32 **Abstract**

33 Stressed plants and polymer production can emit many unsaturated volatile organic
34 esters (UVOEs). However, secondary organic aerosol (SOA) formation of UVOEs
35 remain unclear, especially under complex ambient conditions. In this study, we mainly
36 investigated ethyl methacrylate (EM) ozonolysis. Results showed that a substantial
37 increase in secondary H₂SO₄ particles promoted SOA formation with increasing SO₂.
38 An important reason was that the homogeneous nucleation of more H₂SO₄ at high SO₂
39 level provided greater surface area and volume for SOA condensation. However,
40 increased primary H₂SO₄ with seed acidity enhanced EM uptake, but reduced SOA
41 formation. This was ascribed to the fact that the ozonolysis of more adsorbed EM was
42 hampered with the formation of surface H₂SO₄ at higher particle acidity. Moreover, the
43 increase in secondary H₂SO₄ particle via homogeneous nucleation favored to the
44 oligomerization of oxidation products, whereas the increasing of primary H₂SO₄ with
45 acidity in the presence of seed tended to promote the functionalization conversion
46 products. This study indicated that the role of increased H₂SO₄ to EM-derived SOA
47 maybe not the same under different ambient conditions, which helps to advance our
48 understanding of the complicated roles of H₂SO₄ in the formation of EM-derived SOA.

68 **1. Introduction**

69 Unsaturated volatile organic esters (UVOEs) are oxygenated volatile organic
70 compounds (OVOCs) with many large-scale commercial uses. They are not only used
71 as potential replacements of traditional solvents and additive in diesel fuels but are
72 widely used in the production of polymers and resins (Wang et al., 2010; Teruel et al.,
73 2016; Blanco et al., 2014; Taccone et al., 2016; Colomer et al., 2013; Srivastava, 2009).
74 Thus, the production, processing, storage, and disposal of industrial products all
75 contribute to UVOE emissions. In addition, emissions of green leaf volatiles (GLVs),
76 a class of wound-induced OVOCs, also contribute to UVOEs in the atmosphere
77 (Hamilton et al., 2009; König et al., 1995; Arey et al., 1991). Once emitted into the
78 atmosphere, these UVOEs quickly undergo complex chemical reactions with OH
79 radicals and ozone in sunlight (Blanco et al., 2010; Bernard et al., 2010; Sun et al., 2015),
80 NO₃ radicals during night-time (Wang et al., 2010; Salgado et al., 2011), and Cl atoms
81 in certain environments (Blanco et al., 2010; Rivela et al., 2018). OH-initiated oxidation
82 of GLVs, including *cis*-3-hexenylacetate (CHA) to secondary organic aerosol (SOA),
83 is estimated to contribute 1–5 TgC/y, with up to a third of that from isoprene (Hamilton
84 et al., 2009). In addition, CHA-derived SOA is a more efficient absorber (between 190
85 and 900 nm) than other OVOCs (such as *cis*-3-hexenol) due to the high proportion of
86 carbonyl-containing species (Harvey et al., 2016). Thus, UVOEs can be considered as
87 a class of potential SOA precursors. Further investigations on UVOE-derived SOA
88 under complex ambient conditions will help to better understand their contribution to
89 ambient aerosol.

90 Recent studies ascertained that the presence of SO₂ and sulfate seed particles all
91 have a significant impact on the yield, composition, and formation mechanism of SOA
92 (Zhang et al., 2019; Kristensen et al., 2014; Wong et al., 2015; Han et al., 2016). For
93 example, an increase in SO₂ can enhance SOA production due to the formation of more
94 sulfates and the enhanced acid-catalysis role during the atmospheric oxidation of
95 various VOCs (Chu et al., 2016; Zhao et al., 2018; Lin et al., 2013). In the presence of

96 alone seed particles, however, increased particle acidity will not always enhance SOA
97 formation and may have a negligible effect on the SOA formation (Zhang et al.,
98 2019;Kristensen et al., 2014;Wong et al., 2015;Han et al., 2016;Surratt et al.,
99 2010;Eddingsaas et al., 2012;Riva et al., 2016). Furthermore, it is worth noting that
100 several studies have indicated that an increase in SO₂ can promote the average oxidation
101 state (OS_c) of SOA due to organosulfate formation (Zhang et al., 2019;Shu et al.,
102 2018;Liu et al., 2019a). whereas other studies have suggested that an increase SO₂ can
103 have a suppression effect on SOA OS_c (Friedman et al., 2016). Similarly, the effect of
104 increased aerosol acidity on SOA OS_c depends on the contribution of functionalization
105 and oligomerization reactions to SOA composition as increased aerosol acidity can
106 promote these reactions (Shu et al., 2018). This implies that the roles of increased
107 sulfate particles and particle acidity in SOA production and composition are very
108 complicated and need to be further studied.

