21

22 **Abstract:** According to current estimates, atmospheric new particle formation (NPF) produces a  
23 large fraction of aerosol particles and cloud condensation nuclei in the earth's atmosphere, therefore  
24 having implications for health and climate. Despite recent advances, atmospheric NPF is still  
25 insufficiently understood in the upper parts of the boundary layer (BL). In addition, it is unclear  
26 how NPF in upper BL is related to the processes observed in the near-surface layer. The role of the  
27 topmost part of the residual layer (RL) in NPF is to a large extent unexplored. This paper presents  
28 new results from co-located airborne and ground-based measurements in a boreal forest  
29 environment, showing that many NPF events (~42%) appear to start in the upper RL. The freshly  
30 formed particles may be entrained into the growing mixed layer (ML) where they continue to grow  
31 in size, similar to the aerosol particles formed within the ML. The results suggest that in the boreal  
32 forest environment, NPF in the upper RL has an important contribution to the aerosol load in the  
33 BL.

34

## 35 **1. Introduction**

36

37 It has been estimated that atmospheric new particle formation (NPF) is responsible for most of the  
38 cloud condensation nuclei (CCN) in the atmosphere (Dunne et al., 2016; Gordon et al., 2017; Pierce  
39 and Adams, 2009; Yu and Luo, 2009). Aerosol-cloud interactions, in turn, have important but  
40 poorly-understood effects on climate (Boucher et al., 2013). Being a major source of ultrafine

41 aerosol particles in many environments (e.g. Brines et al., 2015; Posner and Pandis, 2015; Salma et  
42 al., 2017; Yu et al., 2019), NPF may have implications for human health.

43

44 The majority of NPF observations come from ground-based measurements (Kerminen et al., 2018;  
45 Kulmala et al., 2004), which can be argued to represent NPF within the mixed layer (ML).

46 Measurements from aircrafts (e.g. Clarke and Kapustin, 2002; Rose et al., 2017) and high-altitude  
47 research stations (e.g. Bianchi et al., 2016) demonstrate that NPF frequently takes place in the free  
48 troposphere (FT). Entrainment of particles formed in the upper FT was identified as an important  
49 source of CCN in the tropical boundary layer (BL) (Wang et al., 2016; Williamson et al., 2019).

50

51 To what extent NPF happens in the lower FT and in the upper parts of the BL is not clear. Freshly  
52 formed particles were observed in the inversion capping a ML (Chen et al., 2018; Platis et al., 2015;  
53 Siebert et al., 2004) and in turbulent layers inside the residual layer (RL) (Wehner et al., 2010). NPF  
54 was frequently observed in the lower FT over a megacity in a year-long campaign (Quan et al.,  
55 2017). Also Qi et al. (2019) reported NPF just above the ML over Yangtze River Delta. In the  
56 marine BL, sub-10 nm particles were observed in the entrainment zone above a cloud topped BL  
57 (Dadashazar et al., 2018). Layers of sub-10 nm particles, usually less than 500 m in thickness, were  
58 often observed in the lower FT over a boreal forest environment (Leino et al., 2019; Schobesberger  
59 et al., 2013; Väänänen et al., 2016). On the other hand, Junkermann and Hacker (2018) attributed  
60 their observations of ultrafine particle layers to flue gas emissions from stacks with subsequent  
61 chemistry taking place during air mass transport over long distances.

62

63 In this study we used co-located airborne and ground-based measurements to study NPF in the BL  
64 over a boreal forest. We aimed to answer the following questions: (1) where, how often and why  
65 does NPF take place in the upper parts of the BL, and (2) how the upper-BL NPF is related to  
66 ground-based observations, and what implications this has for data interpretation.

67

## 68 **2. Materials and methods**

69

### 70 ***2.1. Airborne measurements***

71

72 We used data from airborne measurement campaigns conducted between 2011 and 2018 around  
73 Hyytiälä, Finland. Figure 1 shows the data availability from these measurements. Most of the flights  
74 were carried out during spring and early autumn because that is when NPF events are most common

75 in Hyytiälä. Here we focused on the data that was measured within a 40-km radius from Hyytiälä.  
76 The measurement setups changed slightly over the years. Detailed descriptions of the setups on  
77 board can be found in our previous studies (Leino et al., 2019; Schobesberger et al., 2013;  
78 Väänänen et al., 2016).

