Abstract. Masaya volcano (Nicaragua, 12.0°N, 86.2°W, 635 m a.s.l.) is one of the few volcanoes hosting a lava lake, today. This study has two foci: (1) discussing the state of the art of long-term SO₂ emission flux monitoring on the example of Masaya and (2) the provision and discussion of a continuous dataset on volcanic gas data with a large temporal coverage, which poses a major extension of the empirical data base for studies in volcanology as well as on atmospheric bromine chemistry. We present

- 5 time series of SO₂ emission fluxes and BrO/SO₂ molar ratios in the gas plume of Masaya from March 2014 to March 2020 — covering the three time periods (1) before the lava lake appearance, (2) period of high lava lake activity (November 2015 to May 2018), (3) after the period of high lava lake activity. For these three time periods, we report average SO₂ emission fluxes of $(1000 \pm 200) \text{ t d}^{-1}$, $(1000 \pm 300) \text{ t d}^{-1}$, and $(700 \pm 200) \text{ t d}^{-1}$ and average BrO/SO₂ molar ratios of $(2.9 \pm 1.5) \cdot 10^{-5}$, $(4.8 \pm 1.9) \cdot 10^{-5}$, and $(5.5 \pm 2.6) \cdot 10^{-5}$.
- 10 Our SO₂ emission flux retrieval is based on a comprehensive investigation of various aspects of spectroscopic retrievals, the wind conditions, and the plume height. We observed a correlation between the SO₂ emission fluxes and the wind speed in the raw data. We present a partial correction of this artefact via applying dynamic estimates for the plume height as a function of the wind speed. Our retrieved SO₂ emission fluxes are on average a factor of 1.4 larger than former estimates based on the same data.
- 15 Further, we observed different patterns in the BrO/SO₂ time series: (1) an annual cyclicity with amplitudes between $1.4\text{--}2.5 \cdot 10^{-5}$ and a weak semi-annual modulation, (2) a step increase by $0.7 \cdot 10^{-5}$ in late 2015, (3) a linear trend of $1.4 \cdot 10^{-5}$ per year from November 2015 to March 2018, and (4) a linear trend of $-0.8 \cdot 10^{-5}$ per year from June 2018 to March 2020. The step increase in 2015 coincided with the lava lake appearance and was thus most likely caused by a change in the magmatic system. We suggest that the cyclicity might be a manifestation of meteorological cycles. We found an anti-correlation between
- 20 the BrO/SO₂ molar ratios and the atmospheric water concentration (correlation coefficient of -0.47) but in contrast to that neither a correlation with the ozone mixing ratio ($+0.21$) nor systematic dependencies between the BrO/SO₂ molar ratios and the atmospheric plume age for an age range of 2–20 min after the release from the volcanic edifice. The two latter observations indicate an early stop of the autocatalytic transformation of bromide Br[−] solved in aerosol particles to atmospheric BrO.

1 Introduction

25 Volcanic gas emissions consist predominantly of water (H_2O), followed in abundance by carbon dioxide (CO_2) and sulphur dioxide (SO_2), as well as by a large number of trace gases such as halogen halides (Giggenbach, 1996; Aiuppa, 2009; Oppenheimer et al., 2014; Bobrowski and Platt, 2015).

Monitoring the magnitude or chemical composition of volcanic gas emissions can help to forecast volcanic eruptions (e.g. Carroll and Holloway, 1994; Oppenheimer et al., 2014). SO_2 emission fluxes, carbon to sulphur ratios, and halogen to sulphur ratios turned out to be powerful tools enabling the detection of events of magma influx at depth, and respectively the arrival of magma in shallow zones of the magmatic system (e.g. Edmonds et al., 2001; Métrich et al., 2004; Allard et al., 2005; Aiuppa et al., 2005; Burton et al., 2007; Bobrowski and Giuffrida, 2012).

Monitoring of volcanic gas emissions furthermore allows a quantification of the global volcanic volatile emission fluxes (e.g. Carn et al., 2017; Fischer et al., 2019), it is thus an important tool for the validation of satellite data (e.g. Theys et al., 35 2019), provides empirical data on the impact of volcanoes on the chemistry in the local atmosphere (e.g. Bobrowski and Platt, 2015), and is one of the rare possibilities to gain information about the interior of the Earth (e.g. Oppenheimer et al., 2014, <https://deepcarbon.net/>).

The magnitude of volcanic gas emissions can be determined by passive remote sensing techniques such as Differential Optical Absorption Spectroscopy (DOAS, Platt et al., 1980; Platt and Stutz, 2008; Kern, 2009), which allow the recording of 40 semi-continuous (only during daytime) long-term time series (e.g. Galle et al., 2010). In particular, SO_2 emission fluxes are considered to be relatively easy to obtain because of the high spectroscopic selectivity for SO_2 , the typically negligible atmospheric SO_2 background, and a typical atmospheric lifetime of SO_2 of at least 1 day. The accuracy of the SO_2 emission fluxes depends, however, strongly on the accuracy of the available information on the wind conditions and the altitude of the volcanic plume as well as on the radiative transport conditions. The emission fluxes of other volcanic gas species are usually retrieved 45 by scaling the SO_2 emission fluxes with the abundance of these species relative to SO_2 .

The chemical composition of volcanic gas plumes can be determined for many different gas species by in-situ sampling and subsequent sample analysis in the laboratory. More recently, automated in-situ "Multi-Gas" sensors are installed in the field, which measure and transmit the concentration of volcanic gases at the location of the instrument with an hourly to daily resolution (e.g. Shinohara, 2005; Aiuppa et al., 2006; Roberts et al., 2017). Chemical composition data retrieved by in-situ methods 50 are, however, usually not representative for the bulk gas emissions. Furthermore, in-situ methods are rather labour-intensive and dangerous for the scientist and the instruments due to the need to place them in direct proximity of an active volcanic vent. This leads to vulnerability to destruction by a volcanic explosion and the permanent contact with poisonous and corrosive volcanic gases.

Retrieval of the chemical composition by remote sensing overcomes these limitations. For the remote sensing of a molar ratio 55 at least one additional gas species besides SO_2 is required. The most desired candidates are the highly abundant H_2O or CO_2 , however, it has not yet been possible to retrieve their volcanic contributions by remote sensing routinely due to their rather high atmospheric backgrounds—although some recent developments succeeded for special conditions (La Spina et al., 2013; Kern

et al., 2017; Butz et al., 2017; Queisser et al., 2017). Other obvious candidates are chlorine and fluorine compounds due to their relatively high abundance. Remote sensing techniques allow a retrieval of hydrogen chloride (HCl) and hydrogen fluorine 60 (HF) via Fourier Transform InfraRed (FTIR) spectroscopy (e.g. Mori and Notsu, 1997; Mori et al., 2002), and chlorine dioxide (OCIO) via UV-DOAS (e.g. Bobrowski et al., 2007; Donovan et al., 2014; Gliß et al., 2015; Kern and Lyons, 2018). FTIR systems, however, require high intensity light sources (i.e. the diffuse solar radiation which is used by passive DOAS systems is usually not sufficient for FTIR) and are significantly more expensive. This is the reason why no continuous monitoring of chlorine or fluorine species has been established, except for the remote-controlled FTIR scanner systems installed at Stromboli 65 volcano since 2009 and at Popocatepetl volcano since 2012 (La Spina et al., 2013; Taquet et al., 2019).

A further emitted halogen species — but with a much lower abundance — is hydrogen bromide (HBr). HBr is rapidly converted in the atmosphere by photochemistry to several bromine species by the so called bromine explosion process (Platt and Lehrer, 1997; Wennberg, 1999; von Glasow, 2010). One of these secondary species is bromine monoxide (BrO), which can be retrieved from the same UV-spectra used for the retrieval of the SO₂ emission fluxes. BrO/SO₂ time series are thus in principle available 70 or retrievable for all volcanoes which are monitored for SO₂ emission fluxes by UV-spectrometers. In consequence, although BrO is not on the list of the most desired plume constituent species, time series of the BrO/SO₂ molar ratios in volcanic gas plumes are the easiest accessible remote-sensing gas proxy for volcanic processes so far (besides the SO₂ emission fluxes).

