds may be present but are optically thin and mainly composed
of ice. The "opaquely cloudy" mode is characterised by low pressures and relatively higher temperatures, and often associ-
ated with so-called "moisture and temperature intrusions" from the midlatitudes (Woods et al., 2013). Clouds are then liquid
or mixed-phase, and optically thick. These intrusions are one of the main drivers of interannual variability of netLW, with a
375 contribution of about 40% (Woods et al., 2013).

Here, we used radiative flux data from the N-ICE field campaign (second period, April - June 2015) to complement the
IAOOS lidar observations (Hudson et al., 2016). Measurements from the first period (January to March 2015) of N-ICE have
already been shown to confirm the wintertime bimodality of the netLW distribution (Graham et al., 2017). This result is
replicated in Fig. 5b. A more striking point is that the netLW distribution is also bimodal in spring to early summer (Fig. 5c).
380 During this period, netLW values range from -90 to 0 W m^{-2}. The most predominant netLW mode, containing around 80%
of data points, is centered around -11 W m^{-2}, while the other is centered around -72 W m^{-2}. As a IAOOS buoy drifted
near the main ice camp during April-June 2015, the IAOOS profiles were used to determine whether the sky was cloudless or
cloudy at a given moment. The comparison with netLW measurements is represented in Fig. 5a. Low netLW values (< -60
W m^{-2}) are associated with IAOOS profiles that are cloudless at least up to ≈ 5 km, which is the maximum range of the lidar.
385 Meanwhile, profiles containing at least one low level cloud (grey lines) corresponded to netLW values larger than -20 W m^{-2}.
16

Figure 5. Panel a: time series of surface net longwave measurements during the N-ICE field experiment (second period, April-June 2015). IAOOS buoys were deployed near the main ice camp where radiative fluxes were measured. The vertical lines indicate the time of IAOOS lidar profiles, with red lines corresponding to cloudless profiles. Panels b and c: histogram of the measured (filled line) and ERA5 (dashed line) net longwave flux during the N-ICE winter (b) and spring/summer (c) campaign periods. Panels d and e: hourly ERA5 vs measured net longwave in during the N-ICE winter (d) and spring/summer (e) campaign periods, with red dashed line indicating the 1:1 line. The colour corresponds to point density as calculated by a Gaussian kernel.

This shows that the observed low netLW mode corresponds to a cloudless state and the high netLW mode to a cloudy state. By analogy with the previously established winter radiative states, we name the spring/summer low-netLW mode "radiatively clear" and the high-netLW mode "opaquely cloudy". However, these two modes differ from their winter analogues in several ways. Firstly, the netLW mode values are lower than in the winter, due to the higher surface temperatures in spring/summer.

390 Secondly, the difference between the two states is ≈ 60 W m^{-2}, much larger than in the winter. This implies that clouds have a larger longwave warming effect in the spring/summer than in the winter, probably linked to larger liquid contents and higher cloud temperatures in this season. Thirdly, the opaquely cloudy mode is much more frequent in spring/summer than in the winter, representing a large majority of cases. This is coherent with the fact that cloud frequency is much higher in spring/summer than in winter, with a transition in April (Sect. 4.1.1).

395 **4.2.2 Comparison of ERA5 to N-ICE measurements**

The two atmospheric winter states (radiatively clear and opaquely cloudy) are not well reproduced by models (Cesana et al., 2012; Pithan and Mauritsen, 2014; Graham et al., 2017). In fact, it has been suggested that representing the bimodality of the netLW, pressure and temperature distributions in the wintertime is a key quality criterion for models. ERA-Interim and its successor, ERA5, are among those that partially achieve this (Graham et al., 2017). This is visible in Fig. 5d. The opaquely cloudy

400 state lies on the 1:1 line and is therefore well represented. However, the radiatively clear netLW values are underestimated by about 15 W m^{-2}. This is mainly due to an error in the upwards component of the longwave flux. Indeed, ERA5 overestimates the clear mode 2 m temperature by about 5 K; its measured value is $T_{meas} = -32$°C (Graham et al., 2017), while the ERA5 clear mode temperature is $T_{ERA5} = -27$°C. This leads to an error on the longwave upwards flux at the surface (LWu) of:

$$\Delta(\mathrm{LWu}) = 4\sigma \cdot (T_{ERA5} - T_{meas}) \cdot (T_{meas} + 273.15)^3$$
$$\approx 15.8 \text{ W m}^{-2} \tag{5}$$

405 The result of Eq. (5) is in line with the observed netLW error. It should be noted that this overestimation of near-surface temperatures in clear, stable winter conditions, leading to an underestimation of netLW, is a feature shared by the six reanalyses evaluated by Graham et al. (2019) using the N-ICE campaign data.