79

80 The instrumented aircraft was a Cessna 172 operated from the Tampere-Pirkkala airport (ICAO:  
81 EFTP). The sample air was collected through an outside inlet into a main sampling line that was  
82 inside the aircraft's cabin. The forward movement of the aircraft during flight provided adequate  
83 flow rate inside the main sampling line. The flow rate was maintained at 47 lpm by using a manual  
84 valve. The instruments drew air from the main sampling line using core sampling inlets. The  
85 necessary flow rate to the instruments was provided by pumps. The flow rate in the main sampling  
86 line corresponded to roughly isokinetic sampling at the core sampling inlets. The airspeed was kept  
87 at 130 km/h during the measurement flights.

88

89 The on-board aerosol instruments considered in this study were an ultrafine condensation particle  
90 counter (uCPC, TSI, model: 3776), measuring the >3 nm particle number concentration at a 1-s  
91 time resolution, a particle size magnifier (PSM, Airmodus, model: A10) operated with a TSI 3010  
92 CPC, measuring the >1.5 nm particle number concentration at a 1-s time resolution, and a custom-  
93 built scanning mobility particle sizer (SMPS) with a short Hauke type DMA and a TSI 3010 CPC,  
94 measuring the aerosol number size distribution in the size range of 10-400 nm at a 2-min time  
95 resolution. In addition, basic meteorological data (temperature, relative humidity and pressure) and  
96 water vapor concentration from Licor Li-840 gas analyzer were used.

97

98 Vertically, the measurement profiles extended approximately from 100 m to 3000 m above the  
99 ground. This altitude range covered the ML, RL and roughly 1 km of the FT (Figure 2). The  
100 measurement flights lasted about 2-3 hours and were flown mostly during the morning (~8:00-  
101 12:00 local time) and the afternoon (~13:00-16:00 local time). Horizontally, the profiles were flown  
102 perpendicular to mean wind in order to avoid the airplane's exhaust fumes.

103

## 104 **2.2. Ground-based measurements**

105

106 Comprehensive atmospheric measurements have been done at the SMEAR II station in Hyytiälä  
107 (61°50'40" N, 24°17'13" E, 180 m above sea level) since 1996 (Hari and Kulmala, 2005).The

108 landscape around the site is flat and dominated by Scots pine forests, with small farms and lakes  
109 scattered nearby. The station represents typical rural background conditions.

110

111 We used data from the BAECC (Biogenic Aerosols–Effects on Clouds and Climate) campaign,  
112 which took place in Hyytiälä during Feb-Sep 2014 (Petäjä et al., 2016), to study the relationship  
113 between BL evolution and NPF observed at the station. High spectral resolution lidar (HSRL)  
114 measurements and meteorological balloon soundings released every 4 hours by the U.S. Department  
115 of Energy ARM mobile facility allowed us to monitor the evolution of the BL (Nikandrova et al.,  
116 2018).

117

118 From the HSRL data we looked at the values of backscatter cross section in order to see the  
119 development of the ML during the day. The data were averaged into 30-m altitude bins and 10-min  
120 temporal bins. The ground-based measurements during the BAECC campaign were also  
121 supplemented by aircraft measurements using the instrumented Cessna. In case of missing  
122 soundings, we also looked at the balloon soundings released from Jokioinen ~120 km south-west  
123 from Hyytiälä (WMO: 02963).

124

125 The number size distribution of aerosol particles between 3 and 1000 nm was measured at the  
126 station using a differential mobility particle sizer (DMPS, Aalto et al., 2001). A neutral cluster and  
127 air ion spectrometer (NAIS, Airel Ltd., Mirme and Mirme, 2013) measured the number size  
128 distribution of air ions and particles in the size ranges of 0.8–42 nm and 2–42 nm, respectively  
129 (Manninen et al., 2009). The time resolutions of the DMPS and NAIS were 10 min and 4 min,  
130 respectively. The vertical flux of particles >10 nm was measured by the eddy covariance method  
131 from 23 m above ground, which is a couple of meters above the canopy (Buzorius et al., 2000).