The volcanological interpretation of BrO/SO₂ molar ratios is yet difficult and much work is still required in order to use them as a fully reliable proxy for volcanic activity variations. The challenge is to understand the interplay of the physico-chemical 75 behaviour of bromine causing the relative Br/S abundance ratio to be significantly altered by virtually any involved compartment of the volcanic system. The two major sources of uncertainty are the bromine partitioning between the magmatic melt phase and the magmatic gas phase and the bromine chemistry in the volcanic gas plume. With respect to the latter, a robust understanding of the quantitative link between the emitted HBr and the observed BrO is crucial in order to quantify the total volcanic bromine emissions. This link has been studied by empirical observations (Oppenheimer et al., 2006; Bobrowski and 80 Giuffrida, 2012; Gliß et al., 2015; Roberts, 2018; Rüdiger et al., 2020), theoretical models and simulations (Bobrowski et al., 2007; Roberts et al., 2009, 2014; Roberts, 2018; von Glasow, 2010), and lab experiments (Rüdiger et al., 2018). Gutmann et al. (2018) summarised the current state of the art in their review article. The HBr \rightleftharpoons BrO conversion rate and the stationary equilibrium HBr/BrO ratio may depend on the chemical plume composition and on the atmospheric conditions such as the solar irradiance, the absolute/relative humidity, the tropospheric background ozone level, and the in-mixing rate of air in the 85 volcanic plume. Based on empirical observations, the equilibrium of the HBr \rightleftharpoons BrO conversion is typically reached within the first 2–10 min after the release of HBr to the atmosphere and remains constant for the next at least 30 min (Bobrowski and Giuffrida, 2012; Lübecke et al., 2014; Platt and Bobrowski, 2015; Gliß et al., 2015). Model simulations have proposed relative BrO equilibrium fractions between BrO/Br_{total} = 10–50% (von Glasow, 2010; Roberts et al., 2014).

Masaya volcano (12.0°N, 86.2°W, 635 m a.s.l.) is located on the Nicaraguan portion of the Central American Volcanic Arc. 90 Its volcanic complex consists of an older shield volcano now hosting a 6 km x 11 km caldera created by three highly explosive basaltic eruptions during the last 6,000 years: a VEI6 eruption at \sim 6 ka, a VEI5 eruption at 2.1 ka, and a VEI5 eruption at \sim 1.8 ka. (VEI: volcanic explosivity index, Williams, 1983; Pérez et al., 2009, Smithsonian Institution). There is a nearly con-

tinuous historic record of its activity since the arrival of the Spanish conquistadors in 1524 (de Oviedo, 1855; McBirney, 1956; Rymer et al., 1998). The Smithsonian Institution lists two major eruptions which occurred in 1670 (VEI3) and 1772 (VEI2) and 95 28 eruptions (mainly VEI1 and some VEI2) since 1852. Masaya's currently active Santiago pit crater formed in 1858/1859 and since hosted occasionally incandescence vents and lava lakes usually lasting several years (McBirney, 1956; Rymer et al., 1998). Masaya's most recent lava lake cycle started in late 2015 when a lava lake appeared (incandescence observed since November 2015, INETER, 2015a, b; Aiuppa et al., 2018) and started to cease in October 2018 when Masaya's thermal activity decreased to relatively low levels (Smithsonian Institution, 2018). Masaya is one of the strongest degassing volcanoes in the 100 Central American Volcanic Arc (Martin et al., 2010; Aiuppa et al., 2014, 2018). The volcanic gas plume often hovers close to the ground causing serious issues to the local agriculture and health conditions of the local population (Baxter et al., 1982; Delmelle et al., 2002; van Manen, 2014).

This manuscript reports and discusses time series of the SO_2 emission fluxes and BrO/SO_2 molar ratios in the gas plume of 105 Masaya volcano from 2014–2020 measured by UV-spectroscopy. We present a comprehensive investigation of frequently ignored effects influencing in the SO_2 emission flux retrieval and propose a set of technical extensions which aim to reduce the impact of these systematic effects. Next, we discuss the impact of the meteorology on the bromine chemistry in the volcanic gas plume. Finally, we compare the retrieved gas data with the general volcanic changes from 2014–2020.

2 Measurement site and meteorology

The SO_2 and BrO emissions of Masaya are monitored by the Instituto Nicaragüense de Estudios Territoriales (INETER) 110 which is part of the Network for Observation of Volcanic and Atmospheric Change (NOVAC, Galle et al., 2010). The NOVAC instruments are automated remote-sensing UV-spectrometers whose design is simplified in order to reduce their power consumption, costs, and maintenance (e.g. the spectrometers are not actively temperature-controlled). First NOVAC measurements were conducted at Masaya from April–June 2007 and from September 2008 to February 2009 (these data are not presented in this manuscript but listed for completeness in Table 5). From March 2014 to March 2020 (end of this study), the NOVAC 115 station “Caracol” (instrument: D2J2124_0, see Figure 1 and Table 1) operated continuously, except for two data gaps of several months. From March–October 2014, a second NOVAC station “Nancital” (D2J2375_0) operated quite close to Caracol (Figure 1).

No direct measurements of the meteorological conditions in the volcanic gas plume were available (except for the plume heights and the wind directions from March–October 2014 retrieved from the NOVAC data via a triangulation, see next section). Therefore, we accessed the meteorological conditions at Masaya by European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-Interim model data for an altitude of 700 m a.s.l. (Figure 2), by operational ECMWF reanalysis data for 120 an altitude of 700 m a.s.l. (Figure 3), and by ground-based data from Managua airport, which is located 15 km north of Masaya (see Appendix A).

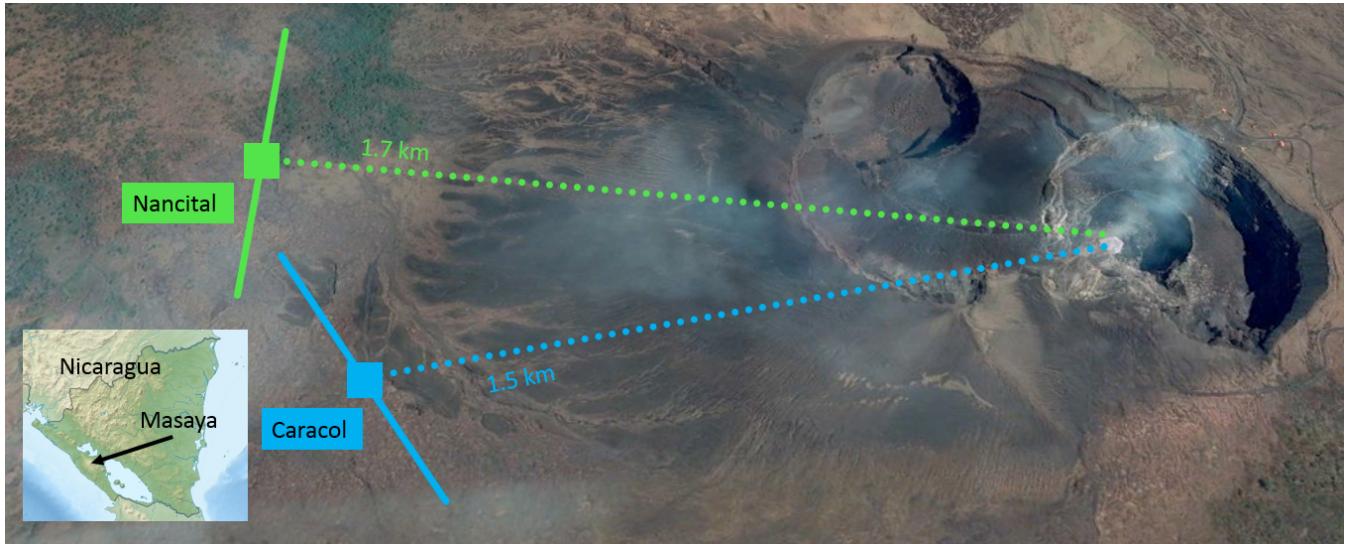

Figure 1. Location and scan geometries of the NOVAC stations Caracol and Nancital at Masaya volcano. Coloured squares indicate the instrument location and solid lines the scan direction. For further parameters see Table 1. The map was created with graphical material from https://commons.wikimedia.org/wiki/File:Nicaragua_relief_location_map.jpg and from Google Earth.

