20 **Abstract:**

21 Secondary aerosols (SA, including secondary organic and inorganic aerosols, SOA and SIA) are  
22 predominant components of aerosol particles in the North China Plain (NCP) and its formation has  
23 significant impacts on the evolution of particle size distribution (PNSD) and hygroscopicity. Previous  
24 studies have shown that distinct SA formation mechanisms can dominate under different relative  
25 humidity (RH). This would lead to different influences of SA formation on the aerosol hygroscopicity  
26 and PNSD under different RH conditions. Based on the measurements of size-resolved particle  
27 activation ratio (SPAR), hygroscopicity distribution (GF-PDF), PM<sub>2.5</sub> chemical composition, PNSD,  
28 meteorology and gaseous pollutants in a recent field campaign, McFAN (Multiphase chemistry  
29 experiment in Fogs and Aerosols in the North China Plain), conducted during the autumn-winter  
30 transition period in 2018 at a polluted rural site in the NCP, the influences of SA formation on cloud  
31 condensation nuclei (CCN) activity and CCN number concentration ( $N_{CCN}$ ) calculation under different  
32 RH conditions were studied. Results suggest that during daytime, SA formation could lead to a  
33 significant increase in  $N_{CCN}$  and a strong diurnal variation in SPAR at Super-saturations lower than  
34 0.07%. During periods with daytime minimum RH exceeding 50% (high RH conditions), SA  
35 formation significantly contributed to the particle mass/size changes in a broad size range of 150 nm  
36 to 1000 nm, led to  $N_{CCN}$  increases within the size range of 200 nm to 300 nm, and mass concentration  
37 growth mainly for particles larger than 300 nm. During periods with daytime minimum RH below 30%  
38 (low RH conditions), SA formation mainly contributed to the particle mass/size and  $N_{CCN}$  changes for  
39 particles smaller than 300 nm. As a result, under the same amount of mass increase induced by SA  
40 formation, the increase of  $N_{CCN}$  was stronger under low RH conditions and weaker under high RH  
41 conditions. Moreover, the diurnal variations of SPAR parameter (inferred from CCN measurements)  
42 due to SA formation varied with RH conditions, which was one of the largest uncertainties within  
43  $N_{CCN}$  predictions. After considering the SPAR parameter (estimated through the number fraction of  
44 hygroscopic particles or mass fraction of SA), the relative deviation of  $N_{CCN}$  predictions were reduced  
45 to within 30%. This study highlights the impact of SA formation on CCN activity and  $N_{CCN}$  calculation,  
46 which provides guidance for future improvements of CCN predictions in chemical-transport models  
47 and climate models.

## 48 1. Introduction

49 Cloud condensation nuclei (CCN) activity of aerosol particles describes its ability to activate  
50 and grow into cloud droplets at given supersaturations and thus has important impacts on cloud  
51 microphysics and the aerosol indirect effect on climate. CCN activity is dependent on the  
52 physicochemical properties of aerosol particles, including particle size distributions, hygroscopicity  
53 (determined by chemical composition) and mixing state. Thus, atmospheric processes influencing  
54 these aerosol properties may exert influences on CCN activity.

55 Secondary aerosols (SA) formation contributes greatly to aerosol populations and impacts  
56 CCN properties in many ways, generally increasing CCN number concentrations ( $N_{CCN}$ ) and leading  
57 to changes in the CCN activity (Wiedensohler et al., 2009; Kerminen et al., 2012; Wu et al., 2015;  
58 Farmer et al., 2015; Ma et al., 2016; Zhang et al., 2019 and reference therein). Differences in precursor  
59 and oxidant concentrations as well as SA formation mechanisms lead to particle size growth in  
60 different size ranges (Dal Maso et al., 2005; Kulmala et al., 2007; Zhang et al., 2012; Farmer et al.,  
61 2015; Cheng et al., 2016; Kuang et al., 2020c), thus would impact CCN activities in different ways.  
62 SA formation includes both the formation and subsequent growth of new particles (New Particle  
63 Formation, NPF), and the growth of existing particles. NPF can directly provide particles large enough  
64 to act as CCNs (Wiedensohler et al., 2009; Kerminen et al., 2012; Farmer et al., 2015), generally  
65 affecting aerosol particles smaller than 100 nm, thereby elevating  $N_{CCN}$  at higher supersaturations  
66 ( $SSs > 0.2\%$ ) (Wiedensohler et al., 2009; Kerminen et al., 2012; Ma et al., 2016; Zhang et al., 2019 and  
67 reference therein). SA formation on existing particles, especially under polluted conditions,  
68 significantly adds mass to and changes the chemical composition of accumulation mode particles  
69 (Farmer et al., 2015), thus affecting CCN at lower  $SSs$  ( $< 0.2\%$ ) (Wiedensohler et al., 2009; Mei et al.,  
70 2013; Yue et al., 2016; Thalman et al., 2017; Duan et al., 2018).  $SSs$  varies greatly among different  
71 clouds categories. Cumulus clouds are formed under higher  $SSs$  and are thus mostly influenced by  
72 Aitken mode particles formed in NPF events (Reuter et al., 2009; Gryspeerd and Stier, 2012; Fan et  
73 al., 2016; Jia et al., 2019 and reference therein). Stratus clouds and fogs that exert stronger effects on  
74 climate and environment, however, are generally formed at  $SSs$  lower than 0.2%, indicating that only  
75 accumulation mode particles can serve as CCN (Ditas et al., 2012; Hammer et al., 2014a, b; Krüger et  
76 al., 2014; Shen et al., 2018). Numerous studies have investigated the impact of NPF on CCN (Gorden  
77 et al., 2016; Ma et al., 2016; Yu et al., 2020 and reference therein), however, only few studies have  
78 focused on the influence of SA formation on CCN activity of accumulation mode particles, which  
79 might exhibit strong climate and environment impacts and urgently requires attention.

SA formation affects CCN activity of accumulation mode particles not only by enlarging their size, but also by changing their chemical compositions. At a specific particle size, the CCN activity is determined both by the chemical composition of particles, which originally were and stayed this size, and that of particles, which grew into this size via added SA mass. These two groups of particles can exert different variations to CCN activity at the same particle size (Wiedensohler et al., 2009 and reference therein). In general, the SA formation can increase the hygroscopicity of particles by adding chemical compounds with lower volatility and higher oxidation state, which are usually more hydrophilic, thereby enhancing CCN activity of accumulation mode particles (Mei et al., 2013; Yue et al., 2016). However, CCN activity may also remain unchanged (Wiedensohler et al., 2009) or be weakened in some cases (Thalman et al., 2017; Duan et al., 2018). In SA formation observed in central Amazon forests, Thalman et al. (2017) reported enhanced CCN activity in dry season while constant CCN activity in wet season. In SA formation events under polluted conditions in Guangzhou (Pearl River Delta, China), Duan et al. (2018) found that bulk CCN activity can be enhanced in summer due to the formation of large and inorganic-rich particles, but weakened in winter due to the formation of small and organic-rich particles, where RH seemed to have been an important factor in the variations of bulk CCN activity due to different particle formation pathways. Aside from variations of particle chemical composition, changes in aerosol mixing states caused by SA formation can also change CCN activity (Su et al., 2010; Rose et al., 2011; Cheng et al., 2012). The fast condensation of SA components on accumulation mode particles led to the turnover of soot particle mixing state from externally to internally mixed, which contributed mostly to enhancements of CCN activity (Cheng et al., 2012). Thus, SA formation influences the CCN activity of accumulation mode particles through its integrated impacts on their size, hygroscopicity and mixing state, which requires more detailed and comprehensive investigations.

The North China Plain (NCP) frequently experiences severe aerosol pollution due to both strong emissions of primary aerosol and strong SA formation caused by the abundance of gaseous precursors and oxidants (Zheng et al. ACP, 2015; Liu et al., 2010; Huang et al., 2014; Xu et al., 2019). In the SA formation events on the NCP, both aqueous-phase processes and gas-phase photochemical processes can play important roles, depending on atmospheric conditions such as RH (Hu et al., 2016; Xu et al., 2017a; Wang et al., 2019). A recent observational study on the NCP found that SA formation dominantly contributed to different particle size since SA formation mechanisms varied with RH conditions (Kuang et al., 2020c). Under dry conditions, SA were mainly formed through gas-phase photochemical processing and mostly added mass to accumulation mode particles. While under high RH conditions or super-saturated conditions, SA was also formed in aqueous phase, contributing to

the formation of both accumulation mode and coarse mode particles. The difference in particle size where SA formation took place and the difference in SA chemical compositions could result in distinct variations of CCN activity, which has not been evaluated yet. In this study, we will study the influence of SA formation on Size-resolved Particle Activation Ratio (SPAR) of accumulation mode particles in the NCP under different RH conditions, which fills a gap of knowledge within CCN studies in the NCP and may provide guidance for the improvement of current CCN parameterization schemes in chemical-transport and climate models.