109 Methacrylate was one of the main effluents in the class of UVOEs. Just in China,
110 the net import of methacrylate has up to about 930 thousand tons in 2019. It was worth
111 noting that ethyl methacrylate, one of methacrylate, has been widely detected in
112 ambient air due to the wide variety of sources and high volatility (Pankow et al., 2003).
113 Moreover, some exposure measurement studies indicated that the concentration of ethyl
114 methacrylate was up to 31-108 μg m⁻³ in the salons working air, which was notably
115 higher than other methacrylate (Henriks-Eckerman and Korva, 2012). Thus, we used
116 ethyl methacrylate (EM) as an UVOE proxy to investigate the effects of different SO₂
117 levels and seed particle acidity on the formation and evolution of EM-derived SOA in
118 this work. This work will help to better understanding the formation of EM-derived
119 SOA under complex conditions.

120

121 **2 Materials and methods**

122 Multiple EM ozonolysis experiments were conducted in a 30-m³ cuboid Teflon smog
123 chamber (L × W × H = 3.0 × 2.5 × 4.0 m) under 298 K temperature and atmospheric
124 pressure. Experimental conditions are summarized in Table S1. The chamber operation,

125 analytical techniques, and experimental procedures are described in detail elsewhere
126 (Chen et al., 2019). Only a brief description on the specific procedures relevant to this
127 work is presented here.

128 Prior to each experiment, the smog chamber was cleaned for at least 24 h until
129 certain conditions were reached (i.e., <30 particle cm^{-3} and O_3 , NO_x , and SO_2
130 concentrations of <1 ppb). The O_3 (generated by passing 4 L min^{-1} dry zero air over two
131 UV photochemical tubes (40-cm length and 4-cm inter-diameter)), SO_2 (520 ppm in N_2 ,
132 Beijing Huayuan, China), and CO (0.05% in N_2 , Beijing Huayuan, China) were added
133 into the chamber in sequence. EM were first added into a stainless-steel tee at $80 \text{ }^\circ\text{C}$
134 and subsequently flushed into the chamber by zero gas with the flowrate of 20 L min^{-1} .
135 We applied CO to decrease the effect of OH radical reaction via scavenging of OH
136 radicals. The EM (98% purity, Sigma-Aldrich, USA) was added to the chamber by
137 injection of a known volume into a heated three-way tube ($80 \text{ }^\circ\text{C}$) and flushed into the
138 chamber by dry zero air. A fan made of stainless steel coated using Teflon was fixed at
139 the bottom of the chamber, which is used to ensure homogeneous mixing of reactants.

140 To minimize losses in the sampling line, various monitoring instruments
141 surrounded and are next to the smog chamber. The length of sampling pipes of various
142 monitoring instruments ranged from 0.5-1.0 m. A scanning mobility particle sizer
143 (SMPS, TSI, Inc.), consisting of a nano-differential mobility analyzer (DMA; model
144 3082), condensation particle counter (CPC; model 1720), and Po210 bipolar neutralizer,
145 was applied to measure number size distribution. Total particle number and mass
146 concentrations were calculated assuming a uniform density for aerosol particles of 1.4
147 g cm^{-3} (Liu et al., 2019b; Chen et al., 2019). The sheath flow and aerosol flow in the
148 SMPS were set to 3.0 and 0.3 L min^{-1} , respectively. The SMPS results were further
149 corrected via the wall loss rate of $(\text{NH}_4)_2\text{SO}_4$ particles and the correction magnitude is
150 about 10% in 5 h-reaction (Figure S1). Based on the different characterized fragments,
151 both mass concentration and evolution of the different chemical compositions of
152 aerosol particles were simultaneously measured online using High-Resolution Time-
153 of-Flight Aerosol Mass Spectrometric Analysis (HR-ToF-AMS; Aerodyne Research

154 Inc., USA). The AMS working principles and modes of operation are explained in detail
155 elsewhere. According to standard protocols, the inlet flow rate, ionization efficiency
156 (IE), and particle sizing were calibrated using size-selected pure ammonium nitrate (AN)
157 particles (Drewnick et al., 2005). The HR-ToF-AMS analysis toolkit SQUIRREL
158 1.57I/PIKA v1.16I in Igor Pro v6.37 was employed to process and analyze the
159 experimental data obtained by the HR-ToF-AMS. To reduce the sampling errors
160 resulting from calibrating HR-TOF-AMS before each experiment, the HR-ToF-AMS
161 results were further corrected using mass concentration derived from the SMPS as per
162 Gordon et al (Gordon et al., 2014). A series of gas analyzers from Thermo Scientific
163 (USA) were used to monitor the evolution of SO₂ (model 43i), CO (model 48i), and O₃
164 (model 49i) concentrations as a function of reaction time. Moreover, to make sure
165 results reliable and rule out potential artifacts including the adding sequence of CO, O₃,
166 and SO₂ during experimental preparation and the injection process of EM, parallel
167 experiments (twice experiments at the same experimental conditions) under selected
168 experimental conditions (135 ppb SO₂ and in the presence of AS seeds, respectively)
169 were conducted (Figure S2 and S3).