Table 1. Spatial set-up of the NOVAC stations at Masaya: altitude A , horizontal distance D to and angular orientation σ to the volcanic edifice, orientation of the scan plane β (see Figures 1 and 5).

station	coordinates	A	D	σ	β
Caracol	11.98, -86.18	382 m a.s.l.	1.5 km	75°	54°
Nancital	11.99, -86.18	340 m a.s.l.	1.7 km	95°	100°

ECMWF ERA-Interim data

125 The ECMWF ERA-Interim dataset has an original spatial resolution of about $0.7^\circ \times 0.7^\circ$ (at and close to the equator), a temporal resolution of 6 h (0:00, 6:00, 12:00, and 18:00 UTC), and 60 hybrid pressure layers which follow the terrain close to ground and in the lower atmosphere and are constant in the higher atmosphere. They reach up to 10 Pa, i.e. about 66 km. The presented
 130 ECMWF data are vertically interpolated to an altitude of 700 m a.s.l. and horizontally gridded on a $1^\circ \times 1^\circ$ grid (i.e. about 110km x 110km at 12°N). The preparation of the ERA-Interim data on such a grid was chosen for in general better compatibility with other global data. For local studies using the original $0.7^\circ \times 0.7^\circ$ data may be more appropriate though this distinction becomes mostly obsolete due to our local calibration approach (see Section 3).

The following meteorological parameters are presented and discussed in this study: (1) the wind speed and (2) the wind direction in order to reconstruct the plume propagation direction, (3) the barometric pressure, (4) the ambient air temperature,

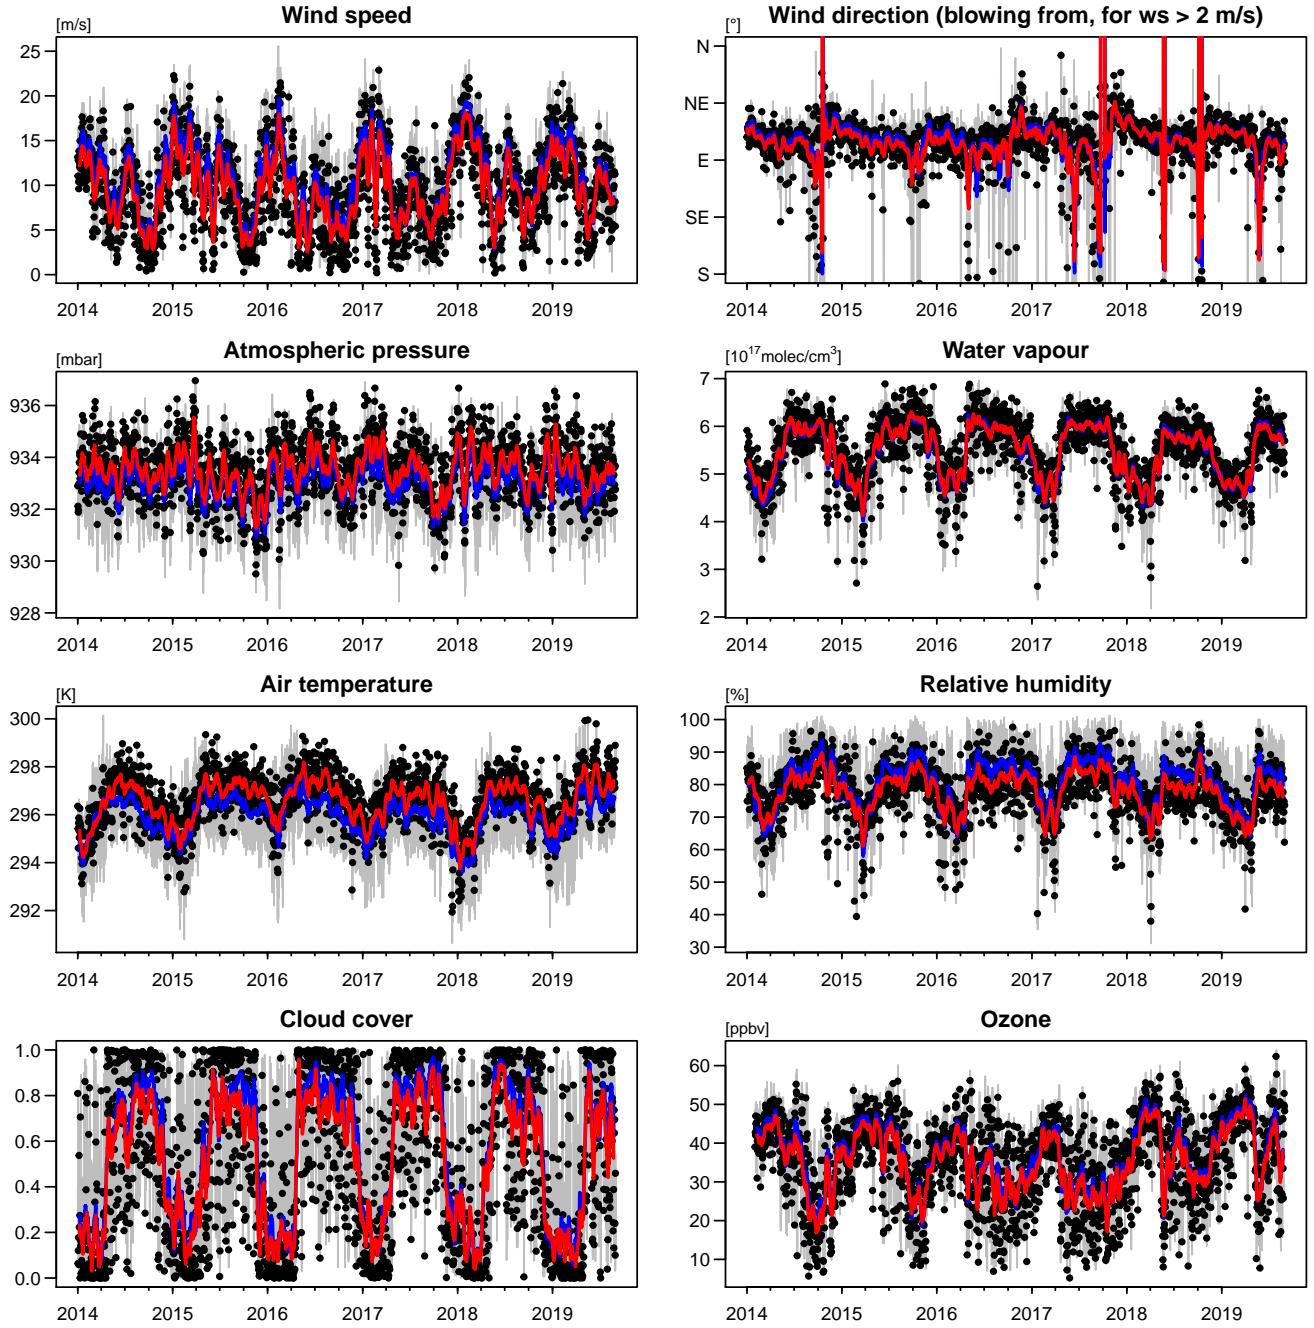

Figure 2. Meteorological conditions at Masaya volcano retrieved from ECMWF ERA-Interim data with resolutions of 6 h and $1^\circ \times 1^\circ$ and interpolated to an altitude of 700 m a.s.l. **Grey lines:** 6-hourly data. **Blue lines:** running means over the 6-hourly data with an averaging window of ± 7 days. **Black dots:** around noon (18:00 UTC) data. **Red lines:** running means over the around noon data with an averaging window of ± 7 days. Absolute variations are almost the same for the full data set and the around noon data only, except for the air temperature and the relative humidity which follow their expected diurnal cycles.