132

133 Vertical profiles of horizontal and vertical winds were measured with a Halo Photonics Stream Line  
134 scanning Doppler lidar since year 2016. The Halo Photonics Stream Line is a 1.5  $\mu\text{m}$  pulsed  
135 Doppler lidar with a heterodyne detector and 30-m range resolution, and the minimum range of the  
136 instrument is 90 m (Pearson et al., 2009). At Hyytiälä, a vertical stare of 12 beams and integration  
137 time of 40 s per beam is scheduled every 30 min, whereas the other scan types operated during the  
138 30-min measurement cycle were not utilized in this study. The lidar data were corrected for a  
139 background noise artifact (Vakkari et al., 2019). The turbulent kinetic energy (TKE) dissipation rate  
140 was calculated from the vertical stare according to the method by O'Connor et al. (2010) with a  
141 signal-to-noise-ratio threshold of 0.001 applied to the data. Data availability is limited by relatively

142 low aerosol concentration at Hyytiälä, but TKE dissipation rate can be retrieved on most days up to  
143 the top of the BL.

144

### 145 **3. Results and discussion**

146

147 In the aircraft data we frequently observed a layer of nucleation mode (sub-25 nm) particles above  
148 the ML. First we introduce how the phenomenon was observed in the airborne and ground-based  
149 measurements using a case study. Then we show that the particle layers occurred in the topmost part  
150 of the RL, by studying the average vertical profile of particle number-size distribution and  
151 temperature as well as the BAECC data. Finally, by using the BAECC data, we associate the  
152 nucleation mode particles in the upper RL to a specific signal in the ground-based measurements  
153 and use the observations at the SMEAR II station to gather long-term statistics.

154

#### 155 ***3.1 Case study: May 2, 2017***

156

157 On May 2 during the measurement airplane's ascend over Hyytiälä, we observed a layer of freshly  
158 formed aerosol particles approximately between 1200 and 2000 m above the ground, in the top parts  
159 of the ML (Figure 3). The layer had increased number concentrations of sub-20 nm and sub-3 nm  
160 particles. The small size of the particles suggests that they were recently formed in the atmosphere.  
161 The lower edge of the aerosol particle layer was observed at 12:24 UTC. The airplane entered back  
162 into the ML at 12:56 UTC and at this point there were no signs of the particle layer, but the particle  
163 number concentration had increased inside the ML. On the same day, an early morning flight before  
164 the sunrise was also performed. During this flight no elevated particle layer was observed below  
165 3000 m, suggesting that this particle layer had been formed after the sunrise. The air masses came  
166 from a non-polluted sector over the Arctic Ocean and northern Scandinavia.

167

168 After the aerosol layer was observed from the airplane during the ascend, a new particle mode with  
169 a geometric mean diameter of about 10 nm suddenly appeared at the ground-level at 12:36 (Figure  
170 4). The appearance of this new particle mode was characterized by a negative peak in the vertical  
171 particle flux, suggesting that the particles had been mixed down from aloft.

172

173 We then studied the vertical profiles of meteorological quantities measured on board the Cessna on  
174 May 2, and the turbulent kinetic energy (TKE) dissipation rate calculated from the Doppler lidar  
175 measurements during May 1-2 (Figure 5). In the Doppler lidar measurements, the increase in the

176 TKE dissipation rate clearly reveals the development of the ML on both days. On May 1 the ML  
177 reached roughly 1700 m above the ground, while on May 2 the first potential temperature profile  
178 measured on board the Cessna revealed the presence of a stable layer (upper RL) at roughly the  
179 same altitude. This matches with the height of the aerosol particle layer in Figure 3. The Doppler  
180 lidar measurements further show that on May 2 the ML reached this height around the noon UTC,  
181 which is when the particle layer was observed to be mixing down. This leads us to hypothesize that  
182 NPF was taking place in the upper RL.