170

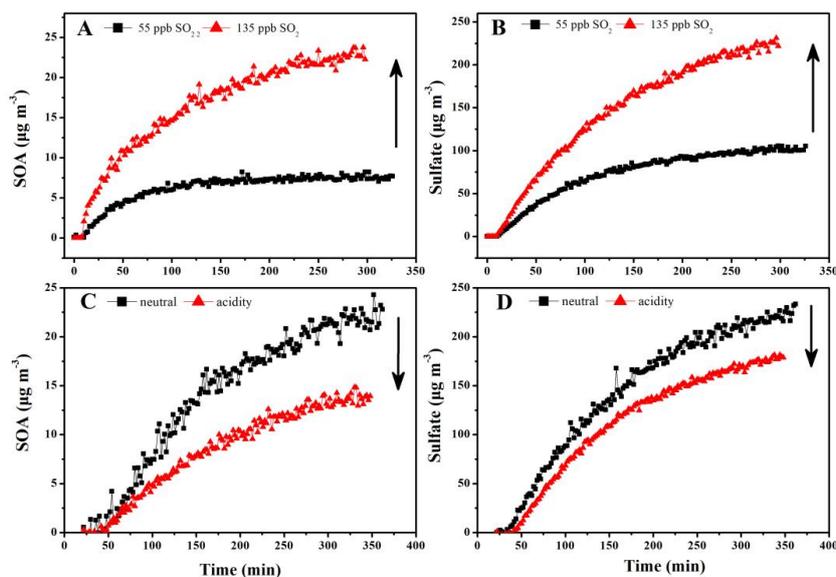

171 **3. Results and discussion**

172 **3.1. Overview of EM-derived SOA Formation with and without Seed Particles**

173 We first investigated the ozonolysis of alone EM. As shown in Figure S4, the
174 ozonolysis of alone EM could not produce SOA in the absence of seed and SO₂.
175 Similarly, the increased particle acidity did not promote SOA formation during the
176 ozonolysis of alone EM in the absence of SO₂ (Figure S5). Thus, this study mainly
177 focused on EM ozonolysis in the presence of SO₂. Secondary particle formation from
178 EM ozonolysis with different SO₂ levels was first investigated in the absence of seed
179 particles. As shown in Figure 1, SOA and sulfate were significantly produced once EM
180 was introduced into the reaction chamber. Moreover, both SOA and sulfate formation
181 were markedly enhanced with the increase in initial SO₂ concentration (Figure 1A and
182 B). This indicated that EM-derived SOA formation was closely related to sulfate

183 formation compared with that the ozonolysis of alone EM. Subsequently, EM
184 ozonolysis with the same level of SO₂ was also conducted in the presence of seed
185 particles with different acidity (neutral and acidic). Two different solutions, including
186 AS (0.02 mol L⁻¹) and AS + H₂SO₄ (0.02 + 0.04 mol L⁻¹), were nebulized into the
187 chamber, respectively, to provide the corresponding seed aerosol for acidity
188 experiments. The initial seed concentrations have been added in the Table S1.
189 Interestingly, with the increase of seed acidity, the maximum mass concentrations of
190 SOA and sulfate decreased from 19.1 to 12.9 μg m⁻³ (Figure 1C) and 192.6 to 169.7 μg
191 m⁻³ (Figure 1D), respectively. This indicated that increased particle acidity suppressed
192 secondary particle formation in the presence of SO₂, which was inconsistent with the
193 enhancement effect of particle acidity via acid-catalysis on SOA formation during
194 alkene photooxidation (such as isoprene, isoprene epoxydiols, and glyoxal) (Kristensen
195 et al., 2014; Lin et al., 2011; Riva et al., 2016; Wong et al., 2015). In order to evaluate
196 whether the effect is atmospherically relevant, these experiments of seed particle role
197 were also conducted at higher RH (45-50% RH). As shown in Figure S6, it could be
198 found that increased particle acidity also suppressed the formation of SOA and sulfate
199 at higher RH. Moreover, the lower the concentration of both SOA and sulfate at 45%
200 RH relative to 10% RH proved that increased RH was adverse to SOA and sulfate
201 formation (Figure S7). Thus, these results imply that the increase of primary H₂SO₄
202 proportion with particle acidity in seed particles and the increase of secondary H₂SO₄
203 particles with SO₂ concentration exhibited the opposite role in EM-derived SOA
204 formation.