In the spring/summer period, Graham et al. (2019) further notes that ERA5 is the least biased of the six evaluated reanalyses with regards to netLW, but has the worst correlation coefficient ($R = 0.15$). Indeed, we find that ERA5 fails to represent the

410 two spring/summer netLW modes. The ERA5 netLW distribution is not bimodal (Fig. 5c) and does not align with the measurements (Fig. 5e). Three zones have been outlined on figure 5e to aid with the following discussion of ERA5 spring/summer netLW error. Zone OC corresponds to measured opaquely cloudy values over all spring/summer. The opaquely cloudy mode is somewhat reproduced by ERA5 (yellow dots denoting a peak in the calculated gaussian kernel density), although its values are underestimated by 11 W m^{-2} on average. The two other boxes correspond to measured radiatively clear values from

415 April/May (RC1) and June (RC2) respectively. June values are well reproduced by ERA5. However, ERA5 vastly overestimates radiatively clear netLW in April and May: there is a 40 W m^{-2} difference with measurements in these month (Fig. 5e, RC1).

The difference in ERA5 netLW values between radiatively clear April/May (RC1) and June (RC2) points is due to the downwards component of the longwave flux (LWd). ERA5 LWd is fairly close to measured values in RC2, but is overestimated by

420 ≈ 53 W m^{-2} in RC1. This is partly compensated by a 14 W m^{-2} error on LWu in April/May, similar to what is observed during
Figure 6. Panel a: evolution longwave downwards radiative flux with near-surface (2 m) temperature as measured during the spring/summer period of the N-ICE field campaign. Dark grey points correspond to values for which $\text{netLW} < -50\,\text{W}\,\text{m}^{-2}$ ("radiatively clear" mode) while for light grey points $\text{netLW} > -20\,\text{W}\,\text{m}^{-2}$ ("opaquely cloudy" mode). The filled line correspond to the results of a simple parametrisation of LWd (Eq. (6)) in the absence of clouds, while the dashed lines represent the results of the parametrisation for $\tau_{LW} = 1.5$ and $\tau_{LW} = 4.1$. Panel b: same, for shortwave downwards radiative flux vs solar zenith angle. The dashed lines are the results of Eq. (7) for $\tau_{SW} = 1.7$ and $\tau_{SW} = 28.2$. For both panels, points are 30-minute averages of measurements.

the winter. Ultimately, the overestimation of LWd in RC1 is due to a faulty representation of cloud fraction in April/May. The ERA5 mean low cloud cover in RC1 is 0.96, even though measurements indicate a radiatively clear, and therefore cloudless, situation. On the other hand, mean low cloud cover in RC2 is 0.06: ERA5 has correctly identified that the sky was cloudless.

425 The logical conclusion is that ERA5 overestimates low cloud cover in April and May, but not June, leading to the observed errors in netLW. This may ultimately be due to an error in the satellite data that is assimilated by the ERA5 reanalyses. Indeed, as noted in Sect. 4.1.3, cloud fraction and optical depth is often overestimated by satellite measurements at high solar zenith angles over bright surfaces (Chan and Comiso, 2013). These are the predominant conditions in April and May, whereas in June the solar zenith angle is lower and areas of open water start to appear, decreasing the surface albedo.

4.3 Cloud impact on the summer surface radiative budget

430 Section 4.2.1 showed that the spring/summer netLW distribution exhibits two modes, termed radiatively clear ($\text{netLW} < -50$ W m^{-2}) and opaquely cloudy ($\text{netLW} > -20$ W m^{-2}). These were linked respectively to the absence and presence of clouds

in the lidar profiles. However, Sect. 4.1.4 showed that there is very little difference between 2 m temperatures of cloudless and cloudy profiles in the summer. A more complete analysis of the summer surface radiative budget is therefore required.

In the Arctic summer, clouds impact the surface radiative budget in two competing ways: they have a longwave warming effect and a shortwave cooling effect. The longwave effect depends on cloud temperature and phase. Warm, liquid-containing clouds are optically thicker and have much more radiative impact than cold, ice-containing clouds (Shupe and Intrieri, 2003). This is most likely the reason behind the greater difference between netLW modes observed in the spring/summer (≈ 60 W m^{-2}) N-ICE measurement period as compared to the winter (≈ 40 W m^{-2}). The shortwave radiative forcing also depends on cloud characteristics as optically thick clouds have higher albedos. It also depends on the solar zenith angle θ and, to a lesser extent, the surface albedo α, due to reflections between the bright surface and the clouds (Shupe and Intrieri, 2003).