135 (5) the water vapour concentration, (6) the relative humidity, and (7) the ozone mixing ratio in order to investigate their possible influences on the plume chemistry, and (8) the total cloud cover (i.e. the fraction of the ground pixel area hidden from direct solar irradiation by visible clouds anywhere between ground and the top of the model domain) as a proxy for the radiative conditions.

140 The following quantitative discussion focuses on the two-weekly moving average of ECMWF data around noon time, though a discussion of the unfiltered time series comes to similar results (see red and blue lines in Figure 2). The time series exhibit annual cycles for all parameters, however, with different timing and spacing of their extrema and different significance of their amplitudes. The total cloud cover varied between two clearly distinguishable plateaus with mostly clear skies (values of 0.1 ± 0.1) from December–March and predominantly dense coverage (values of 0.8 ± 0.1) from May–October, indicating that Masaya is affected by the intertropical convergence zone (ITCZ) during that latter time interval. The wind speed varied between $3\text{--}17 \frac{\text{m}}{\text{s}}$, with maxima in January/February, and weaker secondary maxima in July, and with minima in June and 145 in October. The average of the wind direction mainly indicates easterlies (75 ± 28)° subject to an about linear trend each year with a step change each year towards east-northeasterly in October followed an about linear trend towards easterly in September. In addition, the wind conditions are rather unstable each year in June and in October (which corresponds to the times when Masaya is located at the edge of the ITCZ). When those exceptions are ignored by limiting the set of wind directions to 40–110° (which contains 88% of the raw data), the wind conditions were rather stable with almost exclusively 150 east–northeasterly winds from (75 ± 10)° almost all the year. The barometric pressure varied between 931–935 mbar, with weak minima in October/November. The ambient air temperature varied between 294–298 K with maxima in April and minima in January. The water vapour concentration and the relative humidity varied between $4\text{--}6 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^3}$ and 60–90%, respectively, with minima in February/March and maxima from June–October. The ozone mixing ratio varied between 20–50 ppbv with minima usually around October and maxima in March.

155 **Operational ECMWF reanalysis data**

The accuracy of weather data especially in the mountainous regions around the volcano is directly related to the accuracy of the model topography. Therefore an enhanced (fundamental) model resolution should result in general in more representative data. For this purpose, we investigated the meteorological conditions at Masaya also by using the operational ECMWF reanalysis data with a higher spatial resolution of $0.14^\circ \times 0.14^\circ$ (modelled in spectral domain with a truncation of T1279, interpolated to 160 the Gaussian grid N640). The underlying model of the operational ECMWF reanalysis data is, however, updated frequently (e.g. since March 8 2016 the model uses a finer horizontal resolution of 0.07° instead of 0.14°) and thus there are potentially artificial jumps in its time series. Because this study analyses a long time series, a model setup with such artificial changes is not suitable for direct application. A full list of modifications to the model setup in addition to the change in horizontal model resolution can be found at <https://www.ecmwf.int/en/forecasts/documentation-and-support/changes-ecmwf-model>.

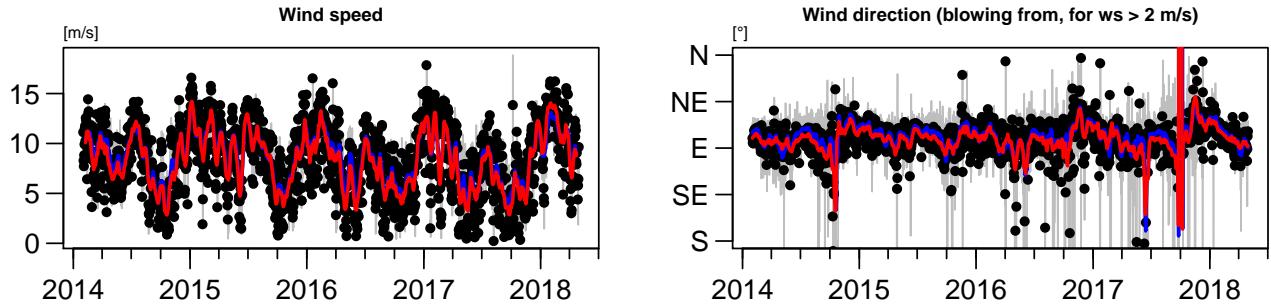

Figure 3. Meteorological conditions at Masaya volcano retrieved from the operational ECMWF reanalysis data. See Figure 2 for details.

165 **Estimates for the wind speed and the wind direction**

We based our analysis in general on the meteorological parameters from the ECMWF ERA-Interim data because this dataset allows an analysis consistent in time, i.e. without potential jumps in the time series. Nevertheless, the ERA-Interim data have to be expected to provide only limited accuracy in particular in the complex topology around volcanoes. Therefore, we applied the following local calibrations of the ERA-Interim data.

170 We compared the wind speeds v_{era} provided by the ERA-Interim dataset and v_{oad} provided by the operational ECMWF reanalysis data. We consider the latter to be in general more accurate estimates due to its higher spatial resolution. Despite the wind speeds from both dataset being highly correlated (coefficient of +0.89), their scatter plot deviates significantly from a proportional relationship. Instead,

$$v_{\text{oad}} = 0.53 \cdot v_{\text{era}} + \sqrt{v_{\text{era}}} \quad (\equiv v_{\text{calibrated}}) \quad (1)$$

175 being apparently a good fit (Figure 7a). All wind speed data used in our further evaluation steps were retrieved from the ERA-Interim data but calibrated according to eq. 1.

We consider the wind directions retrieved via the triangulation of the NOVAC results as the “ground truth” (see Section 3). The operational ECMWF reanalysis data match well with these data, which further supports this assumption. The ERA-Interim data, however, provide wind directions which are further to the East-Northeast by 11° (Figure 7b). All wind direction data used 180 in our further evaluation steps were retrieved from the ERA-Interim data but calibrated according to eq. 2:

$$\omega_{\text{calibrated}} = \omega_{\text{era}} + 11^\circ \quad (2)$$

(the addition of 11° corresponds to a shift from east-northeasterly towards easterly).

These two calibrations could not be expected to improve the accuracy for every individual data point but result arguably on average in a more accurate data set.

We derived semi-continuous (only during daytime) time series of the differential slant column densities (dSCD) of SO₂ and BrO via Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) applied on UV-spectra of the diffuse solar irradiation recorded by the NOVAC stations (e.g. Edmonds et al., 2003; Galle et al., 2003; Bobrowski et al., 2003). The SO₂ emission fluxes and the BrO/SO₂ molar ratios in the volcanic plume were then derived from the dSCD data.

190 The spectroscopic retrieval of the SO₂ and BrO dSCDs as well as the spectroscopic and post-spectroscopic retrieval of the BrO/SO₂ molar ratios applied in this manuscript follow in large parts the evaluation described by Dinger (2019) which itself follows mainly Lübcke et al. (2014) and Dinger et al. (2018).

Our retrieval of the SO₂ emissions fluxes is based on the standard NOVAC approach described by Johansson et al. (2009) but (1) extended by a set of data filters which aim to reduce the amount of potentially problematic measurement conditions (see 195 Table 2), (2) the spectroscopic retrieval was adapted to the high SO₂ emission fluxes at Masaya, and (3) information on the plume height and the wind conditions were assessed partially via a triangulation of NOVAC observations. One of these filters uses the absolute SO₂ background calibration method described by Lübcke et al. (2016).

In this section, we describe the applied retrieval steps and data filters (see Table 2, further information on the retrieval can be found in the Appendices B–D). A summary and critical assessment of our retrieval steps can be found in the discussion section 200 of this manuscript.

Spectroscopic retrieval of the SO₂ dSCD distribution

The NOVAC data were recorded by UV-spectrometers which scan across the sky from horizon to horizon in steps of 3.6° by means of a small field-of-view telescope yielding a mean temporal resolution of about 5–15 min per scan. Each scan contains 53 spectra: an initial zenith spectrum, a dark current spectrum, and 51 measurement spectra (Galle et al., 2010).