183 |

### 184 | **3.2 Evidence of NPF in the upper RL based on long-term measurements**

185 |

186 We analyzed the airborne data measured during 2011-2018. We plotted the median and 75<sup>th</sup>  
187 percentile number size distributions measured on board the aircraft as a function of altitude during  
188 NPF event days (65 days out of 130 measurement days) between 09:00 and 12:00 (Figure 6). NPF  
189 event days are characterized by a new growing particle mode appearing in the sub-25 nm size range  
190 (Dal Maso et al., 2005). If aerosol formation in the upper RL occurs on less than half of the NPF  
191 event days, it might not be visible in the median plot, but might still appear in the 75<sup>th</sup> percentile  
192 plot.

193 |

194 Interestingly, in the 75<sup>th</sup> percentile plot a layer of nucleation mode particles is observed at 2500-  
195 3000 m above sea level. In the mean temperature profile, an inversion is observed at the same  
196 altitude level. The ML and RL are commonly capped by temperature inversions (Stull, 1988).  
197 In this case, the inversion is likely where on average the top of the RL was, since the the top of the  
198 ML was well below this altitude. The probable reason for the unusually deep RL is that the NPF  
199 event days tend to be sunny spring days and the ML can grow exceptionally high, which also leads  
200 to a very deep RL. The vertical profile of particle number size distribution supports the idea that  
201 NPF was taking place in the upper RL.

202 |

### 203 | **3.3 Connection between NPF in the upper RL and ground-based observations**

204 |

205 With the BAECC dataset we wanted to investigate whether the sudden appearance of nucleation  
206 mode particles with downward particle flux was associated with the ML reaching the upper RL.  
207 This would not only test the hypothesis that NPF happens in the topmost part of the RL, but also  
208 provide us with a tool to identify upper RL NPF from the ground-based data alone.

209 |

210 We looked for cases where a new particle mode suddenly appeared in the nucleation mode size  
211 range during the daytime and the appearance of the particles was associated with a downward  
212 particle flux. We noted the times when the particles first appeared, and also estimated a confidence  
213 interval of the observation. Then we checked if we could find out the height of the RL from balloon  
214 soundings or the Cessna flights. We looked for an elevated temperature inversion that was roughly  
215 at the same altitude as the ML of the previous day had reached. We noted the base height of the  
216 temperature inversion and took this as the top of the RL. Then we followed the height of the new  
217 ML from the HSRL measurements and noted the time when the ML reached the inversion base, also  
218 estimating a confidence interval. Figure 7 illustrates an example for this procedure.

219 |  
220 We found 8 cases during the campaign where the analysis could be fully carried out. Figure 8 shows  
221 a strong positive correlation between the new particle mode appearance time and the time when the  
222 ML reached the top of the RL. This suggests that the suddenly appearing nucleation mode particles  
223 were entrained into the ML from the upper RL. We found only a weak positive correlation between  
224 the new particle mode appearance time and the geometric mean diameter of particles in the new  
225 mode at the moment they were first observed. This is probably explained by the NPF starting at  
226 different times during the day and variability in growth rates, coupled with the small sample size.

### 227 | 228 **3.4 Implications for classifying NPF events**

229 |  
230 Previous studies that classified NPF events observed in Hyytiälä have collected statistics on the  
231 occurrence of suddenly appearing particle modes. For example Buenrostro Mazon et al., (2009)  
232 collected statistics on “tail events” where a new particle mode appears at particle diameters greater  
233 than 10 nm and grows for several hours. Dada et al., (2018) collected statistics on “transported  
234 events” where elevated number concentration of 7-25 nm particles persisted for more than 1.5  
235 hours, but no elevated number concentrations at smaller particle sizes were observed. It was found  
236 that ~36% of the NPF events observed for over 10 years in Hyytiälä were transported events. They  
237 occurred especially when the conditions inside the ML were less favorable for nucleation.