## **2. Method:**

### **2.1. Measurements**

#### **2.1.1. Site**

Under the framework of McFAN (Multiphase chemistry experiment in Fogs and Aerosols in the North China Plain) (Li et al., 2021), from 16<sup>th</sup> November to 16<sup>th</sup> December 2018, physical and chemical properties of ambient aerosol particles as well as meteorological parameters were continuously measured at the Gucheng site in Dingxing county, Hebei province, China. This site is an Ecological and Agricultural Meteorology Station (39°09'N, 115°44'E) of the Chinese Academy of Meteorological Sciences, which is located between Beijing (~100km) and Baoding (~40km), two mega cities in the North China Plain, and surrounded by farmlands and small towns. Measurements at this site can well represent the polluted background conditions of the NCP. All aerosol measurement instruments were placed in a container with temperature maintained at 24 °C, while conventional trace gas instruments including CO were housed in an air-conditioned room on a two-story building located ~80 meters to the south of the container, with no taller buildings between them blocking the air flow.

#### **2.1.2 Instrumentation**

In this study, ambient aerosol was sampled by an inlet system consisting of a PM10 inlet (Rupprecht & Patashnick Co., Inc., Thermo, 16.67 L/min), a Nafion dryer that dried relative humidity to below 30% and an isokinetic flow splitter directing the air sample to each instrument.

A DMA-CCNC system measured SPAR at five supersaturations (SSs), 0.05%, 0.07%, 0.2%, 0.44% and 0.81%, with a running time of 20 min for 0.05% and 10 min for the other SSs. This system consisted of a differential mobility analyzer (DMA model 3081; TSI, Inc, MN USA), a condensation particle counter (CPC model 3772; TSI, Inc., MN USA) and a continuous-flow CCN counter (model CCN200, Droplet Measurement Technologies, USA; Roberts and Nenes, 2005). The system was operated in a size-scanning mode over the particle size range from 9 to 400 nm. SPAR can be obtained by combining the measurements of CPC and CCNC at different particle size. The sample and sheath

145 flow rate of the DMA were set to 1 lpm and 5 lpm, respectively, hence the resultant measured particle  
146 diameter ranged from 9 nm to 500 nm. Since the low number concentration of particles above 300 nm  
147 could lead to large uncertainty in CCNC counting, the measurements for particles larger than 300 nm  
148 were excluded, except for 0.05% SS. In order to characterize the variations of particles with low  
149 hygroscopicity of about 0.1, SPAR measurement up to about 400nm is used at 0.05% SS. There are  
150 12 size distribution scans during a complete 1-hour cycle, with four scans for first SS and two scans  
151 for each of the rest four SSs. Only the last scan for each SS is used as the CCNC needs time for SS  
152 stabilization. The SSs of CCNC were calibrated with monodispersed ammonium sulphate particles  
153 (Rose et al., 2008) both before and after the campaign. The flowrates were checked regularly (every  
154 few days) during the campaign, as the flows (sample flow and sheath flow) of the instrument can affect  
155 both the counting of droplets and the SS in the column. A modified algorithm based on Hagen and  
156 Alofs (1983) and Deng et al. (2011, 2013) was used to correct the influence of multiple-charge particles  
157 and DMA transfer function on SPAR. Details about the system are described in Ma et al. (2016) and  
158 the description about the inversion method can be found in the supplements.

159 Non-refractory particulate matter (NR-PM) including  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{Cl}^-$  and organics with  
160 dry aerodynamic diameters below  $2.5\ \mu\text{m}$  was measured by an Aerodyne Time-of-Flight Aerosol  
161 Chemical Speciation Monitor (ToF-ACSM hereafter) equipped with a  $\text{PM}_{2.5}$  aerodynamic lens  
162 (Williams et al., 2010) and a capture vaporizer (Xu et al., 2017b; Hu et al., 2017a) at 2-minute time  
163 resolution. The ToF-ACSM data were analyzed with the standard data analysis software (Tofware  
164 v2.5.13; <https://sites.google.com/site/ariacsm/>, last access: 21 January 2020). The organic mass spectra  
165 from  $m/z$  12 to 214 were analyzed with an Igor Pro based positive matrix factorization (PMF)  
166 evaluation tool (v3.04) and then evaluated following the procedures described in Zhang et al. (2011).  
167 The chosen five-factor solution includes four primary factors i.e. hydrocarbon-like OA (HOA),  
168 cooking OA (COA), biomass burning OA (BBOA), and coal combustion OA (CCOA), and a  
169 secondary factor, i.e. oxygenated OA (OOA). More detailed descriptions on the ACSM measurements  
170 and data analysis can be found in Kuang et al. (2020b) and Sun et al. (2020).

171 A Humidified Tandem differential mobility analyzer (HTDMA, Tan et al., 2013) measured the  
172 size-resolved aerosol growth factor (GF) at 90% RH. The sampled particles were subsequently charged  
173 by a neutralizer (Kr85, TSI Inc.) and size selected by a DMA (DMA1, model 3081L, TSI Inc.). A  
174 Nafion humidifier (model PD-70T-24ss, Perma Pure Inc., USA) was used to humidify the  
175 monodisperse particles with a specific diameter ( $D_d$ ) at a fixed RH of  $(90 \pm 0.44)\%$  and then the  
176 number size distribution of the humidified particles ( $D_{\text{wet}}$ ) was measured by another DMA (DMA2,

model 3081L, TSI Inc.) and a condensation particle counter (CPC, model 3772, TSI Inc.). Thus, GF of the particles can be calculated as:

$$GF = \frac{D_{wet}}{D_d} \quad (1)$$

During the campaign, four dry mobility diameters (60, 100, 150, and 200 nm) were selected for the HTDMA measurements. A full scan takes about 1 hour in order to cover the four sizes. Regular calibration by using standard polystyrene latex spheres and ammonium sulfate were performed to ensure the instrument functioned normally. The tandem differential mobility analyzer (TDMA) inversion algorithm (Gysel et al., 2009) was applied to calculate the Probability Density Function of GF (GF-PDF). More details about this system can be found in Cai et al. (2018) and Hong et al. (2018).

Particle number size distributions (PNSDs) were measured by combining the measurements of a scanning mobility particle sizer (SMPS, TSI model 3080) and an aerodynamic particle sizer (APS, TSI Inc., Model 3321), that measured particle mobility diameter size distributions in the range of 12 nm to 760 nm and particle aerodynamic diameter size distribution in the range of 700 nm to 10  $\mu$ m, respectively. A commercial instrument from Thermo Electronics (Model 48C) was used to measure CO concentration. Besides monthly multipoint calibrations and weekly zero-span check, additional 6-hourly zero checks were also performed for the CO instrument.

## 2.2. Data processing

### 2.2.1. Aerosol hygroscopicity and cloud activation: $\kappa$ -Köhler theory

The ability of particles to act as CCN and its dependence on particle size and particle chemical composition on CCN activity can be described by the Köhler theory (Köhler, 1936). A hygroscopic parameter  $\kappa$  is calculated based on the  $\kappa$ -Köhler theory (Petters and Kreidenweis, 2007) to evaluate the influence of particle chemical compositions:

$$\kappa = \left( \frac{D_{wet}^3 - D_d^3}{D_d^3} \right) \left[ \frac{1}{S} \exp \left( \frac{4\sigma_{s/a} M_w}{RT \rho_w D_{wet}} \right) - 1 \right], \quad (1)$$

where  $S$  represents the saturation ratio,  $\rho_w$  is the density of water,  $M_w$  is the molecular weight of water,  $\sigma_{s/a}$  is the surface tension of the solution/air interface,  $R$  is the universal gas constant,  $T$  is the temperature,  $D_d$  is the diameter of dry particle and  $D_{wet}$  is the diameter of the humidified particle. In this study,  $\sigma_{s/a}$  is assumed to be the surface tension of pure water/air interface. Based on the  $\kappa$ -Köhler theory, the surface equilibrium water vapor saturation ratio of particles with a specific  $\kappa$  at different wet particle size can be calculated, and the maximum value of surface equilibrium saturation ratio (which is generally supersaturated) is defined as the critical SS for CCN activation. As a result, the

variation of the critical diameter for particles with different hygroscopicity (or GF at a specific RH) at different SSs can be determined.

### 2.2.2. Aerosol growth factor and its probability density function

In practice, the growth factor probability density function (GF-PDF) was inversed from the measured GF distribution using a TDMA<sub>inv</sub> algorithm (Gysel et al., 2009). After obtaining the GF-PDF, the ensemble average GF and corresponding critical diameter under a certain SS ( $D_{a,GF}$ ) can be calculated. Furthermore, the number fraction and the weighted-average GF of hygroscopic particles ( $\kappa > 0.1$  and  $GF(90\%, 200\text{ nm}) > 1.22$ ) were calculated as:

$$NF_{\text{hygro}} = \int_{1.2}^{\infty} \text{PDF}(\text{GF}) \times d\text{GF} \quad (2)$$

$$GF_{\text{hygro}} = \int_{1.2}^{\infty} \text{GF} \times \text{PDF}(\text{GF}) \times d\text{GF} \quad (3)$$

Based on the  $\kappa$ -Köhler theory, the hygroscopicity parameter  $\kappa$  and corresponding critical diameter ( $D_{a,\text{hygro}}$ ) under a certain SS for particles with  $GF_{\text{hygro}}$  can be calculated. As  $GF_{\text{hygro}}$  is higher than the average GF,  $D_{a,\text{hygro}}$  is smaller than  $D_{a,GF}$ .