205 Prior to the spectroscopic retrieval, the individual spectra of a scan were checked for their spectroscopic quality. A scan was rejected if its initial zenith spectra was either over- or underexposed (accept only spectra whose channel with the highest number of counts has recorded within 12–88% of the maximum possible count number, where only the lower boundary is assessed after the dark current correction) or the single exposure time was unreliable (less than 20 ms or more than 2 s). For a passing scan, all its measurement spectra were checked for over- or underexposure and individually rejected if necessary.

210 Furthermore, all spectra recorded at scan zenith angles ε with $|\varepsilon| > 76^\circ$ were rejected in order to avoid large light paths or spectroscopic artefacts due to obstacles in the light path. Accordingly, at most 43 measurement spectra could pass the quality filters. A scan was entirely rejected if less than 30 of its spectra passed.

A remark on the overexposure filter: It was chosen as described above in order to assure that BrO DOAS fits were not degraded by saturation effects. For the sole retrieval of the SO₂ emission fluxes, it may be sufficient to check for overexposure exclusively 215 in the SO₂ fit range. Nevertheless, we aimed for the same data base for both, the BrO/SO₂ molar ratios and the SO₂ emission fluxes in order to assure a consistent comparison of both time series. Further arguments for applying the overexposure filter on the overall spectrum are: (1) Overexposure in the spectrum indicates significant variations in the intensity of the back-scattered

Table 2. Applied filters in chronological order (if condition fulfilled, reject data). See text for details. For comparison, the standard NOVAC retrieval applies the five following filter conditions (Johansson et al., 2009): (1) overexposure of (any) spectrum by more than 99%, (2) underexposure of (any) spectrum by less than 2.5%, (3) $\chi^2_{\text{SO}_2} > 0.9$ for a measurement spectrum, (4) number of passing spectra < 10, (5) a “plume completeness filter” which rejects a scan if most of the large dSCDs are close to the margin of the effective angle range.

Filter	Filter condition
Zenith spectrum	
exposure time	< 20 ms or > 2 s
overexposure	> 88% in channel with highest intensity
underexposure	< 12% in channel with highest intensity
Measurement spectra	
overexposure	> 88% in channel with highest intensity
underexposure	< 12% in channel with highest intensity
zenith angle	$ \varepsilon > 76^\circ$
SO₂ VCD distribution	
number of spectra	< 30
maximum VCD	at margin of effective angle range
relative background	$> 2 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$
Gaussian fit ($b = 0$)	did not converge or negative amplitude
Gaussian fit (b free)	$b < -1 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$
Gauss vs. Discrete	$I_{\text{SO}_2}^{\text{discr}} \notin 0.8\text{--}1.6 \cdot I_{\text{SO}_2}^{\text{fit}}$
absolute background	$> 5 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$
Meteorological conditions	
wind speed	< 5 m/s

220 solar radiations during a scan (caused presumably by variations in the cloudiness of the sky). Accordingly, the overexposure filter would (conveniently?!) reject those times with unstable meteorological conditions. (2) The saturation of any pixel of the charge-coupled device detector may cause the additional photo-electrons to spill over to other pixels and thus could lead to the degradation of the entire spectrum.

225 For every scan passing the quality filters, SO₂ DOAS fits were applied on each of the passing spectra where the initial zenith spectrum of the respective scan was used as reference spectrum (the DOAS fit scenarios are summarised in Table 3). The result was a distribution of SO₂ dSCDs with respect to the zenith spectrum depending on the viewing direction. These SO₂ distributions were used for three purposes: (1) the calculation of the SO₂ emission fluxes, (2) the triangulation of the plume centre position for a retrieval of the plume height and the wind direction, and (3) the identification of the plume region in preparation of the BrO/SO₂ retrieval.

Table 3. Applied DOAS fit scenarios. The two lowest lines give the parameter ranges of the Levenberg–Marquardt fit routine. See Appendix B for the chosen wavelength range of the SO₂ fit.

SO ₂ fit		BrO fit
Fit range	314.8–326.8 nm	330.6–352.75 nm
<i>(Pseudo-)Absorption cross sections:</i>		
SO ₂	Vandaele et al. (2009), @298 K	(same)
O ₃	Burrows et al. (1999), @221 K	(same)
BrO		Fleischmann et al. (2004), @298 K
O ₄		Hermans et al. (2003)
NO ₂		Vandaele et al. (1998), @294 K
CH ₂ O		Meller and Moortgat (2000), @298 K
Ring spectrum (Grainer and Ring, 1962) calculated from the particular reference spectrum		
Ring spectrum multiplied with the wavelength ⁴ (see Wagner et al., 2009)		
<i>Further DOAS fit parameters:</i>		
Polynomial of order $n = 3$ in the optical depth space		
Stray light polynomial of order $n = 0$ in the intensity space		
log(Reference) and Ring spectra (linked together): $a_{\text{shift}} \in \pm 0.2 \text{ nm}$ and $a_{\text{squeeze}} \in 1 \pm 0.02$		
Absorption cross sections (linked together): $a_{\text{shift}} \in \pm 0.2 \text{ nm}$ and $a_{\text{squeeze}} \in 1 \pm 0.02$		

Table 4. Four different approaches for the retrieval of the background SO₂ slant column density.

Approach 1	$\text{SCD}_{\text{SO}_2,\text{ref}} = -\text{dSCD}_{\text{SO}_2}(\varepsilon_{\text{bg}})$
Approach 2	$\text{SCD}_{\text{SO}_2,\text{ref}}$ via absolute retrieval using solar-atlas spectrum and measured zenith spectrum
Approach 3	Approach 1 followed by absolute retrieval using solar-atlas spectrum and measured background spectrum
Approach 4	Approach 3 but if background spectrum contaminated, then use a background spectrum from time without contamination

Retrieval of the background SO₂ slant column density

The subsequent data analysis requires the absolute SO₂ slant column density (SCD) distribution rather than the SO₂ dSCD distribution, where $\text{SO}_2 \text{ SCD} = \text{SO}_2 \text{ dSCD} + \text{SCD}_{\text{SO}_2,\text{ref}}$. An accurate estimate for the absolute slant column density $\text{SCD}_{\text{SO}_2,\text{ref}}$ of the reference spectrum (here: of the initial zenith spectrum) is non-trivial. In the following, four different retrieval approaches are discussed (see Table 4).

A pragmatic approach is the assumption that the scan included viewing directions which were not at all affected by a contamination with volcanic gases. This assumption would imply $\text{dSCD}_{\text{SO}_2}(\varepsilon_{\text{bg}}) = -\text{SCD}_{\text{SO}_2,\text{ref}}$ for the background direction ε_{bg} . In order to be less susceptible to negative outliers, we calculated $\text{SCD}_{\text{SO}_2,\text{ref}}$ as the mean of the 8 lowest dSCDs (orange squares

in Figure 4).

It has been observed, however, that the assumption of a non-contaminated background direction is not always justified (e.g. Lübcke et al., 2016). Another approach which does not rely on that assumption is the direct retrieval of $\text{SCD}_{\text{SO}_2,\text{ref}}$ via a SO_2 DOAS fit of the zenith spectrum against a solar-atlas spectrum (see Salerno et al., 2009; Lübcke et al., 2016; Esse et al., 2020; 240 Chance and Kurucz, 2010). This second approach requires, however, to retrieve the instrument characteristics (e.g., via a principal component analysis of the residual spectroscopic structure), which is not only a time expensive procedure but also prone to introducing systematics when not carefully applied.

A third approach is the hybrid of these two approaches with the following subsequent steps: (1) apply the first approach to identify the viewing directions of the 8 lowest SO_2 dSCDs, (2) co-add these 8 spectra, (3) apply the second approach (i.e. 245 evaluate against a solar-atlas spectrum) on this “added-reference-spectrum” (instead of on the zenith spectrum, see Appendix C). In comparison to the pure second approach, the absolute retrieval step in this hybrid approach faces in general low—and mostly negligible— SO_2 SCDs. Therefore, the SO_2 DOAS fit of the absolute calibration retrieval can start at a wavelength of 310 nm or even lower (see also Appendix B), resulting in general in lower statistical fit errors and weaker effects from possible spectroscopic interferences of the SO_2 absorption cross section with, e.g., the imperfect estimation of the instrument characteristics. The results of the hybrid approach could be used either as a filter or for correcting the SCD data with respect to the 250 retrieved background SO_2 SCD.