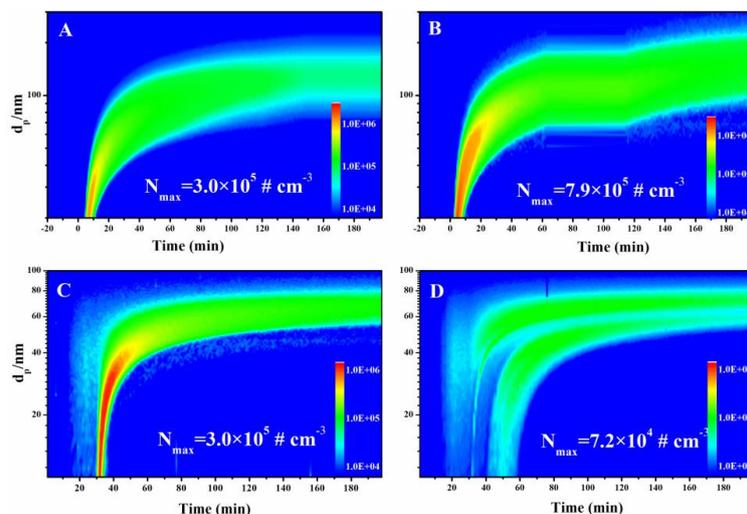

205
206 **Figure 1.** Time-dependent growth curves of SOA (A) and sulfate (B) under different
207 initial concentrations of SO₂ in absence of seed particles; SOA (C) and sulfate (D) after
208 subtracting seeds in presence of neutral and acidic seed particles.

209 As shown in Figure 2, the size distributions of secondary particles under different
210 experimental conditions were also compared. The detected maximum particle
211 concentration (790 000 particle cm⁻³) under 135 ppb SO₂ was higher than that observed
212 under 55 ppb SO₂ (300 000 particle cm⁻³) in the absence of seed particles (Figure 2A
213 and B). Recent studies suggested that the reaction between SO₂ and stable Criegee
214 intermediates (sCI) dominated the formation of H₂SO₄ particles and was enhanced with
215 increased SO₂ concentration. An important reason for this is the rapid homogeneous
216 nucleation of H₂SO₄ not only can provide greater surface area and volume for the
217 condensation of low-volatile products, but reduce the fraction of these semi-volatile
218 species lost to the wall (Zhang et al., 2019; Chu et al., 2016; Liu et al., 2017; Zhang et al.,
219 2014). In the presence of seed particles, we used similar average concentration
220 (~25 000-30000 particles cm⁻³) and mode diameter (45 nm) of seed particles under
221 different acidities to reduce the disturbance of seed particle concentration (Figure 2C
222 and 2D). Results showed ~300 000 newly produced particles cm⁻³ for neutral AS seeds
223 (Figure 2C) and ~74 000 newly produced particles cm⁻³ for acidified AS seeds (Figure

224 2D), respectively. The reduction of NPF in the presence of acidic particles most likely
225 result from that acidic seed particles promoted the condensation of gaseous nucleation
226 species onto seed surface. However, this could not explain why both SOA and sulfate
227 were all suppressed with the increase in particle acidity. Thus, one reasonable
228 explanation is that acidic seed particles also enhanced EM uptake on the particle surface
229 as well as promoting the condensation of nucleation species. As a result, the
230 heterogeneous formation of fresher H₂SO₄ on the surface of seed particles subsequently
231 reduced SOA formation by hampering the ozonolysis of absorbed EM. To further
232 supported this speculation, the experiments on EM uptake and degradation on different
233 acidic seed particle were also checked using Fourier spectra and Mass spectrum
234 instruments. Result indicated that higher particle acidity indeed promoted EM uptake
235 on the particle surface and the presence of SO₂ resulted in the residual of more adsorbed
236 EM on particle surface (Figure S8 and S9).

237 In addition, as shown in Figure S5, the negligible change of SOA with acidity in
238 the absence of SO₂ also supported that the reducing effect of increasing particle acidity
239 on secondary particle formation was closely related to the formation of H₂SO₄ particles
240 in the presence of SO₂. And some recent studies proved that some surface secondary
241 reactions involved Sci (Wang et al., 2016; Hearn et al., 2005), thus we couldn't
242 completely exclude the possibility that the suppressing role is likely related to the role
243 of increased acidity to sCI lifetime, which needed to be further explored in the future.
244 Moreover, the ozonolysis experiments of α -pinene at 45% RH in the presence of SO₂
245 with seed particles of different acidity were also carried out. Experimental results
246 indicated that increased particle acidity also suppressed the formation of both SOA and
247 sulfate during α -pinene ozonolysis at higher RH (Figure S10). This indicated the
248 reducing effect of increasing particle acidity to secondary particle in the presence of
249 SO₂ also could happen for other systems. Taken together, these results imply that the
250 SOA formation under different SO₂ levels and different particle acidities may be closely
251 related to the homogeneous or heterogeneous formation of H₂SO₄.

252

253 **Figure 2.** Size distribution of secondary aerosol as a function of time at 55 ppb SO₂ (A)
254 and 135 ppb SO₂ (B) and under AS seed particle (C) and Acidic AAS seed particle (D).