### 2.2.3 Calculations of aerosol hygroscopicity from aerosol chemical-composition measurements

For the calculation of aerosol hygroscopicity parameter  $\kappa$  based on measured chemical composition data ( $\kappa_{\text{chem}}$ ), detailed information on the chemical species are needed. The ACSM can only provide bulk mass concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{Cl}^-$  ions and organic components, which cannot be used to calculate size resolved hygroscopicity. However, in the North China Plain, accumulation mode particles are the dominant contributors to the bulk particle mass concentration (Liu et al., 2014; Xu et al., 2015; Hu et al., 2017b) and thus the bulk chemical compositions can be used as a proxy for that of accumulation mode particles. For the inorganic ions, a simplified ion pairing scheme was used to convert ion mass concentrations to mass concentrations of corresponding inorganic salts (Gysel et al., 2007; Wu et al., 2016). Thus, mass concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$  and  $\text{Cl}^-$  are specified into ammonium sulfate (AS), ammonium nitrate (AN), ammonium chloride (AC) and ammonium bisulfate (ABS), for which the  $\kappa$  values under super-saturated conditions were specified according to Petters and Kreidenweis (2007). For a given internal mixture of different aerosol chemical species, the Zdanovskii–Stokes–Robinson (ZSR) mixing rule can be applied to predict the overall  $\kappa_{\text{chem}}$  using volume fractions of each chemical species ( $\varepsilon_i$ ) (Petters and Kreidenweis, 2007):

$$\kappa_{\text{chem}} = \sum_i \kappa_i \cdot \varepsilon_i \quad (4)$$

where  $\kappa_i$  and  $\varepsilon_i$  represent the hygroscopicity parameter  $\kappa$  and volume fraction of chemical component  $i$  in the mixture. Based on Eq.2,  $\kappa_{\text{chem}}$  can be calculated as follows:

$$\kappa_{\text{chem}} = \kappa_{\text{AS}}\varepsilon_{\text{AS}} + \kappa_{\text{AN}}\varepsilon_{\text{AN}} + \kappa_{\text{ABS}}\varepsilon_{\text{ABS}} + \kappa_{\text{AC}}\varepsilon_{\text{AC}} + \kappa_{\text{BC}}\varepsilon_{\text{BC}} + \kappa_{\text{Org}}\varepsilon_{\text{Org}} \quad (5)$$

where  $\kappa_{\text{BC}}$  is assumed to be zero as black carbon is hydrophilic.  $\kappa_{\text{Org}}$  and  $\varepsilon_{\text{Org}}$  represent  $\kappa$  and volume fraction of total organics. The values of hygroscopicity parameter for inorganic compounds can be found in Table 1 of Kuang et al. (2020b). Large variations in  $\kappa_{\text{Org}}$  has been reported in former studies and a linear relationship between  $\kappa_{\text{Org}}$  and organic aerosol oxidation state (f44) was detected in our campaign (Kuang et al., 2020b), which was adopted to calculate  $\kappa_{\text{Org}}$  in this study:

$$\kappa_{\text{Org}} = 1.04 \times f44 - 0.02 \quad (6)$$

It should be noted that the  $\kappa$ -Köhler theory is not perfect, even for inorganic compounds. Numerous studies have been focusing on the performance of its application on measurements under different RH conditions (Liu et al., 2011; Wang et al., 2017). And  $\kappa_{\text{Org}}$  used in this study was determined by the measurement of humidified nephelometer at RH of 85% in Petters and Kreidenweis, (2007), due to the lack of  $\kappa_{\text{Org}}$  measured under super-saturated conditions. In this study, we focus on the variations of  $\kappa$  values derived from HTDMA and CCN measurement during the SA formation events, rather than the closure between  $\kappa$  values derived using different techniques, which will be addressed in an upcoming study.

#### 2.2.4. Fitting parameterization scheme of SPAR

In general, the variation in CCN activity of a particle population can be attributed to the variation in the number fraction of hygroscopic particles or its hygroscopicity, which can be indicated by fitting parameters of SPAR curves parameterization. SPAR curves are often parameterized using a sigmoidal function with three parameters. This parameterization assumes aerosols to be an external mixture of apparently hygroscopic particles that can act as CCN and non-hygroscopic particles that cannot be measured by CCNC within the measured particle size range below 400 nm (Rose et al., 2010). SPAR ( $Ra(D_p)$ ) at a specific SS can be described as follows (Rose et al., 2008):

$$Ra(D_p) = \frac{\text{MAF}}{2} \left( 1 + \text{erf} \left( \frac{D_p - D_a}{\sqrt{2}\sigma} \right) \right) \quad (7)$$

where erf is the error function. MAF is the asymptote of the measured SPAR curve at large particle sizes.  $D_a$  is the midpoint activation diameter and is associated with the hygroscopicity of CCNs.  $\sigma$  is the standard deviation of the cumulative Gaussian distribution function and indicates the heterogeneity of CCN hygroscopicity. As reported by Jiang et al. (2021), based on the investigation of the

266 covariations between SPAR curves and parameterized hygroscopicity distribution, it was found that  
267 the MAF can be used to estimate the number fraction of hygroscopic (thus CCN-active) particles, for  
268 aerosol hygroscopicity distributions generally observed in ambient atmosphere, and thus half MAF  
269 can be used to represent the number fraction of CCNs to total particles at particle size around  $D_a$ .  
270 Although the influence of particles whose  $\kappa$  is less than 0.1 on SPAR cannot be considered in this  
271 parameterization scheme, significant deviation were only found under higher SSs (Tao et al., 2020)  
272 and need not to be considered under the low SSs discussed in this study.

273 To be noted, the meaning of MAF can be different regard to the SS, and SPAR measurement  
274 up to about 400nm is needed for the MAF fitting for SPAR at SS of 0.05% to represent the particles  
275 with  $\kappa$  value higher than 0.1. For SPAR at SS of 0.8%, MAF should be 1 at 400 nm diameter. However,  
276 a MAF of 1 in this case can lead to overestimations of hygroscopic particle number fraction due to the  
277 significant difference between SPAR curves and sigmodal fitting curves. In the former study on SPAR  
278 fitting curves in the NCP, it was found that a fitting parameterization with the combination of two  
279 sigmodal fitting curves was needed for SPAR fitting at SSs higher than 0.4% (Tao et al., 2020).  
280 However, in this study, we investigate SA formation on accumulation mode particles and particle CCN  
281 activity at SSs below 0.1%, under which condition non-hygroscopic particles smaller than 400 nm are  
282 typically CCN-inactive. The MAF fitted in the particle size range below 400 nm was used to indicate  
283 the variations of SPAR that was of the main focus here in this work. In addition, due to the very low  
284  $N_{CCN}$  in particle size ranges larger than 400 nm, the deviations of  $N_{CCN}$  due to the limited range of  
285 measured particle size are also very small.

286

## 287 3. Results

### 288 3.1. Overview of the measurements

289 The timeseries of meteorological parameters, SPAR,  $N_{CCN}$  at SS of 0.05% and mass  
290 concentration of Non-refractory particulate matter of  $PM_{2.5}$  (NR- $PM_{2.5}$ ),  $PM_{2.5}$  SA and  $PM_{2.5}$  PA  
291 (primary aerosol, defined as the sum of POA) are shown in Fig. 1. During the campaign,  $PM_{2.5}$  PA  
292 were generally lower than  $100 \mu g m^{-3}$  under both high and low RH periods. Meanwhile,  $PM_{2.5}$  SA can  
293 approach about  $400 \mu g m^{-3}$ , especially during the strong SA formation events under high RH  
294 conditions, but can be lower than  $100 \mu g m^{-3}$  under low RH conditions. Strong diurnal variations were  
295 found in SPAR with varying meteorological parameters. During the whole period, the wind speed was  
296 generally lower than  $4 m s^{-1}$ , which is in favor of aerosol particle accumulation and SA formation on  
297 existing particles. However, RH,  $N_{CCN}$ ,  $PM_{2.5}$  SA and NR- $PM_{2.5}$  mass concentrations revealed very  
298 distinct levels before and after 4<sup>th</sup> Dec, and thus the whole campaign was divided into two stages with  
299 different RH and SA pollution conditions: higher RH and stronger SA pollution before 4<sup>th</sup> Dec, and  
300 lower RH and lighter SA pollution after 4<sup>th</sup> Dec. In the following discussions, the high RH stage  
301 corresponds to days before 4<sup>th</sup> Dec with daily maximum and minimum RH higher than 75% and 50%,  
302 respectively. Two events that occurred during 25<sup>th</sup> Nov to 27<sup>th</sup> Nov (Event 1) and 30<sup>th</sup> Nov to 2<sup>nd</sup> Dec  
303 (Event 2), respectively, displayed especially high RH conditions with successive nighttime fogs (blue  
304 shaded areas). The low RH stage corresponds to the period after 4<sup>th</sup> Dec with daily maximum and  
305 minimum RH below 70% and 30%, which was represented by two events that occurred during 9<sup>th</sup> Dec  
306 to 11<sup>th</sup> Dec (Event 3) and 13<sup>th</sup> Dec to 15<sup>th</sup> Dec (Event 4), respectively. These events were selected  
307 based on the similarity of  $PM_{2.5}$  concentration and evolution, while the time window was fixed to two  
308 days for the convenience of intercomparing. In addition, during these events, the wind speed was  
309 generally low, the RH followed a general diurnal variations and SA mass grew steadily and  
310 continuously. Thus the interference of the variations of air mass and short-term local emissions can be  
311 eliminated and the influence of SA formation can be highlighted. It should be noted that variations of  
312  $N_{CCN}$  at 0.07% were similar to those at 0.05%, which followed the variations of SA mass concentration.  
313 While at higher SSs, the variations of  $N_{CCN}$  differed from those of SA mass concentration, especially  
314 under high RH conditions, suggesting different responses of CCN activity towards distinct SA  
315 formation processes. As reported in Kuang et al. (2020c), during the high RH stage aqueous phase SA  
316 formation was promoted, leading to persistent increases in  $N_{CCN}$ , mass concentration of NR- $PM_{2.5}$  and  
317 especially mass concentration of  $PM_{2.5}$  SA during Event 1 and 2. During the low RH stage, the SA  
318 formation dominantly occurred in the gas-phase, that generated much less SA than aqueous-phase  
319 formation (Kuang et al., 2020c). Thus, the persistent increases of  $N_{CCN}$  and  $PM_{2.5}$  during Event 3 and