A fourth approach extends the third approach by (1) checking for a background contamination but then (2) using a reference spectrum from another time (e.g. from the previous day at the same time) where a background contamination has been ruled out (e.g. via the second approach) for a subsequent iteration of the SO_2 fits. Both, the third and the fourth approach, have in 255 common that the chosen reference spectrum was not recorded under the same conditions as the measurement spectrum. The advantage of the fourth approach with respect to the third approach would be that the chosen reference spectra are expected to be recorded at least under similar conditions as the measurement spectra (at least when the time-of-day and the ambient temperature have been considered for the selection). The drawback of the fourth approach is the temporal variation of these systematics while the third approach would cause the same systematics to all contaminated scans.

260 We applied the third approach to the data but used the results of the absolute calibration only for a rather conservative data filtering: We calculated the absolute background SO_2 VCD as the product of the absolute background SO_2 SCD times the mean air mass factor $\text{mean}(\cos(\varepsilon_{i \in \text{bg}}))$ but corrected by $-5 \cdot 10^{16} \frac{\text{molec}}{\text{cm}^2}$ for Caracol station and $+5 \cdot 10^{16} \frac{\text{molec}}{\text{cm}^2}$ for Nancital station (such that the peaks of the histograms match zero SO_2 , see Figure 7c). A scan was rejected if its (corrected) absolute background SO_2 VCD exceeded $5 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$.

265 Calculation of the SO_2 emission fluxes

The retrieval of the background SO_2 SCD allows the calculation of the (absolute) vertical SO_2 column densities

$$V_{\text{SO}_2}(\varepsilon) = \cos(\varepsilon) \cdot [\text{dSCD}_{\text{SO}_2}(\varepsilon) + \text{SCD}_{\text{SO}_2,\text{ref}}] \quad (3)$$

associated to the coordinates within the scan plane where the horizontal distance with respect to the instrument is $H(\varepsilon) \cdot \tan(\varepsilon)$ and the mean plume height $H(\varepsilon)$ (above the horizon of the instrument) can in general vary horizontally. We highlight that eq. 3
270 assumes geometric air mass factors while the real air mass factors could deviate due to angle-dependent atmospheric radiative transport effects (e.g. Mori et al., 2006; Kern et al., 2010). Examples for retrieved SO₂ VCD distributions are shown in the Figures 4 and D3.

Precise information on the plume height is usually not available—not to mention spatially resolved variations of the plume height. A commonly applied pragmatic approach is thus the assumption of a plume height constant in space and time. Assuming
275 that the plume height $H(\varepsilon) = H$ is constant at least in space, the SO₂ emission fluxes F_{SO_2} for a particular time can be calculated via

$$F_{\text{SO}_2} = M_{\text{SO}_2} \cdot v \cdot \cos(\omega - \beta) \cdot H \cdot \int_{-\infty}^{\infty} V_{\text{SO}_2}(\varepsilon) d(\tan(\varepsilon)) \quad (4)$$

with the molar mass of SO₂ $M_{\text{SO}_2} = 64 \text{ g/mol}$, the absolute wind speed v , and the relative angle $|\omega - \beta| < \frac{\pi}{2}$ between the wind direction and the scan plane (see Figure 5). We highlight that the integral can be understood as a spatial integral which
280 integrates along a straight horizontal line by steps of $d(H \cdot |\tan(\varepsilon)|)$.

The angular integral $I_{\text{SO}_2} = \int_{-\infty}^{\infty} V_{\text{SO}_2}(\varepsilon) d(\tan(\varepsilon))$ can be calculated in good approximation by a discrete summation of the spectroscopically retrieved SO₂ VCD distribution via

$$I_{\text{SO}_2} \approx \sum_{i=1}^{n-1} \frac{V_i + V_{i+1}}{2} \cdot [\tan(\varepsilon_{i+1}) - \tan(\varepsilon_i)] \quad (5)$$

where n is the number of all individual spectra (i.e. individual viewing directions) which passed the filters discussed above
285 and the V_i are the vertical SO₂ column densities calculated according to eq. 3 and associated to the horizontal coordinates $H \cdot \tan(\varepsilon_i)$ as explained above.

Up to here, our methodology followed the standard NOVAC approach (Johansson et al., 2009). This approach tacitly assumes that the measurement conditions did not change significantly during one scan. This assumption could be frequently not justified due to several causes, e.g. unstable wind conditions or intra-minute variations in the volcanic degassing source strength (e.g.
290 Pering et al., 2019). In the next paragraph, we present a set of filters which reject data which is potentially influenced by unstable measurement conditions. Afterwards, we present our approaches to estimate the wind conditions and the plume height.

Filtering of unstable conditions

For stable meteorological and radiative conditions as well as a constant SO₂ emission strength, the horizontal broadening of a volcanic plume is caused predominantly by turbulent diffusion. Under such ideal measurement conditions, the SO₂ VCD
295 distribution would be a Gaussian distribution with respect to the distance (in scan direction) $H \cdot \tan(\varepsilon_i)$. A Gaussian shape is indeed observed in good approximation for the large part of the scans where exactly one plume has been identified (e.g. Figures 4 and D3d). However, there is also a significant number of scans where the retrieved SO₂ VCD distribution differs

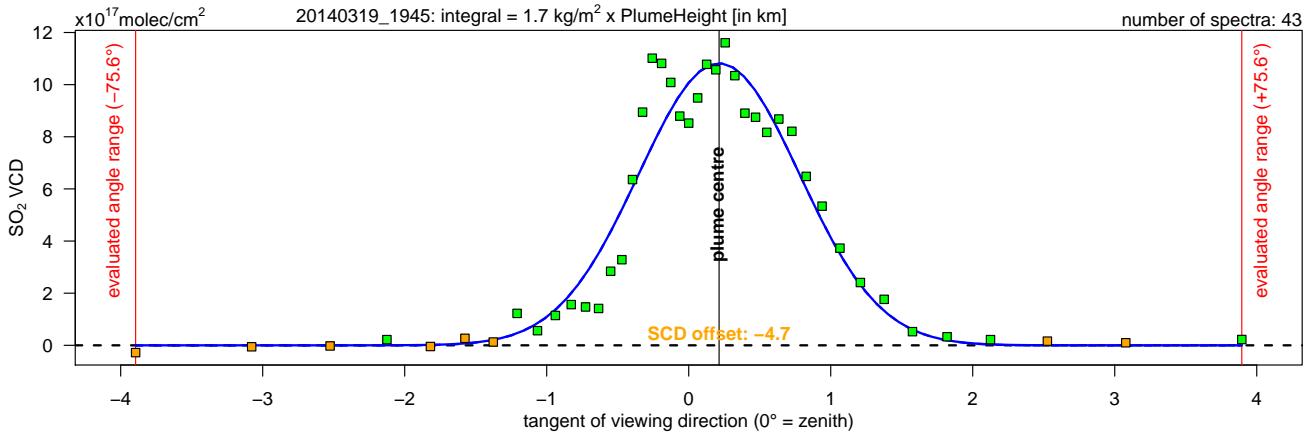

Figure 4. SO₂ VCD distribution retrieved from the scan starting at 2014-03-19 19:45 UTC recorded at Caracol station. The green and orange squares give the retrieved angular SO₂ VCD distribution. Only data for zenith angles between -75.6° and $+75.6^\circ$ were considered. The orange squares were used for the retrieval of the background SCD (the set of the lowest SCDs does not necessarily match perfectly with the set of the lowest VCDs). The (negative) background SCD is given in orange. The plume centre is retrieved via the Gaussian fit (solid blue line).

significantly from an ideal Gaussian shape. The predominant reason for such deviations is an apparent secondary plume (presumably either because there was another plume or because the wind direction changed during the scan) but also less well defined, rather random shapes were observed (see Figure D3a–c).