255

256 3.2. Chemical Interpretation and Elemental Analysis of SOA

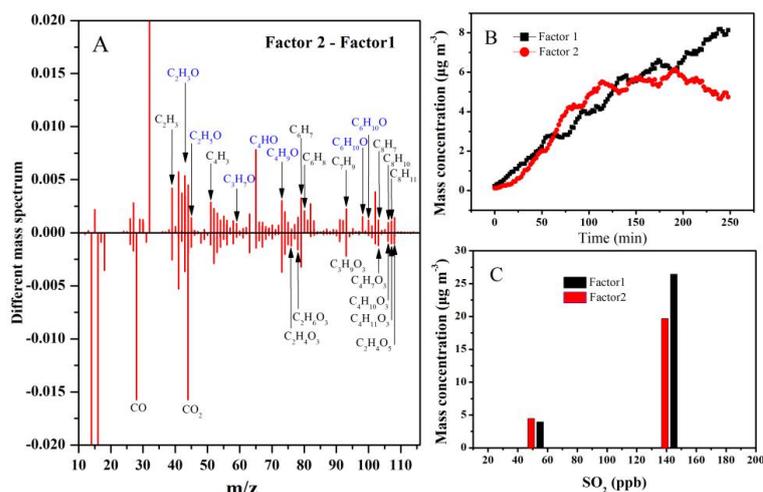

257 Recent studies have suggested that a higher proportion of H₂SO₄ in aerosol can
258 result in greater formation of oligomers and high-oxygenated organic aerosol via
259 acceleration of the acid-catalysis process (Zhang et al., 2019; Liu et al., 2019a; Shu et
260 al., 2018). In order to make clear whether the homogeneous or heterogeneous formation
261 of H₂SO₄ could also affect SOA composition, we further analyze SOA composition and
262 evolution based on positive matrix factorization (PMF) solution and Van Krevelen
263 diagrams (Zhang et al., 2005; Heald et al., 2010). The methodological of PMF analysis
264 has been put into Supporting Information (Figure S11 and S12). The time series and
265 mass spectra of each Factor after PMF analysis were applied to characterize the factor
266 constitution and chemical conversion among factors (Ulbrich et al., 2009; Zhang et al.,
267 2011).

268 *Positive matrix factorization (PMF) solution*

269 In the absence of seed particles, two factors were identified under different SO₂
270 concentrations. As shown in Figure 3A, the 43 (C₂H₃O⁺) higher signals (tracers for
271 alcohols and aldehydes) and prominent fragmental peaks containing one-oxygen atom

272 (i.e., C₂H₄O, C₂H₅O, C₃H₅O, C₃H₆O, C₃H₇O, C₄HO, and C₆H₁₀O) observed in Factor
273 1 implied that Factor 1 consisted of less-oxygenated organic aerosols. The 44 (CO₂⁺)
274 higher signals, tracers for organic acids, and dominant peaks containing multi-oxygen
275 atoms (i.e., C₃H₈O₃, C₃H₉O₃, and C₄H₁₀O₃) observed in Factor 2 implied that Factor 2
276 consisted of more-oxygenated organic aerosols. From the temporal variations in Figure
277 3B, both Factor 1 and 2 continuously increased with reaction progress before 200 min,
278 implying that both factors were simultaneously produced during EM ozonolysis. After
279 200 min, Factor 1 continuously increased but Factor 2 decreased, suggesting that the
280 chemical conversion of part of less-oxygenated species in Factor 2 to more-oxygenated
281 products in Factor 1 in the latter period of reaction. Moreover, the average elemental
282 compositions of Factor 1 and Factor 2 were estimated to be C_{2.29}H₃O_{0.53}S_{0.01} and
283 C_{1.38}H_{1.87}O_{0.37}S_{0.027}, respectively. Higher OS_c of Factor 2 (-0.81) relative to that Factor
284 1 (-0.85) also supported above conclusion. This also implied that the chemical
285 conversion from Factor 2 to Factor 1 could occur only when the H₂SO₄ proportion
286 (acidity) in the particle-phase reached a certain concentration (Offenberg et al.,
287 2009;Liu et al., 2019a). As shown in Figure 3C, the maximum production of both Factor
288 1 and Factor 2 increased with increasing SO₂. One reasonable explanation is that the
289 formation of more H₂SO₄ particles with increasing SO₂ provided a greater surface area
290 and volume for the simultaneous condensation of both less-oxygenated and more-
291 oxygenated organic products (Zhang et al., 2019;Chu et al., 2016;Liu et al., 2017). This
292 also indicated that the chemical conversion between the two factors could be ignored
293 in the absence of seed particles.