The downwards longwave (LWd) and shortwave (SWd) flux components in the radiatively clear and opaquely cloudy modes can be compared in order to evaluate the impact of clouds on the surface. We will use simple estimates of LWd and SWd as a complement to the N-ICE flux measurements (Hudson et al., 2016). Schematically, the atmosphere can be seen as a cloud layer with emissivity ϵ_c overlying a cloudless atmospheric layer with emissivity ϵ_0. If both layers are emitting at temperature T_{2m}, this yields the following expression for LWd:

$$\text{LWd} = [\epsilon_0 + \epsilon_c(1 - \epsilon_0)] \cdot \sigma \cdot T_{2m}^4 \qquad (6)$$

The cloud emissivity can simply be expressed as $\epsilon_c = 1 - e^{-\tau_{LW}}$ with τ_{LW} the longwave COD. Several simple parametrisations exist for ϵ_0; here, we choose $\epsilon_0 = 0.83 - 0.18 \cdot 10^{-0.067 e_0}$, with e_0 the near surface water vapour pressure, which was fitted from summer data at Sodankylä, Finland (Niemelä et al., 2001a). This shows good correspondence to the N-ICE clear mode data (Fig. 6a). In fact, equation (6) corresponds to a model introduced by Schmetz et al. (1986) under two simplifying assumptions. First, that the cloud cover is equal to 1, which is reasonable in the cloudy mode. Second, that the cloud base and two-meter temperatures are approximately equal. This is justified by cross-comparison of the N-ICE (second period) radiosonde data with the IAOOS lidar profiles: the overwhelming majority of lowest layer clouds have a base beneath 120 m and the median difference between surface and 100 m temperature in the radiosonde profiles is only 1.3°C (with 90% of values falling in the range $0.6 - 2$°C).

SWd can be calculated from the downwards shortwave flux in the absence of clouds F$_0$ and the cloud correction or cloud broadband transmittance factor T_c:

$$\text{SWd} = \text{F}_0(\theta) \cdot T_c \qquad (7)$$

F_0 depends on atmospheric gas and aerosol content and is usually parametrised to fit to local data (Reno et al., 2012; Kambezidis et al., 2017). Here, the fit to N-ICE clear mode data is shown on Fig. 6b (filled black line). T_c has been modeled in numerous ways, the simplest depending solely on cloud cover (Niemelä et al., 2001b), while more complicated expressions have been derived from the output of radiative transfer models. Here we used the parametrisation of Fitzpatrick (Fitzpatrick

Discussions

Optical depth	5th percentile	Median	95th percentile
τ_{LW}	1.4	2	2.5
τ_{SW}	1.2	7.8	20.2
τ_{808}	0.5	0.9	1.9

Table 4. Statistical range (5th, 50th and 95th percentiles) of three different estimations of optical depth: τ_{LW} (from the downwards longwave flux), τ_{SW} (from the downwards shortwave flux) and τ_{808} (calculated from the IAOOS lidar profiles). For a robust comparison, τ_{LW} and τ_{SW} values considered here are interpolated on the IAOOS profile times. The percentiles are therefore established over 54 data points which correspond to the 54 IAOOS profiles.

et al., 2003), which assumes a cloud cover of 1 and depends on the solar zenith angle θ, the surface albedo α and the shortwave COD τ_{SW}. We chose to use a fixed value of $\alpha = 0.8$, as the measured albedo over the N-ICE second period varied from
465    $0.75 - 0.84$ and the model performs poorly for albedos above 0.83 (Fitzpatrick et al., 2003).

Downwards longwave radiative flux increased with near-surface temperature T_{2m} and downwards shortwave flux decreased with θ in both radiatively clear and opaquely cloudy modes during the N-ICE April-June measurement period (Fig. 6). This evolution is well reproduced by Eqs. 6 and 7. Furthermore, there is a marked difference in downwards flux between points identified as radiatively clear and opaquely cloudy for both the longwave and shortwave components. In accordance with a
470   cloud longwave warming effect, radiatively clear LWd values are uniformly lower than the opaquely cloudy values for each T_{2m} (Fig. 6a). As netLW is the quantity used to discriminate between clear and cloudy points, this is expected. On the other hand, radiatively clear SWd values are higher than opaquely cloudy SWd values for each θ (Fig. 6b). This corresponds to the shortwave albedo effect, i.e. clouds reflect solar radiation back to space. The magnitude of this shortwave cooling is variable, even for a fixed solar zenith angle. As a first order approximation, this variation is due to the cloud optical properties as the
475   albedo varied little over the measurement period. Equation (7) reproduces the spread of observed values for τ_{SW} between 1.7 to 28.2, a range which is coherent with total column COD values from previous studies (Sect. 4.1.3). In contrast, the longwave warming effect varies little either as a factor of T_{2m} or τ_{LW}, and remains close to 60 W m^{-2}.