320 4 was much weaker than those in Events 1 and 2. Due to the different SA mass fractions, SPAR during  
321 the high RH stage was generally higher than that during the low RH stage. However, the ratios between  
322  $N_{CCN}$  and mass concentration of  $PM_{2.5}$  SA or NR- $PM_{2.5}$ , were lower during the high RH period and  
323 demonstrated strong decreases, especially in Event 1 and 2. The response of CCN activity and  $N_{CCN}$   
324 to the different SA formation mechanisms will be discussed comprehensively in the following parts.

### 325 **3.2. The influence of different secondary aerosol formation on the diurnal variation of CCN** 326 **activity**

327 The diurnal averages of PNSD, SPAR at SS of 0.05%, GF-PDF for 200 nm particle and mass  
328 fraction of particle chemical compositions during high RH periods before 4<sup>th</sup> Dec, low RH periods  
329 after 4<sup>th</sup> Dec and the four events are shown in Fig. 2, respectively. To be noted, the “high (or low) RH  
330 events” is used to refer to the SA formation events under high (or low) RH conditions for convenience,  
331 and it doesn’t mean that RH caused variations of CCN behavior. As can be seen in Figs. 2 (1b) and  
332 (2b), different variations of SPAR due to SA formations can be found during the periods with different  
333 RH conditions. The average diurnal variations of these parameters for the entire high RH stage and  
334 low RH stage as shown in Figs. 2 (1a-1d) and (2a-2d) revealed similar but more smoothed variations  
335 as in the four selected events. The four events are discussed and intercompared in the following to  
336 magnify the differences under distinct RH conditions. For accumulation mode particles, particle  
337 number concentrations were higher during daytime in high RH events, while stronger diurnal  
338 variations occurred in low RH events. Simultaneous daytime increases in particle SPAR,  
339 hygroscopicity and SA mass fraction were found in all four events, suggesting that SA formation led  
340 to increasing hygroscopic particles number concentration, which in turn enhanced particle CCN  
341 activity. This effect was more pronounced in Events 1 and 2 than in Events 3 and 4. In Events 1 and  
342 2, SPAR values were generally higher than 0.4 at 200 nm and reached the maximum of 1 during  
343 noontime at 300 nm. A hygroscopic mode with  $GF > 1.4$  was found throughout the day, which  
344 dominated aerosol hygroscopicity during daytime. Mass fraction of SA were generally higher than 70%  
345 and reach a maximum of 80% at noon. While in Events 3 and 4, SPAR at 200 nm was lower than 0.4  
346 at night and the maximum SPAR at 300 nm was lower than 0.9. A particle mode with  $GF < 1.1$   
347 dominates particle hygroscopicity, and the mass fraction of SA was lower than 60% and 30% at noon  
348 and at night, respectively. However, stronger daytime increase of SA mass fraction and accordingly  
349 larger variation in SPAR was observed in Events 3 and 4 than in Events 1 and 2.

350 Besides SS of 0.05%, variations of SPAR at SSs of 0.07% and 0.2% are also shown in Figs.  
351 S1 and S2 in the supplement. And as shown in Figs. S1 and S2, the variations of SPAR and  $N_{CCN}/PM$   
352 at SS of 0.07% are similar but lighter, compared with those at SS of 0.05%. While for SS of 0.2%, the

353 difference of SPAR between different periods or events are smaller (Fig. S1), and so did the diurnal  
354 variations of SPAR and GF-PDF at particle size of 100nm (Fig. S2). Because CCN activity at SS of  
355 0.2% was strong enough (indicated by SPAR value close to 1) in particle size range where the SA  
356 formation dominates, and thus the different SA formations under high or low RH conditions cannot  
357 lead to significant variations of CCN activity at SS of 0.2%. In summary, based on CCN measurements  
358 in this study, the RH-dependent influence of SA formation on CCN activity can be found obviously at  
359 SSs of 0.05% and 0.07%. As the variations of SPAR at SS of 0.07% were quite similar to those at SS  
360 of 0.05%, further analysis was only based on CCN activity at SS of 0.05%.

361 In Fig. 3a, detailed comparison of particle CCN activity during SA formation events of  $N_{CCN}$   
362 enhancements at SS of 0.05% under different RH conditions are shown as the variations of SPAR  
363 curves. Particle CCN activity in Events 1 and 2 were combined due to their similar diurnal variations  
364 (as shown in Fig. 2). Besides SPAR curves (Fig. 3a), corresponding fitting parameters of the SPAR  
365 curve including  $D_a$  and MAF were also shown in Figs. 3b and c, respectively, as enhanced SPAR for  
366 particle population can be attributed to hygroscopic particle number fraction increase (MAF increase)  
367 or enhancement of hygroscopic particle hygroscopicity ( $D_a$  decrease). Same as demonstrated in Fig. 2,  
368 SPAR was generally higher and thus particle CCN activity were generally stronger in high RH events  
369 than those in low RH events. However, as shown in Fig. 3a, the difference between SPAR in high and  
370 low RH events at 300 nm decreased from 0.2 to 0.1 during the SA formations, indicating for a stronger  
371 enhancement in low RH events, probably due to both the stronger increase of SA mass fraction and  
372 the higher nighttime PA mass fraction (Fig. 2(e)). Furthermore, in high RH events, there were daytime  
373 enhancements of SPAR within the 150 to 300 nm size range, as was indicated by the daytime increase  
374 of MAF and decrease of  $D_a$ , which mainly resulted from number fraction and hygroscopicity increases  
375 of CCN-active particles. While in low RH events, the daytime enhancement of SPAR was only  
376 observed for particles larger than 200 nm. This can be attributed to the strong increase of MAF and  
377 the slight decrease of  $D_a$ , which indicates significant increasing number fraction yet slightly enhanced  
378 hygroscopicity of hygroscopic particles, respectively. Overall, the enhancement of SPAR was weaker  
379 but occurred at a broader particle size range in high RH events than in low RH events, as shown in Fig.  
380 3a. This is in accordance with previous the results from Kuang et al. (2020c), suggesting that SA  
381 formation occurred mainly in aqueous phase within a broad particle size range (up to 1  $\mu\text{m}$ ) in high  
382 RH events, while SA formation dominantly proceeded via gas phase reactions and contributed to  
383 aerosol sizes smaller than 300 nm in low RH events. At SS of 0.05% (Fig. 3(a)), the variation of SPAR  
384 from 8:00-12:00 to 12:00-16:00 in particle size smaller than 200 nm was very small during low RH

385 events, suggesting a smaller CCN activity enhancement due to SA formation compared with those at  
386 high RH events.

387 As there were different influences of SA formation on both CCN activity at SS of 0.05% and  
388 PNSD under different RH conditions, different variation of  $N_{CCN}$  due to SA formation can also be  
389 expected. Fig. 4 displays the diurnal variation of  $PM_{2.5}$  mass concentration, volume concentration  
390 (Vconc), number concentration (Nconc) and  $N_{CCN}$  (all divided by CO to partially compensate for  
391 changes in planetary boundary layer height), as well as the  $N_{CCN}/PM_{2.5}$  mass concentration ratio and  
392 SPAR during high and low RH events, respectively. Variables in Fig. 4 were also presented in Fig. S3  
393 averaged for the entire high RH and low RH stages, respectively. Compared with the selected case  
394 events featuring significant  $N_{CCN}$  enhancement (Fig. 4(1c-2c)), the diurnal variations averaged for the  
395 entire high and low RH stages were similar, with higher levels of particle mass concentration but  
396 weaker enhancement of SA and  $N_{CCN}$ , indicating similar but weakened impact of SA formation on  
397 CCN activity due to the interference of other aerosol processes. Hereinafter, we discuss the variations  
398 in the four events to magnify the discrepancies of SA formation under high RH and low RH conditions  
399 and its distinct impact on  $N_{CCN}$ . The Vconc size distribution variations can be used as a proxy for the  
400 evolution of NR- $PM_{2.5}$  size distributions, considering the relatively small variations in particle density  
401 (ranging from 1.2 to 1.8 and with relative variations within 20% (Hu et al., 2012; Zhao et al., 2019)).  
402 The variations of the ratio between  $N_{CCN}$  (in different particle size range) and the mass concentration  
403 of  $PM_{2.5}$  SA (referred as to  $N_{CCN}/SA$ ) or NR- $PM_{2.5}$  (referred as to  $N_{CCN}/NR$ ) can be used to evaluate  
404 the response of  $N_{CCN}$  to SA formation.