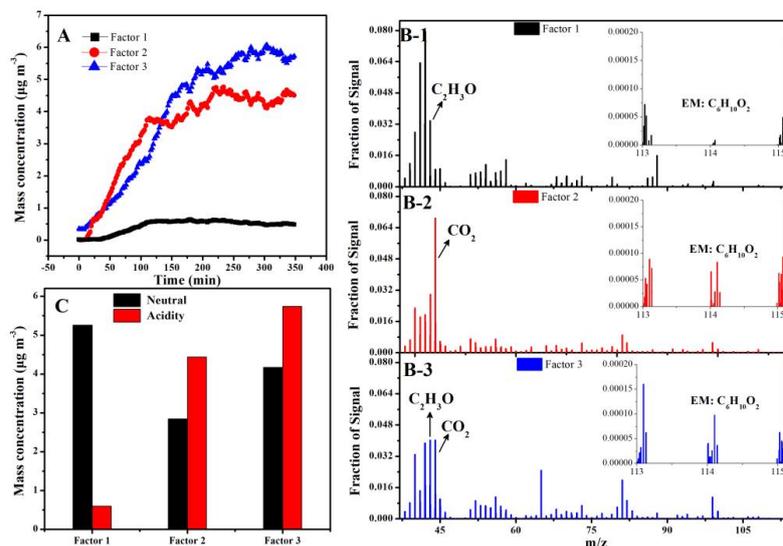

294
295 **Figure 3.** Two-factor solutions for PMF analyses of SOA under different SO₂
296 concentrations: (A) Different mass spectra between two factors (Factor 2-Factor 1) at
297 135 ppb SO₂; (B) Time series of factor concentrations; (C) Maximum concentration of
298 two factors at 55 ppb and 135 ppb SO₂.

299 In the presence of seed particles, the chemical evolution of SOA components under
300 different acidity conditions was also compared based on PMF analysis. From the
301 temporal variations in Figure 4A, three factors were identified and almost
302 simultaneously increased. Based on the mass spectra of the three factors (Figure 4B),
303 the fragments containing less-oxygenated species in Factor 1 (such as typical fragment
304 C₂H₃O⁺ (m/z 43)) were more abundant than in Factor 2. In contrast, the fragments
305 containing more-oxygenated species in Factor 2 (such as typical fragment CO₂⁺ (m/z
306 44)) were more abundant than in Factor 1. Thus, Factor 1 and 2 were tentatively
307 assigned to less-oxygenated and more-oxygenated organic aerosols, respectively. This
308 proved that the increase in particle acidity simultaneously promoted the formation of
309 both less and more-oxygenated species, similar to that in the SO₂ experiments. However,
310 it is worth noting that higher acidity significantly promoted the chemical conversion of
311 less-oxygenated species (Factor 1) to more-oxygenated species (Factor 2) via
312 functionalization based on the comparison between the neutral and acidic seed particles
313 (Figure 4C). As shown in Figure 4B, the ion at m/z 114 (C₆H₁₀O₂) was assigned to

314 precursor-related ions. The highest ion signal fraction (m/z 114) in Factor 3 and the
315 similar mass spectrum between EM and Factor 3 in Figure S13 implied that Factor 3
316 represented precursor-related species (Figure 4C).

317 Based on the comparison of Factors between seed experiments and SO_2 , it should
318 be noted that Factor 1 and Factor 2 in the seed experiments differed from that in the
319 SO_2 experiment. For SO_2 experiments, acidity appeared to convert Factor 2 to Factor
320 1 after 200 minutes, but in seed experiments, the more H_2SO_4 caused the formation of
321 more Factor 2 and less Factor 1. Thus, we concluded that, for the same Factor in two
322 types of experiments, the corresponding composition should be different each other.
323 One possible explanation for this was that the increase in primary and secondary H_2SO_4
324 particles could also affect SOA composition to some extent, such as via changing the
325 reaction pathway of sCI.

326
327 **Figure 4.** Three-factor solutions for PMF analyses of SOA under different seed
328 particles: (A) Time series of factor concentrations under acidic AAS; (B) Mass spectra
329 of three factors; (C) Comparison of maximum concentration of two factors under
330 neutral AS (black) and acidic AAS (red).