COD variations therefore have a non-negligible impact on the surface radiative balance. For $\theta = 60°$, for example, there is an approximately 200 W m^{-2} difference in SWd between the optically thinnest and thickest clouds. This translates into a total
480   shortwave cloud forcing that ranges between -20 to -60 W m^{-2}, assuming an albedo of 0.8. This range is significant when it is contrasted to the typical longwave forcing of ≈ 60 W m^{-2}: even for $\theta = 60°$, only optically thick clouds can have a net radiative cooling effect over high-albedo sea ice. Thinner clouds will continue to warm the surface. This explains that averaged over the IAOOS campaign, the 2 m temperature of cloudless profiles is not different at statistically significant level from that of cloudy profiles (Sect 4.1.4).

4.4 Contribution of the lowest cloud layer to the total column COD

Cloud optical depths measured by the IAOOS lidar correspond only to the lowest cloud layer, and not to the total column (Sect. 4.1.3). Here we attempt to evaluate the contribution of this lowest layer to the total column COD. This would allow better comparison of IAOOS CODs to existing satellite statistics. Furthermore, as seen in Sect. 4.3, total column shortwave COD is the quantity that most impacts the surface radiative balance. Equations 6 and 7 were inverted to calculate the broadband shortwave and longwave CODs τ_{SW} and τ_{LW} from the N-ICE opaquely cloudy SWd and LWd values at the time of the IAOOS profiles. In analysing the results, it must be taken into account that the longwave optical depth of any single cloud layer is smaller than its shortwave optical depth. The shortwave-to-longwave optical depth ratio depends on the microphysical properties of clouds (droplet phase, radius) and a precise determination would require the help of radiative transfer models. In this manner, Garnier et al. (2015) calculates $\tau_{532nm}/\tau_{12\mu m} \approx 1.8$ for ice particles with an effective diameter between 5 and 60 microns. We use this value as a rule of thumb to enable comparison between τ_{LW}, τ_{SW} and the IAOOS optical depths τ_{808}.

90% of τ_{LW} values obtained in this manner fall in the $1.4 - 2.5$ range (Table 4). It must be noted that these τ_{LW} values do not capture the optical depth of the whole column. Indeed, because cloud emissivity ϵ_c tends to 1 exponentially, high τ_{LW} values are likely to be underestimated. Instead, this τ_{LW} must be seen as the part of the cloud cover whose emitted radiation reaches the surface. Inverting Eq. (7) yields shortwave optical depths between 1.2 and 20.2, with a median of 7.8. This range shows much higher values than that of τ_{LW}, even when accounting for the longwave-to-shortwave ratio. This is because the shortwave radiative flux is impacted by the whole cloud column, and not only the first few layers. IAOOS optical depths (τ_{808} in Table 4) are much lower than both τ_{LW} and τ_{SW}, with 90% of values between 0.5 and 1.9. In fact, the ratio $\tau_{808}/(1.8 \cdot \tau_{LW})$ has a median value of 0.22 (range $0.15 - 0.43$), while τ_{808}/τ_{SW} has a median value of 0.11 (range $0.03 - 0.68$). This means that first-layer clouds measured by IAOOS contribute around a quarter of the optical depth of clouds which have a longwave radiative impact on the surface, and 11% of the total cloud column.

While this value is low, it is coherent with the observation that SHEBA-measured total cloud thicknesses are up to 7 times higher than the IAOOS-measured first layer thickness (Sect. 4.1.2). Regardless of potential underestimations in IAOOS measurements, it strongly suggests that further cloud layers must be present at higher altitudes. Some of these, possibly cirrus clouds, would then have a shortwave but no longwave impact on the surface. Furthermore, visual inspection of the relative humidity (RH) and temperature profiles obtained through radiosonde measurements during N-ICE supports the idea that the IAOOS lidar correctly identifies the first cloud layer and probably misses higher cloud layers. Indeed, strong temperature inversion and diminution of RH are most often present at the lidar-identified cloud top. Further inversions and high RH values are often present, marking higher altitude cloud layers that are invisible to the lidar.