As motivated above, scans with unstable conditions should be rejected. We fitted a Gaussian distribution

$$V_i(\varepsilon_i) = a \cdot \exp \left[- \left(\frac{\tan(\varepsilon_i) - \mu}{w} \right)^2 \right] + b \quad (6)$$

as a function of $\tan(\varepsilon)$ to the SO₂ VCD distribution (with the fit parameters a , μ , w , b) as a tool to semi-quantitatively assess the “degree of stability” during that scan. In order to provide an automated test of the “Gaussian shape assumption”, we fitted 305 two Gaussian distributions to the SO₂ VCD distribution, one with a fixed $b = 0$ and one with a free b (see the solid and dashed lines in Figure D3, while both lines perfectly overlap in Figure 4).

The Gaussian fits (and other criteria) were used to filter the data in six subsequent steps (F1)–(F6). A scan was rejected if: (F1) its highest SO₂ VCD was retrieved at the margin of the effective angle range (which is usually at $\pm 75.6^\circ$) because in such a case at least half of the plume area was not included, (F2) the relative SO₂ VCD background exceeded $2 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$ because for 310 stable conditions that offset should be non-positive by construction, (F3) the Gaussian fit with fixed $b = 0$ did not converge or proposed a negative amplitude (20% and 5% of the scans were rejected by these filters for Caracol station and Nancital station, respectively).

We highlight that the Gaussian fit would tend to propose a positive offset parameter $b > 0$, e.g. if a secondary plume elevates the apparent background level. In contrast to that, significant negative values for b indicate that the effective scan range does not

315 include the gas-free background. Accordingly, a scan was rejected if (F4) $b < -1 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$ (3% and 1% of scans rejected). Next, we compared the Gaussian integral $I_{\text{SO}_2}^{\text{fit}} = \sqrt{2 \cdot \pi} \cdot a \cdot w$ (retrieved for $b = 0$) and the discrete integral $I_{\text{SO}_2}^{\text{discr}}$. On the one hand, the Gaussian integral is also for $b = 0$ usually smaller than the discrete integral (e.g. because of a secondary peak or an asymmetric plume shape). On the other hand, our filtering of data with $|\varepsilon_i| > 76^\circ$ implies the tacit assumption of $V_i = 0$ for $|\varepsilon_i| > 76^\circ$ for eq. 5. When this assumption does not hold true, the discrete integral underestimates the overall SO_2 amount 320 while the Gaussian integral could correctly include those contributions. Therefore, a scan was rejected if its two integrals differed rather strongly, that is, a scan passed only if (F5) $I_{\text{SO}_2}^{\text{discr}} \in 0.8\text{--}1.6 \cdot I_{\text{SO}_2}^{\text{fit}}$ (20% and 10% of scans rejected, with 12% and 5% due to the lower threshold and 8% and 5% due to the upper threshold). Furthermore, for a passing scan the higher value $I_{\text{SO}_2}^{\text{finally}} = \max(I_{\text{SO}_2}^{\text{discr}}, I_{\text{SO}_2}^{\text{fit}})$ of the two integrals was chosen (where $I_{\text{SO}_2}^{\text{fit}}$ was chosen for 28% and 23% of the scans). As a last filter (F6), a scan was rejected when its absolute SO_2 background VCD exceeded $5 \cdot 10^{17} \frac{\text{molec}}{\text{cm}^2}$ (see above, 8% and 325 3% of scans rejected).

In total, 57% and 82% of the scans passed the filters for Caracol station and Nancital station, respectively. We consider this a good compromise between the lack of temporal resolution and reducing the risk of systematic errors due to unstable measurement conditions.

Triangulation of the plume centre position

330 When the volcanic gas plume is observed simultaneously by two NOVAC stations (as was the case in the period from March–October 2014), the two associated viewing directions towards the plume centre can be used for a triangulation of the spatial position of the plume centre. The relationship between the plume height H_s above the horizon of the NOVAC station s and the wind direction ω is given by

$$H_s + A_s = D_s \cdot \left| \frac{\sin(\omega - \sigma_s)}{\cos(\omega - \beta_s) \cdot \tan(\varepsilon_s)} \right| \quad (7)$$

335 where the fixed station geometry parameters A , D , σ , β are summarised in Table 1 and the horizontal geometrical considerations are sketched in Figure 5. We highlight that the total plume altitude $H_s + A_s$ is the same for both instruments. If NOVAC station s observes $\varepsilon_s = 0^\circ$, the wind direction is trivially given by $\omega = \sigma_s$ and the plume height can be retrieved by applying eq. 7 on the other station.

We used the peak positions of the above introduced Gaussian fits (with $b = 0$) as estimates for the plume centre position. A 340 practical limitation of the triangulation was that the NOVAC stations did not measure exactly simultaneously. Therefore a temporal binning of their data was required. We calculated bins of 30 min. A bin was rejected if the plume centre varied for one instrument within these 30 min such that the standard deviation exceeded 20° .

The plume centre triangulation proposed an average wind direction of $(84 \pm 3)^\circ$ and average total plume altitudes of $H_s + A_s = (760 \pm 94)$ m which implied an average plume height above ground level of (378 ± 94) m for Caracol station and (420 ± 94) m 345 for Nancital station (Figure 6).

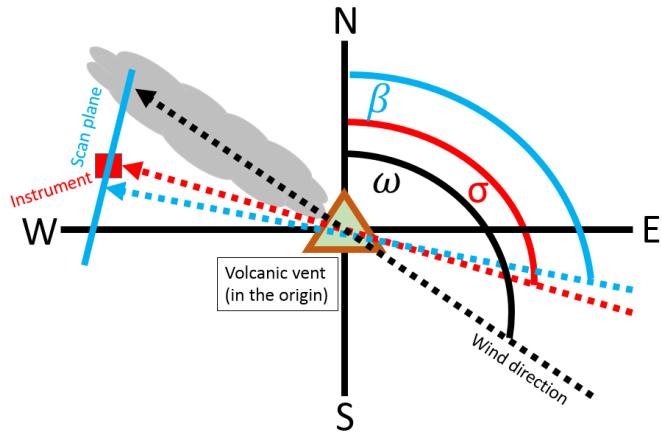

Figure 5. Sketch of the geometric relations which are used to calculate the SO₂ emission fluxes, to conduct the plume centre triangulation, and to estimate the plume age.

Estimates for the plume height

The plume altitude is a major source of uncertainty in the calculation of the SO₂ emission fluxes. When lacking visual observations, the plume altitude is usually assumed to be fixed to the altitude level of the volcano summit or the expected effective plume height of the volcanic plume.

- 350 The plume height can be considered to vary significantly and depends on the wind conditions. The initial buoyancy of the volcanic plume is just one mechanism which links the plume height and the wind speed. The volcanic plume is usually hotter than the ambient atmosphere and thus rises until its temperature is equilibrated due to adiabatic cooling and mixing with ambient air. Accordingly, higher wind speeds should result in average in lower observed plume heights for at least two reasons: First, the higher the wind speed the larger is the atmospheric turbulence, the larger is the cooling rate of the plume, and thus the 355 lower is the effective plume height. Second, the higher the (horizontal) wind speed, the smaller has been the propagation time between release and observation, and thus the lower is the probability that the measured plume has already reached its effective plume height.

- We tested this hypothesis with the triangulation results. For this test, we had to get rid of the artificial "wings" in the triangulation results (see Figure 7). We realised this condition by considering only the 88% of data below an retrieved plume altitude of 360 1200 m a.s.l. for the following analysis.