331 *Elemental analysis in Van Krevelen diagrams*

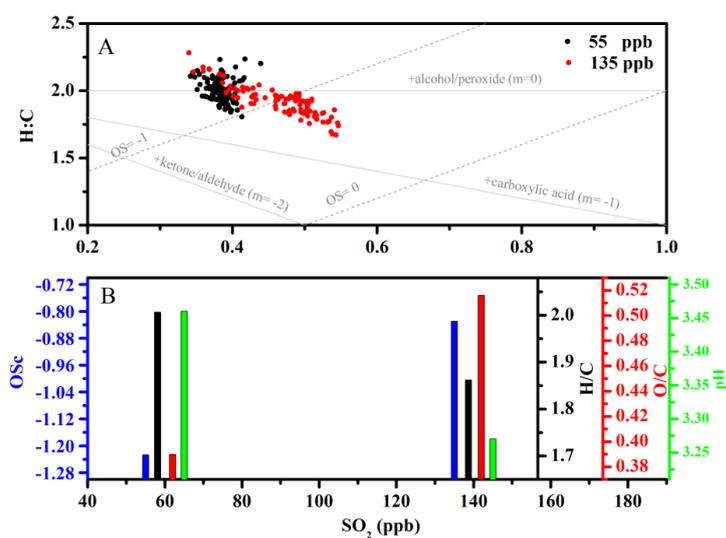

332 The rate at which the H/C ratio changes with the O/C ratio in Van Krevelen

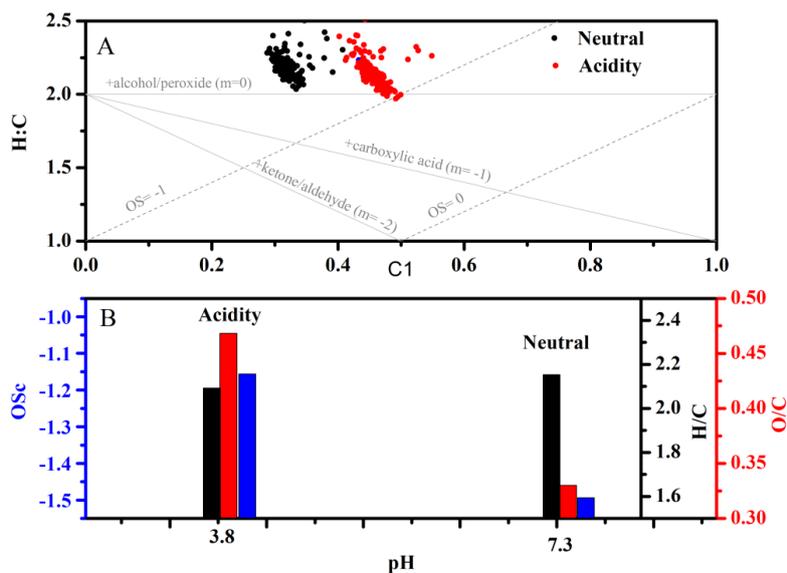

333 diagrams can provide new information about the functional groups formed during
334 oxidation (Lambe et al., 2012;Lambe et al., 2011;Li et al., 2019;Chen et al., 2011). As
335 shown in Figure 5A and 6A, the average (H/C)/(O/C) slopes under different
336 experimental conditions all approached -2. A slope of -2 is due to the formation of
337 carbonyl species (Ng et al., 2011). This is consistent with the acknowledged reaction
338 mechanism of alkene ozonolysis in the presence of SO₂, in which many carbonyl
339 species and H₂SO₄ particles are produced.(Sadezky et al., 2006;Sadezky et al.,
340 2008;Newland et al., 2015a;Newland et al., 2015b) To verify whether increased OS_c
341 was related to particle pH, particle pH was estimated using the E-AIM model (Model
342 II: H⁺ – NH₄⁺ – SO₄²⁻– NO₃⁻ – H₂O) when secondary particle formation peaked under
343 different SO₂ concentrations (Peng et al., 2019;Hennigan et al., 2015). Since no
344 organics are considered in Model II, there was an inherent assumption here that the
345 acidity and the water uptake was dominated by the inorganic ions. From Figure 5B, it
346 could be found that the averaged oxidation state (OS_c) of SOA increased with
347 decreasing particulate pH in the absence of seeds. Similar trend was also observed in
348 the presence of seed particles (Figure 6B). This indicated that increased OS_c was closely
349 related to increased particles acidity either in the presence or absence of seed particles.
350 These results also indicated that both functionalization and oligomerization associated
351 with carbonyls groups dominate the formation of EM-derived SOA. Moreover, it is
352 worth noting that O/C increased when H/C decreased with increased particle acidity in
353 the absence of seed particles. In contrast, the O/C ratio increased but the H/C ratio
354 basically remained stable with increased particle acidity in the presence of seed
355 particles. These result implied that increased particle acidity tended to promote the
356 formation of more highly oxidized products via oligomerization in the absence of seed
357 particles and tended to promote the formation of more highly oxidized products via
358 functionalization in the presence of seed particles (Darer et al., 2011;Zhang et al.,
359 2019;Shu et al., 2018). However, the promoting contribution of SOA functionalization
360 conversion of total SOA could be ignored compared with the reducing effect of acidic
361 particles. Some studies showed that increased OS_c was closely related to the formation

362 of organosulfate (Zhang et al., 2019; Liu et al., 2019a; Shu et al., 2018). However, the
363 similar S/C ratio and sulfate fragments distribution between neutral and acidic seed
364 experiments excluded the contribution of organosulfate formation to increased OS_c
365 (Figure S14).
366

369 concentrations of SO₂ (A); change in H/C ratio (black), O/C ratio (red), OS_c (blue), and
370 particle pH (green) as a function of initial SO₂ concentration (B).

371

372 **Figure 6.** Van Krevelen diagrams of elemental ratios under different seed particle
373 acidity (A); change in H/C ratio (black), O/C ratio (red), and OSc (blue) with particle
374 acidity (B).

375 Taken together, in the absence of seed particles, the homogeneous formation of
376 more H₂SO₄ particles not only promoted the quick condensation of less- and more-
377 oxygenated products and subsequent SOA formation via providing a greater surface
378 area and volume, but enhanced the oligomerization process (Figure 7). In the presence
379 of seed particles, the presence of more primary H₂SO₄ in seed particle enhanced EM
380 uptake and functionalization process, but reduced SOA production due to the formation
381 of surface H₂SO₄. This further indicated that the increase in primary and secondary
382 H₂SO₄ particles could significantly affect SOA formation and composition.