5 Conclusions

The IAOOS field campaign (2014 - 2019) consisted in the deployment of instrumented buoys in the Arctic sea ice. In this study, the whole IAOOS lidar dataset was treated and analysed. This included correcting for window frost as outlined in Mariage (2015) and deconvoluting the signal to reduce the effects of receiver saturation in bright conditions. An algorithm was

implemented to detect cloud layers and calculate their optical depth, either directly when applicable or through the IAB by assuming a constant lidar ratio. Surface radiative flux data from the N-ICE campaign, during which four IAOOS buoys were 520 deployed, and from ERA5 reanalyses, was also exploited.

The results show a significant seasonal variation in cloud cover and optical and geometrical properties of clouds over the seasonal cycle. Low cloud cover (i.e., with a base beneath 2 km) is found to be 76% globally over the course of the campaign. Monthly cloud frequency is minimum in March/April and November/December and over 85% from May - October, with two small maxima in June and October. First-layer clouds are geometrically thickest in October, and thinnest in the summer. This is 525 likely linked to moisture intrusions from the Atlantic in early autumn. Lastly, first-layer cloud bases are found to be extremely low in all seasons: under 120 m in a vast majority of cases.

The IAOOS lidar detects multiple cloud layers at much lower rates than other instruments, because the first cloud layer usually dampens the signal completely. Total cloud optical and geometrical thicknesses from previous campaigns and satellite data are much larger than those measured by IAOOS, especially in the summer when multilayered clouds are known to be 530 most common. We estimate from N-ICE radiometer measurements that the first layer COD measured by IAOOS accounted for 13% of the total column shortwave COD during the April-June 2015 period. The single-layer COD as measured by IAOOS is highest in October.

The surface impact of Arctic clouds is also seasonally variable. In October/November and March, clouds warm the surface: 2 m temperatures associated with cloudless profiles are up to 8 K colder than those associated with profiles containing at least 535 one low cloud. However, there is no statistically significant difference in surface temperatures between cloudless and cloudy profiles in the summer.

Data from the IAOOS lidar deployed during the N-ICE campaign allowed us to identify two modes in the N-ICE measured netLW distribution in late spring/summer. The "radiatively clear" netLW mode, centered around -72 W m^{-2}, is associated with cloudless IAOOS lidar profiles, while the "opaquely cloudy" mode is centered around -11 W m^{-2} and is linked to 540 cloudy lidar profiles. These are analogous to the well-known winter radiative modes, except that the opaquely cloudy mode is much more prevalent (over 80%) and that the two modes have a 60 W m^{-2} difference, compared to 40 W m^{-2} in the winter. Clouds exert a larger longwave warming in the summer than in the winter, probably linked to the higher proportion of liquid water in clouds. Clouds in the spring/summer also have a shortwave cooling effect. This is shown to depend not only on solar zenith angle and albedo, but also strongly on COD.

545 The optically thickest clouds have a net radiative cooling effect around $\theta = 60$ ° over unbroken sea ice, while most thinner clouds contribute to warm the surface. The compensation of the cloud longwave warming effect by the shortwave cooling effect explains that there is no clear difference in near-surface temperature between IAOOS cloudless and cloudy profiles during the summer months.

The measured surface radiative fluxes were compared to the output of the ERA5 reanalyses. ERA5 does not accurately 550 reproduce the observed bimodality of the spring/summer netLW distribution. Indeed, it does not correctly identify cloudless periods during April and May (but not June). This issue should be investigated.

Over the period 2014-2019, the IAOOS buoys have delivered 1805 lidar profiles. Despite technical difficulties with both the lidar and the data analysis, this campaign has offered a medium-term 3-season picture of the Arctic lower troposphere above 82°N from ground-based measurement, which is an important complement to satellite data. These results help to broaden our understanding of the Arctic low cloud cover and its impacts on the surface. However, more measurements would be needed to further characterise Arctic clouds. In particular, combined radiometer-lidar measurements would be crucial to allow the study of radiative impacts to be generalised to late summer and especially autumn, when clouds are optically thick and frequent.

Data availability. N–ICE2015 observational data sets are available from the Norwegian Polar Data Centre (https://data.npolar.no/dataset/) and are cited in the text (Hudson et al., 2016). IAOOS atmospheric data used in this paper are available upon request to the corresponding author and are available through the AERIS Data Portal at https://www.aeris-data.fr/. The ERA5 re–analysis products can be retrieved at http://apps.ecmwf.int/.

Author contributions. JM performed the data treatment and analysis and prepared the manuscript. FR and JCR provided supervision, guidance and editing. JP led the IAOOS project and designed the lidar. VM constructed the lidar and treated its data.

Competing interests. The authors declare that they have no conflict of interest.