405 During high RH events, normalized  $N_{CCN}$  increased by  $\sim 50\%$  from 8:00 to 14:00, with a similar  
406 increase in normalized  $PM_{2.5}$  SA mass concentration (Fig. 4(1a)). As the  $PM_{2.5}$  PA mass concentration  
407 decrease was much smaller than the SA increase, the NR- $PM_{2.5}$  mass concentration increase can be  
408 expected to be similar to the SA increase. As reported by Kuang et al. (2020c), SA during daytime  
409 were mainly formed at larger particle sizes, featuring Vconc increase in the particle size range of 400 to  
410 1000 nm. In Fig. 4(1d), significant increases of particle number concentration (Nconc) in particle size  
411 range of 150nm to 1000 nm can be observed. At larger particle size the increase of Nconc led to  
412 stronger increase of Vconc, which is why there was simultaneous but much weaker increases of Vconc  
413 in particle size range of 150 to 300 nm compared with increases of those in particle size of larger than  
414 300 nm (Fig. 4(1b)). This suggests that  $PM_{2.5}$  SA mainly contributed to particle sizes of larger than  
415 300 nm. In addition, because the SA formation enhanced hygroscopicity and number fraction of CCN-  
416 active particles in particle size range of 150 to 300 nm, simultaneous enhancements of SPAR can be  
417 found throughout the measured particle size range of 180 to 300 nm (Fig. 4(1e)). By combining the

enhancements of  $N_{conc}$  and SPAR in measured particle size ranges, there were increases of  $N_{CCN}$  from 200 to 500 nm (Fig. 4(1c)). While the strongest  $V_{conc}$  increases occurred at particle sizes larger than 300 nm, the  $N_{CCN}$  increased most in the particle size range of 200 to 300 nm, suggesting that particles larger than 300 nm were already CCN-active before SA formation. Thus while SA formation processes contributed to their volume (mass) and hygroscopicity increase, it had no further impact on  $N_{CCN}$ . As a result,  $N_{CCN}(>300\text{ nm})/SA$ ,  $N_{CCN}(<300\text{ nm})/SA$ ,  $N_{CCN}(>300\text{ nm})/NR$  and  $N_{CCN}(<300\text{ nm})/NR$  all decreased during the SA formation (Fig. 4(1f)), suggesting that weakening enhancement of  $N_{CCN}$  in SA formation under high RH condition as SA formation mainly added mass to already CCN-active particles.

During low RH events, weaker increases of both  $N_{CCN}$  and  $PM_{2.5}$  SA mass concentration from 8:00 to 14:00 was found (Fig. 4(2a)). At the same time, PA mass decreased by 50% and the variation of total NR mass was small. Under low RH conditions, SA formation mainly contributed to mass enhancements of smaller particle sizes (Kuang et al., 2020c).  $V_{conc}$  increased mostly in the range of 150 to 300 nm (Fig. 4(2b)), while  $N_{conc}$  only increased within 300 nm (Fig. 4(2d)), suggesting that  $PM_{2.5}$  SA mainly formed in particle size range within 300 nm. SA formation mainly enhanced number fraction of CCN-active particles in particle size of 200 to 300 nm, as SPAR only revealed evident enhancement (Fig. 4(2e)) and  $N_{CCN}$  only significantly increased (Fig. 4(2c)) in that size range. As a result, although  $N_{CCN}(>300\text{ nm})/SA$  decreased similar as that under high RH conditions,  $N_{CCN}(<300\text{ nm})/SA$  and  $N_{CCN}(>300\text{ nm})/NR$  generally stayed constant and  $N_{CCN}(<300\text{ nm})/NR$  even increased during SA formation in daytime (Fig. 4(2f)). The ratio between bulk  $N_{CCN}$  and mass concentration of  $NR-PM_{2.5}$  became larger due to the SA formation, suggesting that stronger enhancement of  $N_{CCN}$  in SA formation under low RH condition, because SA formation mainly added mass to CCN-inactive particles and turned them into CCN-active particles.

In summary, during the campaign in this study, two kinds of SA formation events were observed under different RH conditions with different variations of PM and  $N_{CCN}$  at SSs lower than 0.07%. Under high RH conditions, there were strong SIA dominated SA formation leading to higher particle hygroscopicity and  $N_{CCN}$  enhancements. Meanwhile, under low RH conditions, there were moderate SOA dominated SA formation with moderate particle hygroscopicity and  $N_{CCN}$  enhancements. However, for a unit amount of SA formation, the increase of  $N_{CCN}$  was stronger under low RH conditions and weaker under high RH conditions. This was because SA formation under low RH conditions was more concentrated on particle sizes smaller than 300 nm and added more mass to CCN-inactive particles, turning them into CCN-active particles. In addition, strong and distinct diurnal

450 variations of CCN activity of particles were observed during different SA formation processes, whose  
451 effects on  $N_{CCN}$  calculation need to be further evaluated.

452

### 453 **3.3. The influence of diurnal variation of CCN activity on $N_{CCN}$ prediction**

454 Since PNSD measurements are generally more simple and common than  $N_{CCN}$  measurement,  
455  $N_{CCN}$  is usually estimated from real-time PNSD combined with parameterized CCN activity. In former  
456 sections, it was already manifested that SA formations under different RH conditions led to distinct  
457 variations in PNSD and SPAR at SS of 0.05%, thus different variations in  $N_{CCN}$ . Thus, it is important  
458 for the prediction of  $N_{CCN}$  to quantify its sensitivity towards changes in PNSD and SPAR during SA  
459 formation processes under different RH conditions.

460 In this study, PNSD dominated the  $N_{CCN}$  calculation as was generally found in former studies  
461 (Dusek et al., 2006), but the variation of CCN activity also contributed significantly to the deviation  
462 of  $N_{CCN}$  calculation during SA formation. In former discussions, CCN activity (indicated by SPAR) at  
463 0.05% SS revealed significant diurnal variations during this campaign, which were different during  
464 SA formations under distinct RH conditions. The ratio between  $N_{CCN}$  calculated based on campaign  
465 averaged SPAR ( $N_{CCN\_cal}$ ) to measured  $N_{CCN}$  ( $N_{CCN\_meas}$ ) at 0.05% SS before and after 4<sup>th</sup> Dec are  
466 shown in Fig. 5. SPAR is determined by the variation of  $D_a$  and MAF, which reflect changes in  
467 hygroscopicity and number fraction of hygroscopic particles. Thus, to investigate the separate  
468 influence of MAF and  $D_a$  variations on  $N_{CCN}$  predictions,  $N_{CCN\_AvgMAF}$  (or  $N_{CCN\_avgDa}$ ) was calculated  
469 based on the real-time PNSD and SPAR estimated by replacing MAF (or  $D_a$ ) in Eq. 7 with the  
470 campaign averaged value. During the high RH stage, underestimation of daytime  $N_{CCN\_cal}$  can reach  
471 up to 20%, since SPAR variations due to CCN activity enhancement were not considered. Similar  
472 deviations of both  $N_{CCN\_AvgMAF}$  and  $N_{CCN\_avgDa}$  from  $N_{CCN\_meas}$  were detected, suggesting that both  
473 MAF and  $D_a$  variations contributed to  $N_{CCN\_cal}$  underestimation under high RH conditions. During the  
474 low RH stage, up to 50% overestimation existed in  $N_{CCN\_AvgSPAR}$  beyond SA formation episodes. Only  
475  $N_{CCN\_AvgMAF}$  displayed similar deviations from  $N_{CCN\_meas}$ , indicating that differences between  $N_{CCN\_cal}$   
476 and  $N_{CCN\_meas}$  were mainly contributed by variations in MAF brought on by significant CCN-active  
477 particles number fraction growth due to SA formations. To be noted,  $N_{CCN\_AvgSPAR}$  before and after 4<sup>th</sup>  
478 Dec are both on the basis of the averaged SPAR of this campaign (green dots in Fig. 5a) rather than  
479 the averaged SPAR before or after 4<sup>th</sup>, because the applicability of the campaign averaged SPAR on  
480 the  $N_{CCN}$  calculation in the NCP was confirmed in many former studies (Deng et al., 2012; Wang et  
481 al., 2013; Ma et al., 2016). During the low RH periods, SPAR are generally lower than the averaged

SPAR of the campaign and the ratio between the calculated and measured  $N_{CCN}$  are systematically higher (lasting for the whole night). In summary, SA formation processes can induce significant deviation to  $N_{CCN}$  prediction, which mainly resulted from the variation of MAF and also varied under different RH conditions. Thus, for accurate  $N_{CCN}$  estimations, considering the variation of MAF (changes in aerosol hygroscopicity) is highly essential.

As SOA is generally considered to be more hygroscopic than POA (Frosch et al., 2011; Lambe et al., 2011; Kuang et al., 2020a), the increase of hygroscopic particles or SA particles (both SIA and SOA) were considered to be the cause for the increase of SPAR within 200 to 300 nm size range (Fig. 2). In order to account for the variations of hygroscopic particles or SA particles in  $N_{CCN}$  calculation, Number Fraction of hygroscopic particles ( $GF(90\%, 200\text{ nm}) > 1.22$ ,  $NF_{hygro}$ ) measured by HTDMA and Mass Fraction of SA particles ( $MF_{SA}$ ) measured by ACSM were used to represent MAF variations and to provide calculation of  $N_{CCN}$  at SS of 0.05% combining with PNSD measurement with smaller deviations.