In order to make clear the formation mechanism of EM-derived SOA, the evolutions of some molecular ion peaks have been checked in detail. As shown in Figure S15, the increase of their mass concentrations with reaction time indicated that these molecular ions peaks with m/z 116, 130, 132, 140, 146, 148, 158, 162, 164, 176, 178, 180, 194, 196, and 212 should be the major ozonolysis products. Based on the previously reported mechanism of alkene ozonolysis, the mechanism of EM ozonolysis has been proposed in Scheme S1 (Jain et al., 2014; Vereecken and Francisco, 2012). Briefly, oxidation of EM is initiated by addition of ozone across the double bond resulting in a primary ozonide. The primary ozonide will produce two products (formaldehyde and ketone ester) and two sCIs (sCI-1 and sCI-2). Based on the initial carbonyl and sCI products (Scheme S1), it could be found that the saturated ketone ester couldn't be further oxidized by O₃ and formaldehyde was the terminate products of sCI-2 reaction. Thus, these major oxidation products observed in Figure S13 should come from the further reaction of sCI-1.

Proposed reaction mechanism of sCI-1 was also shown in Scheme 1. These sCI-1 could first convert to alkoxy radical (III) by losing OH group and O₂ addition. Then alkoxy radical with an additional oxygen atom not only could further react with RO₂ to form alcohols (V), but also react with HO₂ to form hydroperoxide product (IV). Moreover,

405 the intramolecular H-shift reaction may also compete with its bimolecular reaction with
406 HO₂ and other RO₂ radicals due to relatively weak C-H bonds in the molecule (Jokinen
407 et al., 2014; Crouse et al., 2013; Shu et al., 2018). Similarly, newly produced alkoxy
408 radical will continually and repeatedly react with HO₂, RO₂, and undergo its
409 intramolecular H-shift to form the higher oxidized alcohols, carbonyls, and
410 hydroperoxide product. The formation of these higher oxidized alcohols, carbonyls, and
411 hydroperoxide product might help to explain or give insight to the increased oxidation
412 state (OS_c) of the aerosol.

413

414

415 **Scheme 1.** Proposed mechanism for EM ozonolysis in the presence of AS particles

416

417 **4. Conclusion**

418 Some exposure measurement studies indicated that the concentration of ethyl
419 methacrylate was notably higher than other methacrylate in the salons working air. The
420 frequently exposure of methacrylate for a long time can trigger asthma or allergic
421 contact dermatitis. Thus, the wide variety of sources and high volatility and toxicity of
422 make EM a potential important source of environmental concern in the atmosphere.

423 In this work, we investigated and compared the formation of secondary particles
424 from EM ozonolysis under complex ambient condition. Results showed that a
425 substantial increase in secondary H₂SO₄ particles promoted SOA formation with
426 increasing SO₂. In contrast, the increase in primary H₂SO₄ proportion with seed acidity
427 enhanced EM uptake but reduced SOA formation. To clarify the underlying causes, we
428 analyzed the size distribution, chemical composition and evolution of SOA based on
429 PMF solutions and Van Krevelen diagrams. In the absence of seed particles, the
430 substantial increase in secondary H₂SO₄ particles with SO₂ provided greater surface
431 area and volume for further condensation of oxidation products. Moreover, enhanced
432 oligomerization functionalization of carbonyl species with increased particle acidity
433 also contributed to the increase in SOA in the absence of seed particles. However, in
434 the presence of seed particles, the increase of primary H₂SO₄ proportion in seed with
435 acidity enhanced more EM uptake, but the direct heterogeneous formation of H₂SO₄ on
436 the particle surface, differing from the condensation or nucleation of gas-phase H₂SO₄,
437 hampered the continuous heterogeneous ozonolysis of these adsorbed EM. Moreover,
438 even though increased particles acidity also caused chemical conversion of SOA via
439 functionalization, the contribution of the produced functionalized products to SOA
440 could be ignored due to the limited change in overall SOA formation. These results
441 indicated that the increase of primary and secondary H₂SO₄ particle has the different
442 effect on EM-derived SOA formation and its composition.

443 Taken together, our findings should not only help to clarify the SOA formation

444 mechanism of UVOEs ozonolysis in certain ambient environments particularly in
445 marine boundary layers and mid-continental regions, but should help to further
446 understand the complicated effects of increased H₂SO₄ components on SOA formation
447 and composition during haze pollution. In addition to EM, many other unsaturated
448 esters such as methyl methacrylate (MA), butyl methacrylate (BMA), and propyl
449 methacrylate (PMA) are also frequently measured in the real atmosphere (Blanco et al.,
450 2014;Ren et al., 2019). Thus more researches are needed to investigate the secondary
451 particles potential of these unsaturated esters, especially under complex ambient
452 conditions, which will help to further effectively evaluate the potential contribution of
453 their atmospheric oxidation process to secondary particle formation.