238  
239 Here we found cases in the SMEAR II data between 2013 and 2017, in which a new growing  
240 particle mode suddenly, without continuous growth from smallest detectable sizes (3 nm), appears  
241 in the nucleation mode and is associated with a negative peak in the vertical particle flux. We also  
242 noted cases where a new particle mode appears with a continuous growth from the smallest

243 detectable sizes. Based on the previous analysis we assume that in the former case NPF took place  
244 in the upper RL and in the latter case inside the ML. The analysis included 1750 days.

245  
246 The monthly fractions of the different cases are shown in Figure 9. We found that NPF within the  
247 ML occurred on 13% of all the days and NPF in the upper RL on 7% of all the days. During spring  
248 (Mar-May) the corresponding percentages were 31% and 17%. On many days NPF took place both  
249 in the upper RL and within the ML. According to this analysis, NPF in the upper RL constitutes  
250 42% of the NPF event days in Hyttiälä. Moreover, on 16% of the NPF event days NPF only took  
251 place in the upper RL but not in the ML.

252  
253 The gaseous precursors involved in NPF may end up in the upper RL because of mixing from the  
254 surface during the previous day (e.g. organic vapors emitted from the forest or sulfuric acid,  
255 ammonia and amines originating from human activities) or because of long-range transport in the  
256 FT (e.g. iodine oxides from the ocean).

257  
258 Many factors favor NPF at higher altitudes, including enhanced photochemistry, reduced sinks and  
259 reduced temperature. However, the unique NPF inducing features of the upper RL are probably  
260 linked to the mixing that takes place in the interface between RL and FT. For example Nilsson and  
261 Kulmala, (1998) found that mixing two air parcels with different initial temperatures and precursor  
262 vapor concentrations can lead to a considerable increase in the nucleation rate.

263  
264 If the new ML reaches the upper RL, particles formed originally in the RL will be mixed into the  
265 ML where they continue to grow in size as low-volatility vapors present in the ML are able to  
266 condense onto these particles. The processes are illustrated in Figure 10. In case the particles will  
267 not be mixed down, they may persist in the FT for a longer time period and possibly have stronger  
268 contribution to cloud formation.

269  
270 **4. Conclusions**

271  
272 We measured aerosol particles, trace gases and meteorological parameters on board an instrumented  
273 Cessna 172 over a boreal forest in Hyttiälä, Finland. The airborne data was complemented by the  
274 continuous, comprehensive ground-based measurements at the SMEAR II station.

275

276 We found multiple evidence that NPF frequently takes place in the topmost part of the RL. This is  
277 likely related to the unique thermodynamic conditions present in this layer due to mixing between  
278 RL and FT air. We estimate that NPF in the upper RL occurs on 42% of the NPF event days in  
279 Hyytiälä. Our results provide new information on NPF in the BL and they should be taken into  
280 account when interpreting and analyzing ground-based as well as airborne measurements of aerosol  
281 particles.

282

283 **Data availability:** The particle flux and DMPS data can be accessed from <https://avaa.tdata.fi/web/smart/smear> (Junninen et al., 2009; last access: Oct 1, 2020). The BAEC HSRL and radiosonde  
284 data is available from <https://adc.arm.gov/discovery/> (Bambha et al., 2014; Keeler et al., 2014); last  
285 access: Oct 1, 2020). The Jokioinen soundings can be accessed using the Finnish Meteorological  
286 Institute's open data service <https://en.ilmatieteenlaitos.fi/open-data> (last access: Oct 1, 2020). The  
287 ERA5 dataset can be accessed from <https://cds.climate.copernicus.eu/cdsapp#!/home> (last access:  
288 May 6, 2020). The rest of the data was gathered into a dataset that can be accessed from  
289 <https://zenodo.org/record/4063662#.X3cHQnUzY88> (Lampilahti et al., 2020; last access: Oct 2,  
290 2020).