Based on the bulk hygroscopicity derived from particle chemical compositions measurements ( $\kappa_{chem}$ ), a critical diameter can be calculated based on  $\kappa$ -Köhler theory and based on which  $N_{CCN}$  can be predicted by combining measured PNSD with this critical diameter ( $N_{CCN\_Chem}$ ). Although there can be significant deviations for  $\kappa$  of accumulation mode particles derived from chemical composition of the bulk aerosol, which leads to significant deviations of  $N_{CCN}$  prediction. However, in practice, the measurements of chemical compositions of accumulation mode particles are not common, and chemical composition of the bulk aerosol is still commonly applied in CCN studies (Zhang et al., 2014; Zhang et al., 2016; Che et al., 2017; Cai et al., 2018), especially when particle hygroscopicity measurements were in lack. In Fig. 6(a), it can be found that  $N_{CCN\_meas}$  at 0.05% SS can be strongly underestimated by  $N_{CCN\_Chem}$ , especially at lower  $N_{CCN\_meas}$  ( $\sim 10^2 \text{ \# cm}^{-3}$ ), which is similar to results of studies that encountered high fractions of organics (Chang et al., 2010; Kawana et al., 2015). This deviation between  $N_{CCN\_meas}$  and  $N_{CCN\_Chem}$  may have resulted from the hypothesis of internal mixing state and the difference of particle hygroscopicity derived by particle chemical composition measurements and CCN activity. Fig. 6(b) depicts the correlation between mass fraction of SA ( $MF_{SA}$ ) and MAF at 0.05% SS.  $MF_{SA}$  was generally positively correlated to MAF ( $r=0.8$ ) with slight underestimations, suggesting that externally mixed SA dominated CCN-active particles. Thus, in the prediction of  $N_{CCN}$ , real-time SPAR can be calculated from average  $D_a$  and MAF assumed to equal to real-time  $MF_{SA}$  ( $N_{CCN\_MF}$ ). As displayed in Fig. 6(c), the underestimation and correlation between  $N_{CCN\_cal}$  and  $N_{CCN\_meas}$  was improved after introducing  $MF_{SA}$  into  $N_{CCN}$  calculation. Additionally, the diurnal variations of  $N_{CCN\_cal}/N_{CCN\_meas}$  ratio based on different methods of  $N_{CCN}$  calculation during

the whole campaign were shown in Fig. 6(d). It can be found that by considering the real-time  $MF_{SA}$ , the deviation of calculated  $N_{CCN}$  (Real-time MF) can be reduced throughout the day, compared with  $N_{CCN\_Chem}$  (Real-time Chem). Meanwhile, if an averaged  $MF_{SA}$  is used to estimate SPAR and  $N_{CCN}$ , the deviations of calculated  $N_{CCN}$  (Averaged MF) can be reduced as well, but demonstrated a much stronger diurnal variations than the deviation of  $N_{CCN\_MF}$ .

Based on the bulk hygroscopicity derived from GF measurement ( $\kappa_{GF}$ ) at 200 nm, a critical diameter can be calculated based on  $\kappa$ -Köhler theory and  $N_{CCN}$  at 0.05% SS can be predicted by combining measured PNSD and the critical diameter ( $N_{CCN\_GF}$ ). Fig. 7(a) shows that  $N_{CCN\_meas}$  were strongly underestimated by  $N_{CCN\_GF}$  (by more than 30%). This deviation may also have result from the hypothesis of internal mixing state and the difference of particle hygroscopicity derived by GF and particle CCN activity measured under different water vapor saturated conditions. Fig. 7(b) depicts the positive correlation between  $NF_{hygro}$  and MAF at 0.05% SS, which was weaker than that between  $MF_{SA}$  and MAF. Similar as before,  $NF_{hygro}$  was applied as a proxy for MAF in the  $N_{CCN}$  calculation, which also improved the underestimation and correlation between  $N_{CCN\_cal}$  and  $N_{CCN\_meas}$  (Fig. 7(c)). The diurnal variations of the  $N_{CCN\_cal}/N_{CCN\_meas}$  ratio based on different methods of  $N_{CCN}$  calculation during the whole campaign were shown in Fig. 7(d). It can be found that by considering the real-time  $NF_{hygro}$ , the deviation of  $N_{CCN\_NF}$  (Real-time NF) can be reduced mainly during nighttime, compared with  $N_{CCN\_GF}$  (Real-time GF). Meanwhile, if an averaged  $NF_{hygro}$  is used to estimate SPAR and  $N_{CCN}$ , the deviations of calculated  $N_{CCN}$  (Averaged NF) can be reduced during nighttime as well, but demonstrated a stronger diurnal variations than the deviation of  $N_{CCN\_NF}$ . If GF-PDF were directly used to calculate  $N_{CCN}$ ,  $N_{CCN\_cal}$  would agree well with measured  $N_{CCN}$  (Fig. S4), because in this way the mixing state of aerosol would have been accounted for. However, compared to the approach using GF-PDF,  $NF_{hygro}$  is easier to apply in  $N_{CCN}$  calculation and can yield similar accuracies.

In summary, MAF exhibited strong diurnal variation that varied under different RH conditions due to different SA formation mechanisms, which contributed most to  $N_{CCN}$  estimation deviations if unaccounted for. The diurnal variations of MAF at the five measured SSs (Fig. S5) reveal significant diurnal variations in MAF at low SSs (0.05% and 0.07%) that are dependent on RH conditions, while small diurnal variations that are insensitive to the RH conditions at SSs over 0.2%. In general, MAF become lower at lower SSs, especially during nighttime. As the fraction of CCN-active particles were generally hygroscopic and composed of secondary compounds, positive correlation was found between MAF,  $MF_{SA}$  and  $NF_{hygro}$ . Although a good prediction of  $N_{CCN}$  was achieved by applying an averaged MAF (Figs. 5, 6d and 7d), in practice, this would still require CCN measurements or HTDMA/chemical composition measurements as proxies. Additionally, deviations of  $N_{CCN\_cal}$  based

548 on the averaged MAF can be large under low RH conditions (Fig. 5c), while time-dependent MAF can  
549 eliminate a great part of these deviations. Thus, by replacing MAF with real-time  $MF_{SA}$  or  $NF_{hygro}$   
550 when deriving SPAR curve, the relative deviation of  $N_{CCN}$  calculation can be reduced. The proposed  
551  $N_{CCN}$  parameterization using  $MF_{SA}$  can also be easily adopted by chemical-transport and climate  
552 models, improving their representation of  $N_{CCN}$  changes due to distinct SA formation processes.

553

#### 4. Conclusions

SA formation drives the development of haze pollution in the NCP and can result in significant variations of PNSD and aerosol hygroscopicity. Studies in the NCP have shown that the mechanism of SA formation can be affected by relative humidity (RH), and thus has different influences on the aerosol hygroscopicity and PNSD under distinct RH conditions. The difference in particle size where SA formation is taking place and the different chemical compositions of formed SA can result in different variations of CCN activity. Thus, it is essential to study the influence of SA formation on CCN activity of existing accumulation mode particles under different RH conditions in the NCP. As  $N_{CCN}$  is often predicted based on real-time PNSD and parameterized SPAR, the influence of varying SPAR in distinct SA formation processes on  $N_{CCN}$  calculation needs to be evaluated in detail.

Based on the measurements of CCN-activity, particle hygroscopicity, particle chemical composition, PNSD during the McFAN campaign in Gucheng winter 2018, the influences of SA formation on CCN activity and  $N_{CCN}$  calculation under different RH conditions were investigated especially at SSs lower than 0.07%. Two kinds of SA formation events were identified under different RH conditions with distinct variations in PM and  $N_{CCN}$  at 0.05% SS. Under high RH conditions, which corresponds to the periods with minimum RH higher than 50% in daytime, strong SA formation and  $N_{CCN}$  enhancements with strong hygroscopic particles and SIA dominated contribution to SA (>70%) was found. While under low RH conditions, which corresponds to the periods with daytime minimum RH below 30%, moderate SA formation and  $N_{CCN}$  enhancements with moderately hygroscopic particles and SOA dominated contribution to SA was found. However, the increase of  $N_{CCN}$  under the a same amount of SA formation was stronger under low RH conditions and weaker under high RH conditions. This was because the formation of SA under low RH conditions was more concentrated in particle size range smaller than 300 nm and added more mass to CCN-inactive particles turning them into CCN-active ones after SA formation.

In addition, strong diurnal variations of CCN activity of particles at 0.05% SS due to the strong SA formations were also observed, both varying with RH conditions.  $N_{CCN}$  was significantly underestimated when MAF (SPAR parameter) variations were not considered. As the fraction of CCN-active particles were generally hygroscopic and composed of secondary compounds, there were good correlation among MAF inferred from measurements of CCN activity, particle hygroscopicity and particle chemical compositions. Thus, the relative deviation of  $N_{CCN}$  estimation can be reduced by applying measurements of particle hygroscopicity or particle chemical compositions as a proxy for aerosol mixing state.

586 This study can further the understanding of the impact of SA formation on CCN activity and  
587  $N_{CCN}$  calculation, specifically for SA formations on existing particles, which can strongly affect cloud  
588 microphysics properties in stratus clouds and fogs. The investigation of the influence of SA formation  
589 on CCN activity of existing particles in this study is important for improving  $N_{CCN}$  parameterizations  
590 in chemical-transport and climate models, so that they can account for the large variations induced by  
591 SA formation processes.

# 900      **Figures:**

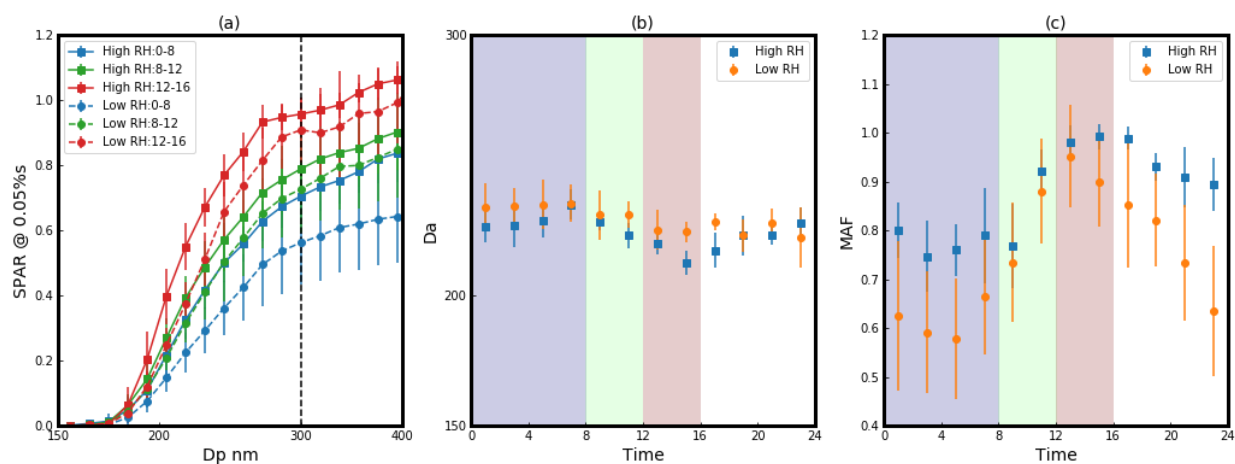

901

902      Fig 1. Overview of the measurements during the campaign: (a) dots represent wind speed with color  
 903      indicating wind direction, and black lines represent RH; (b) SPAR under SS of 0.05%; (c) blue, green  
 904      and yellow dots represent  $N_{CCN}$  under SS of 0.05% and 0.07%, and mass concentration of NR-PM<sub>2.5</sub>,  
 905      respectively; (d) blue, green and yellow dots represent  $N_{CCN}$  under SS of 0.2%, 0.44% and 0.81%,  
 906      respectively; (e) blue and yellow dots represent mass concentration of PM<sub>2.5</sub> PA and PM<sub>2.5</sub> SA  
 907      respectively; (f) blue and yellow dots represent ratio between  $N_{CCN}$  and mass concentration of NR-  
 908      PM<sub>2.5</sub> and PM<sub>2.5</sub> SA, respectively. There were four events with significant enhancements of  $N_{CCN}$   
 909      during the blue shaded periods.

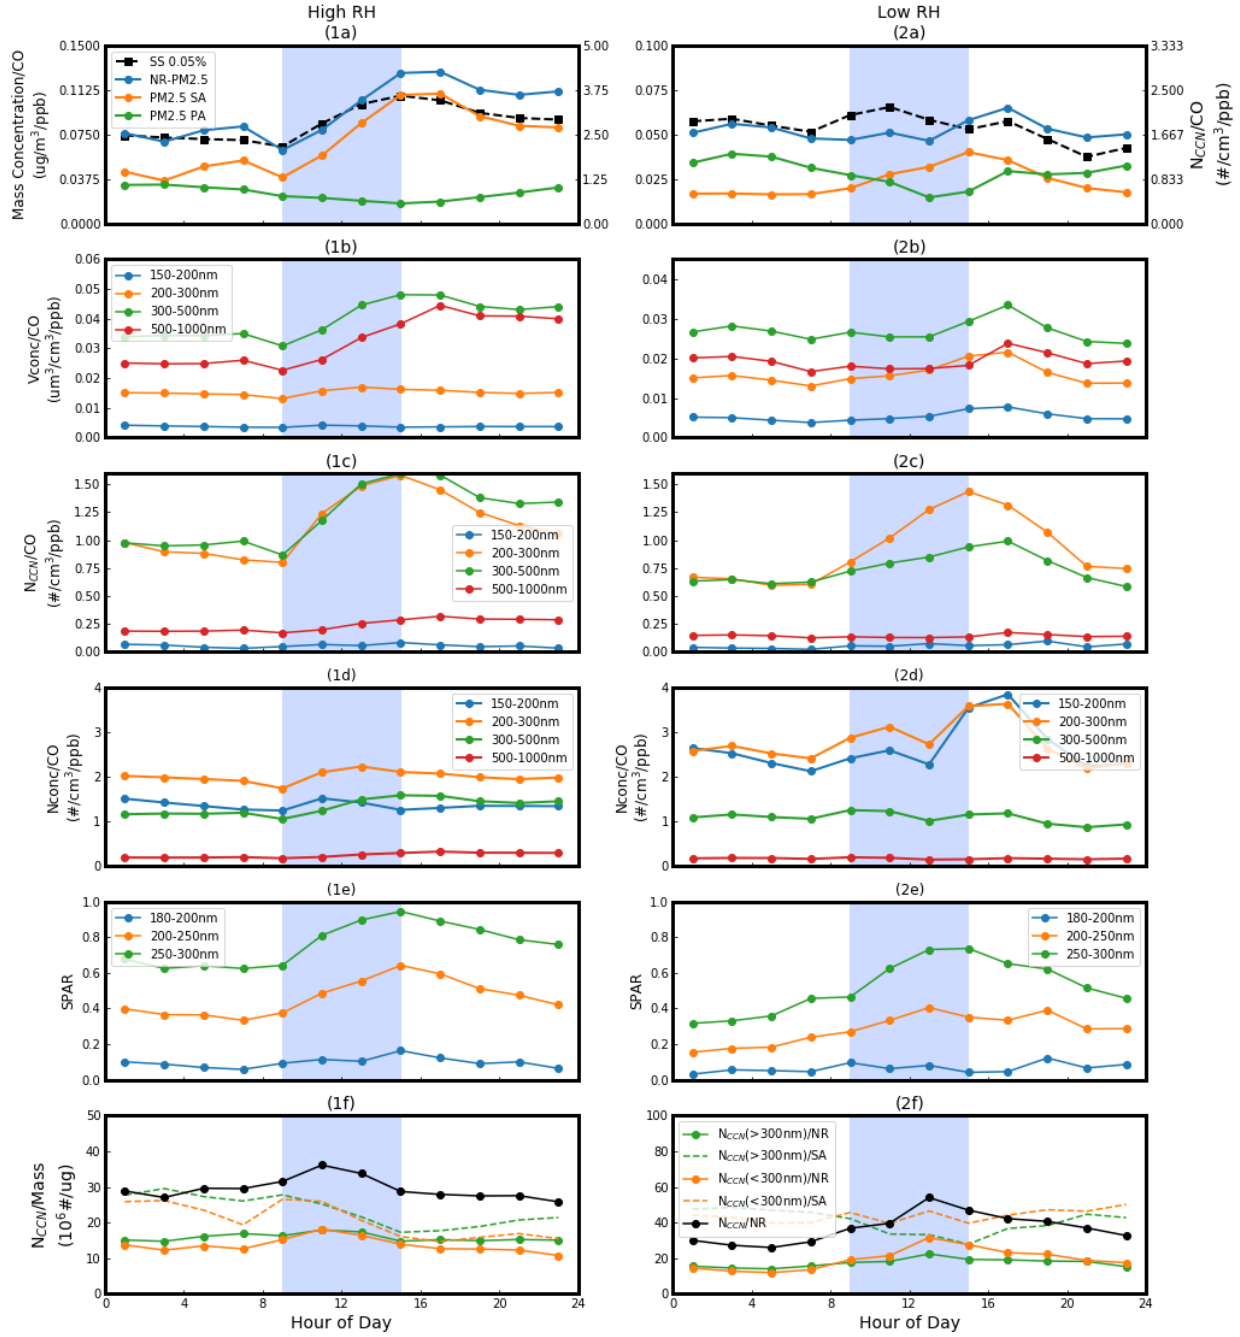

911

912 Fig 2. Diurnal variation of (a) PNSD, (b) SPAR at SS of 0.05%, (c) GF-PDF at 200 nm and (d) mass  
913 fraction of different PM<sub>2.5</sub> chemical species during high RH periods before 4<sup>th</sup> Dec (1), low RH  
914 periods after 4<sup>th</sup> Dec (2) and the four events (3-6), including OA factors: hydrocarbon-like OA  
915 (HOA), cooking OA (COA), biomass burning OA (BBOA), coal combustion OA (CCOA), and  
916 oxygenated OA (OOA).