291

292  
293 **Author contribution:** JL, KL, AM, PP, AF, MP, PH, LD and LJQ conducted the airborne  
294 measurements in 2017. PP wrote processing script for the airborne data. RÖ classified the SMEAR  
295 II data for NPF events between 2013-2017. LB contributed to the data analysis. YZ and ME  
296 analyzed the airborne data between 2011-2018. VV provided the Doppler lidar data. JL prepared the  
297 manuscript with contributions from all co-authors.

298

299 **Acknowledgements:** This project has received funding from the ERC advanced grant No. 742206,  
300 the European Union's Horizon 2020 research and innovation program under grant agreement No.  
301 654109, the Academy of Finland Center of Excellence project No. 272041. SZ acknowledges  
302 support from the Academy of Finland grant 314 798/799. We thank Erkki Järvinen and the pilots at  
303 Airspark Oy for operating the research airplane and we are grateful for their hospitality and  
304 helpfulness.

328 Figure 5: Turbulent kinetic energy (TKE) dissipation rate measured by the Doppler lidar in Hyytiälä  
329 between May 1-2, 2017. In addition the vertical profiles of potential temperature and water vapor  
330 concentration are shown from both the night and the afternoon Cessna flights on May 2, 2017.

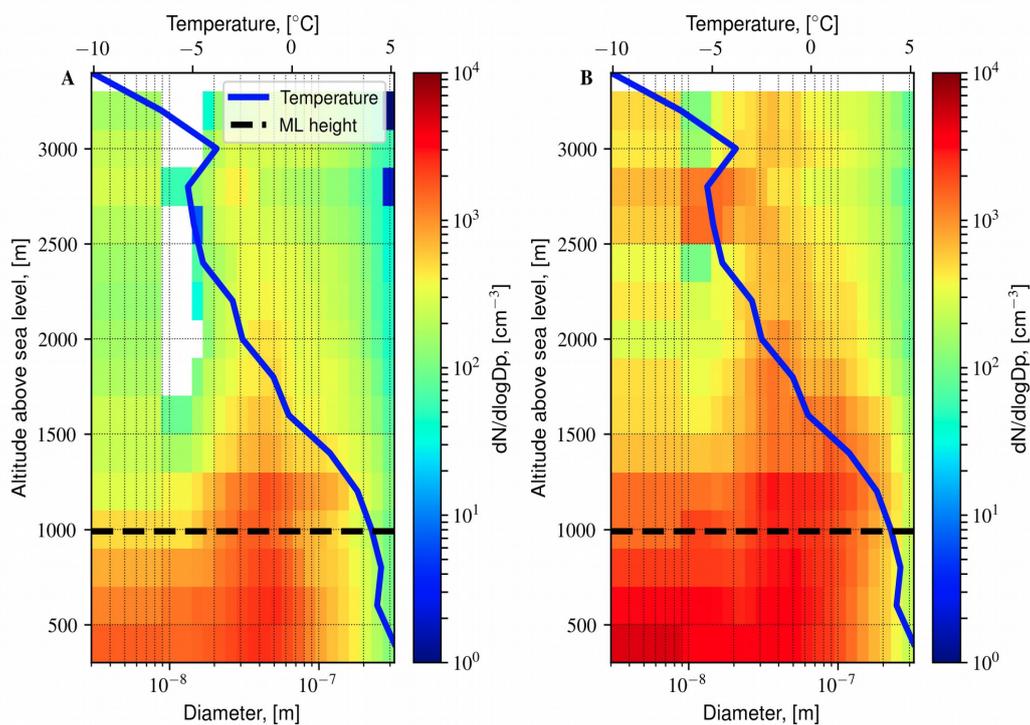

Figure 6: Panel A shows the median and panel B the 75th percentile vertical profile of particle number-size distribution measured on board the Cessna on NPF event days between 9-12 AM. The number-size distribution was binned into 200 m altitude bins. The data is from the campaigns conducted between 2011 and 2018. It includes only the data that was measured within 40 km radius from Hyytiälä. The dashed line is the mean ML height obtained from the ERA5 reanalysis data. The blue line is the mean temperature profile measured on board the airplane.