919 Fig 3. (a) The averages of SPAR curves at SS of 0.05% in three different time periods (blue: 0:00-  
 920 8:00; green: 8:00-12:00; red: 12:00-16:00) during high (squares with solid line, event 1 and 2) and low  
 921 (dots with dashed line, event 3 and 4) RH events. Diurnal variation of (b)  $D_a$  and (c) MAF under high  
 922 (blue) and low (yellow) RH conditions. The blue, green and red shades correspond to with the three  
 923 periods in (a & d). Error bars indicate the standard deviations of data.

924

925

926

927

928

929

930

931

932

933

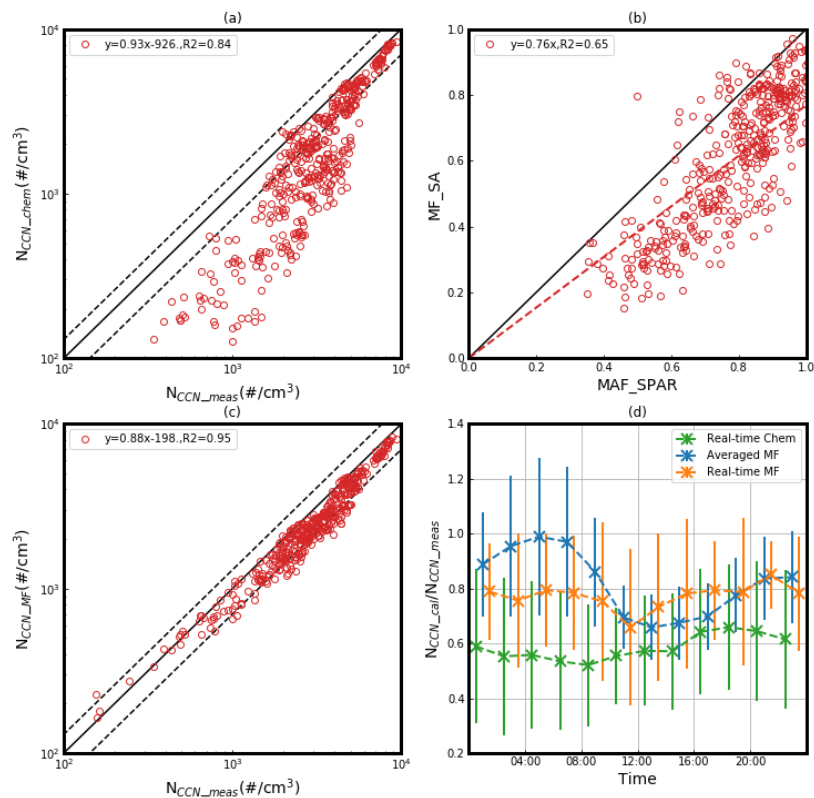

Fig 4. During different RH events, the average diurnal variation of (a) the ratios between particle mass concentration (dots with solid lines; blue: NR-PM<sub>2.5</sub>; yellow: PM<sub>2.5</sub> SA; green: PM<sub>2.5</sub> PA) and CO concentration, and the ratio between N<sub>CCN</sub> at SS of 0.05% and CO concentration (squares with solid line); (b) the ratios between particle volume concentration (Vconc) of different particle size range (indicated by colors) and CO concentration; (c) the ratios between N<sub>CCN</sub> of different particle size range at SS of 0.05% (indicated by colors) and CO concentration; (d) the ratios between particle number concentration (Nconc) of different particle size range (indicated by colors) and CO concentration; (e) SPAR of different particle size range (indicated by colors); (f) the ratios between N<sub>CCN</sub> at SS of 0.05% (black: bulk N<sub>CCN</sub>; yellow: N<sub>CCN</sub> with particle size larger than 300 nm; blue:

934  $N_{CCN}$  with particle size smaller than 300 nm) and mass concentration of NR-PM<sub>2.5</sub> SA and the ratios  
935 between  $N_{CCN}$  and mass concentration of NR-PM<sub>2.5</sub> (dashed lines).

937

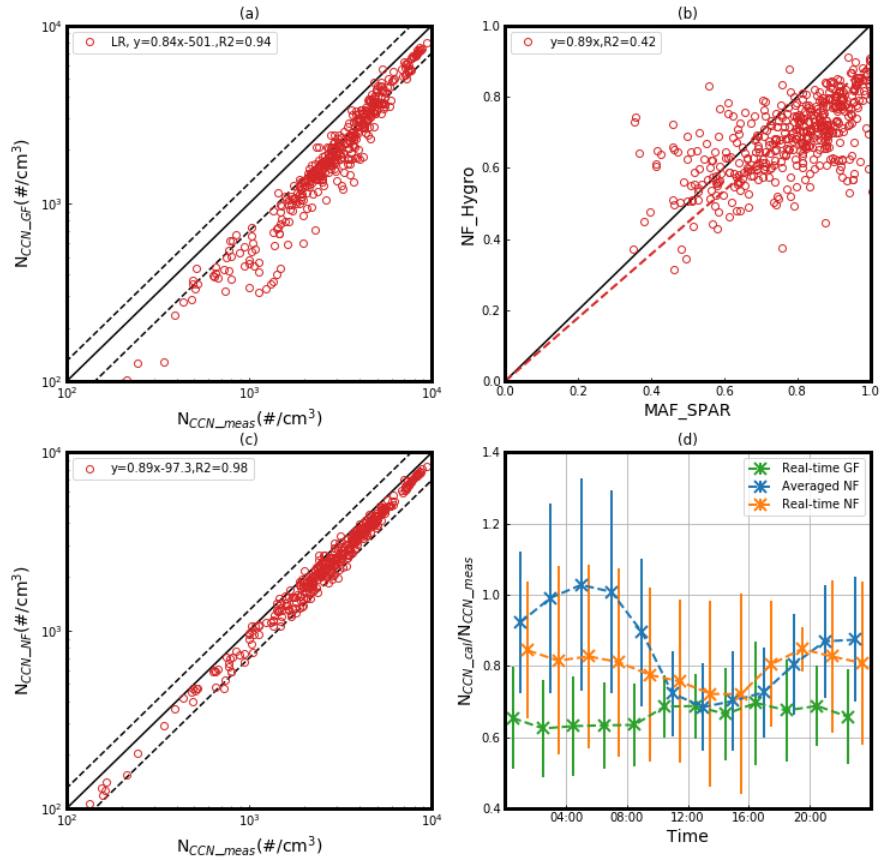

938 Fig 5. (a) The averaged SPAR at SS of 0.05% during the campaign (green scatters), the  
939 corresponding fitting curve (green line) and the averaged fitting parameters (dotted line for D<sub>a</sub> and  
940 dashed line for MAF). The blue and yellow shaded areas represent the variations of SPAR before 4<sup>th</sup>  
941 Dec and after 4<sup>th</sup> Dec, respectively. The ratio between calculated N<sub>CCN</sub> and measured N<sub>CCN</sub> under (b)  
942 before and (c) after 4<sup>th</sup> Dec. Bars represent one standard deviation and colors represent different  
943 calculation of SPAR curves: green represent average SPAR during the campaign (AvgSPAR),  
944 yellow represent SPAR calculated with average D<sub>a</sub> and real-time MAF (AvgDa) and blue represent  
945 SPAR calculated with average MAF and real-time D<sub>a</sub> (AvgMAF).

946

947 Fig 6. (a) The comparison between calculated  $N_{CCN}$  based on  $\kappa$  derived from bulk particle chemical  
 948 compositions ( $N_{CCN\_chem}$ ) and measured  $N_{CCN}$  at SS of 0.05%. (b) The correlation between MAF and  
 949 mass fraction of secondary aerosol ( $MF_{SA}$ ). (c) the comparison between calculated  $N_{CCN}$  based on  
 950 SPAR derived from real-time  $MF_{SA}$  and average  $D_a$  ( $N_{CCN\_MF}$ ) and measured  $N_{CCN}$ . The black dashed  
 951 lines represent the relative deviation of 30%. (d) the diurnal variations of the ratio between the  
 952 calculated and measured  $N_{CCN}$  during the whole campaign based on different methods (green:  
 953  $N_{CCN\_chem}$ ; blue:  $N_{CCN}$  calculated based on SPAR derived from averaged  $MF_{SA}$  and average  $D_a$ ; yellow:  
 954  $N_{CCN\_MF}$ ).

955

956

957 Fig 7. (a) The comparison between calculated  $N_{CCN}$  based on  $\kappa$  derived from bulk GF at 200 nm  
 958 ( $N_{CCN\_GF}$ ) and measured  $N_{CCN}$  at SS of 0.05%. (b) The correlation between MAF and number fraction  
 959 of hygroscopic particles ( $NF_{hygro}$ ,  $GF > 1.2$ ). (c) The comparison between calculated  $N_{CCN}$  based on  
 960 SPAR derived from real-time  $NF_{hygro}$  and average  $D_a$  ( $N_{CCN\_NF}$ ) and measured  $N_{CCN}$ . The black dashed  
 961 lines represent the relative deviation of 30%. (d) the diurnal variations of the ratio between the  
 962 calculated and measured  $N_{CCN}$  during the whole campaign based on different methods (green:  $N_{CCN\_GF}$ ;  
 963 blue:  $N_{CCN}$  based on SPAR derived from averaged  $NF_{hygro}$  and average  $D_a$ ; yellow:  $N_{CCN\_NF}$ ).