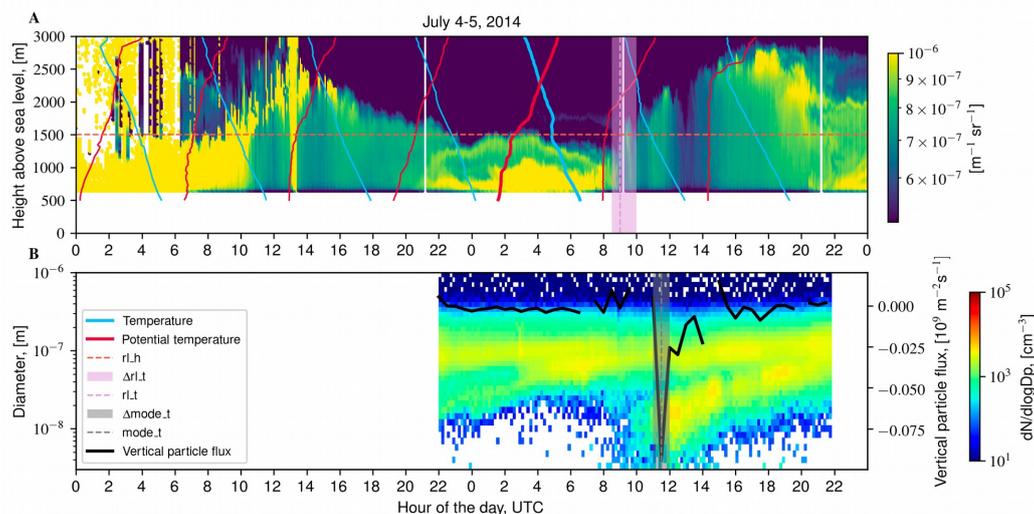

Figure 7: Panel A shows the backscatter cross section measured by the HSRL. The development of the ML is visible from the backscatter cross section signal. Temperature and potential temperature profiles from the 4-hourly balloon soundings are superimposed. The horizontal line  $rl_h$  refers to the height of the inversion base observed during the early morning of July 5<sup>th</sup>. The bold temperature and potential temperature profiles mark the sounding from which  $rl_h$  was determined. The  $rl_t$  and  $\Delta rl_t$  refer to the time when the ML was estimated to reach the  $rl_h$  and the confidence interval for this time respectively. Panel B shows the particle number-size distribution measured at the SMEAR II station, the black line is the vertical particle flux. The  $mode_t$  and  $\Delta mode_t$  respectively refer to the time and the confidence interval, when a nucleation particle mode that is associated with downward particle flux suddenly appears.

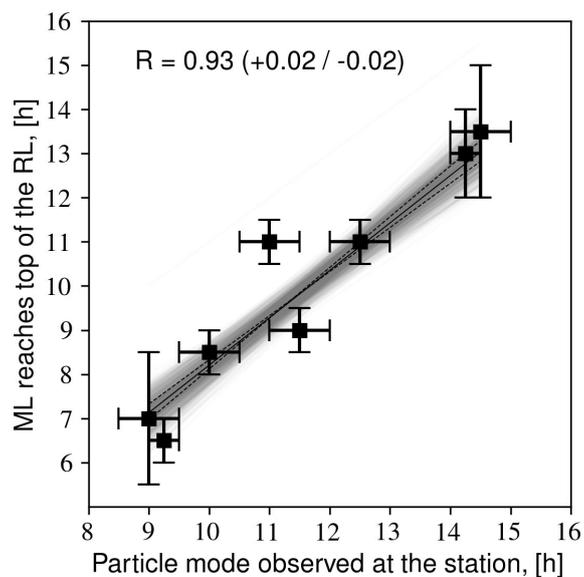

Figure 8: The correlation between the times that a new particle mode coupled with downward particle flux is observed at the field site and the times that the ML reaches the top of the RL.

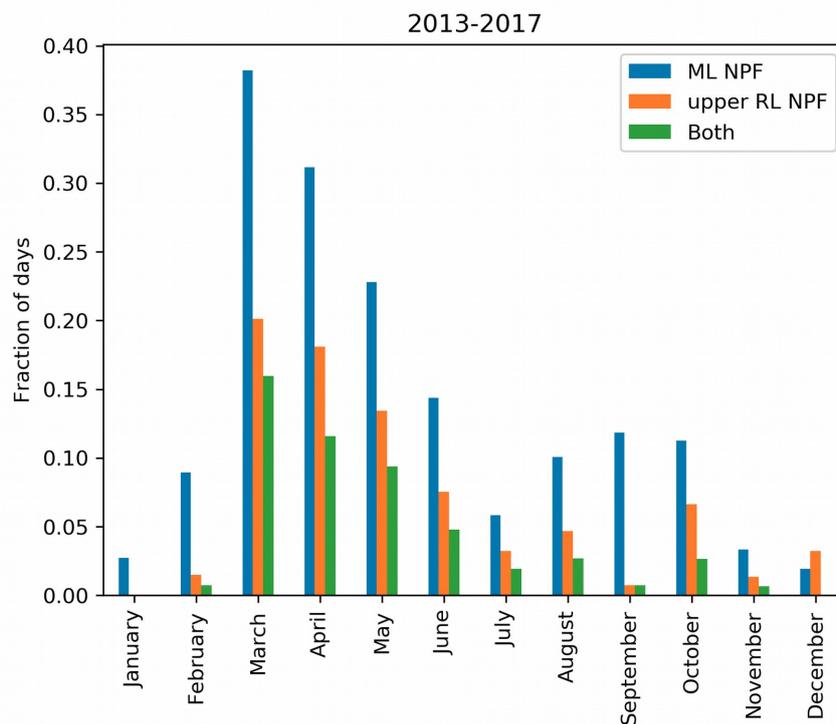

Figure 9: Monthly fractions of NPF within the ML and NPF in the upper RL in Hyttiälä between 2013-2017.

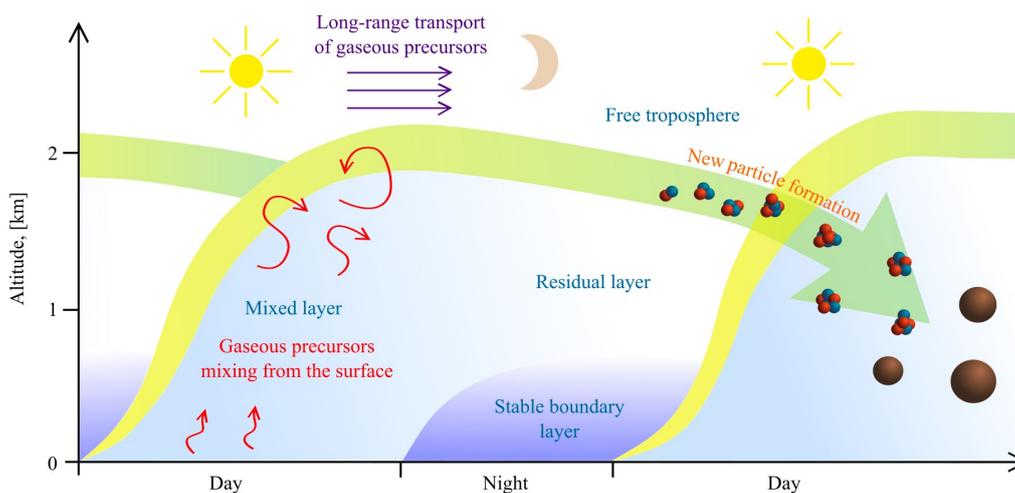

Figure 10: Schematic drawing illustrating the proposed mechanism behind NPF in the upper RL. Gaseous precursors released from the surface are mixed throughout the ML. When the mixing stops during the night the gases are stuck in the RL. Also gaseous precursors may be transported in the FT. In the following morning photochemistry and the thermodynamically favorable conditions in the upper RL initiate NPF. The freshly formed particles remain in the elevated layer or get mixed into the a new ML if it reaches the height of the upper RL. The aerosol particles continue to grow larger, contributing to the aerosol load in the BL.