The comparison of the triangulated plume height with the wind speed (calibrated as explained above) confirmed such a causal link between the plume height and the wind speed (correlation coefficient of -0.28 when considering all wind speeds and of -0.25 when considering only wind speeds larger than 5 m/s). We retrieved for the linear relationship of

$$H_s + A_s = a_0 - a_1 \cdot v_{\text{calibrated}} \quad (8)$$

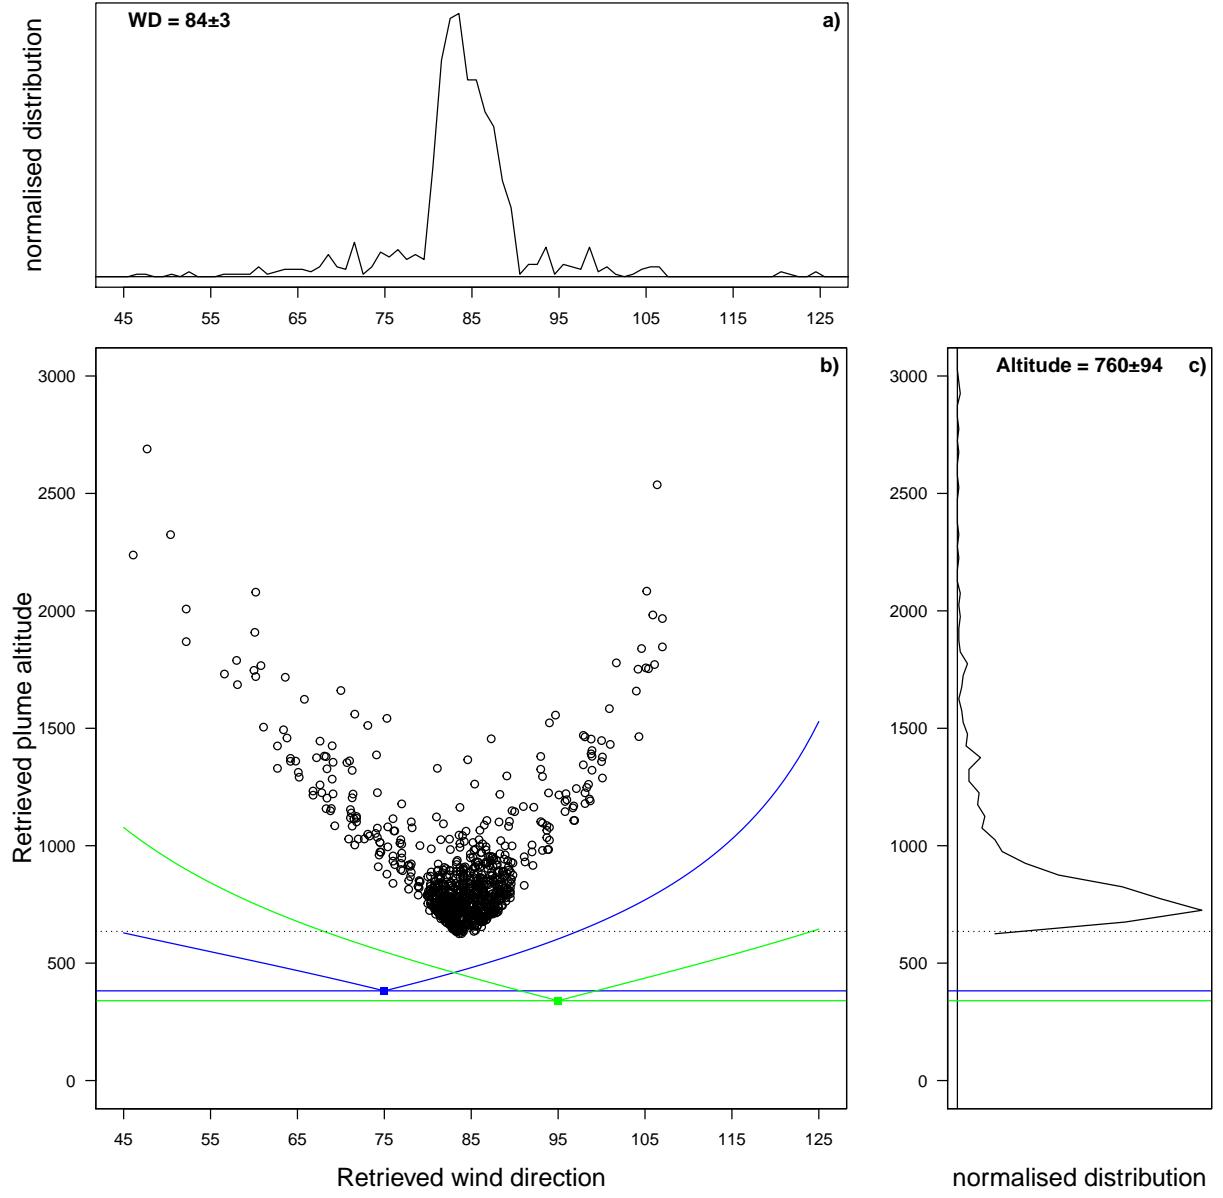

Figure 6. Results of the plume centre triangulation. Data has been binned in 30 min intervals and the means of the plume centre have been compared. A bin has been rejected if the plume centre varied for one instrument such that the standard deviation exceeded 20° . **a)** Histograms of the retrieved wind directions. **b)** Scatter plot of the retrieved plume altitudes and the retrieved wind directions. The altitudes of the Caracol and Nancital stations and of the volcanic edifice are marked by blue, green, and grey lines. The effective field of view $|\varepsilon| < 76^\circ$ of the two instruments is given by the curvy blue and green lines. The dominant bulk of observations centred at approximately $(84^\circ, 756 \text{ m a.s.l.})$ refers to observations when both instruments nearly simultaneously recorded the sample plume while the “wings” to the upper left and upper right corners refer to observation where both instruments recorded at the same time different plumes. The wings are presumably artefacts caused by the simplicity of the triangulation approach given in equation 7. **c)** Histogram of the retrieved plume altitudes.

365 a best fit (when H_s and A_s measured in m and $v_{\text{calibrated}}$ measured in m/s) for $a_0 = (902 \pm 12)$ m and $a_1 = (12.2 \pm 1.5)$ s (when all wind speeds were considered, F-statistics of 64.7, p-value = $3.2 \cdot 10^{-15}$) or $a_0 = (909 \pm 18)$ m and $a_1 = (13.1 \pm 2.0)$ s (when only wind speeds larger than 5 m/s were considered, F-statistics of 41.6, p-value = $2.3 \cdot 10^{-10}$).

As a remark, we retrieved similarly well matching fits also for a quadratic relationship of

$$H_s + A_s = a_0 - a_1 \cdot (v_{\text{calibrated}})^2 \quad (9)$$

370 with a best fit for $a_0 = (860 \pm 8)$ m and $a_1 = (7.7 \pm 1.0) \cdot 10^{-4} \text{ s}^2/\text{m}$ (when all wind speeds were considered, F-statistics of 64.8, p-value = $3.1 \cdot 10^{-15}$) and $a_0 = (850 \pm 10)$ m and $a_1 = (6.8 \pm 1.1) \cdot 10^{-4} \text{ s}^2/\text{m}$ (when only wind speeds larger than 5 m/s were considered, F-statistics of 38.9, p-value = $8.3 \cdot 10^{-10}$).

We chose to use the linear relationship retrieved for winds speeds larger than 5 m/s for dynamic estimates of the plume height as a function of the wind speed, i.e. we applied a H_s retrieved via

375 $H_s + A_s = 909 \text{ m} - 13.1 \text{ s} \cdot v_{\text{calibrated}} \quad (10)$

as the estimate for the plume height in the calculation of the SO_2 emission fluxes.

We are aware that this relationship is subject to a large scatter, though we consider it a better best guess than applying a fixed plume height. In particular, using a fixed plume height could result in apparent seasonal variations in the SO_2 emission fluxes which are, however, possibly only inherited artefacts due to seasonal variations of the wind speed (see next paragraph).

380 **(Apparent) correlation of SO_2 emission fluxes and wind speeds**

We initially observed a strong correlation between the SO_2 emission fluxes and the wind speeds when none of our estimation approaches for the wind speed, the wind direction, or the plume height were applied (correlation coefficient of +0.84 when all wind speeds are considered and of +0.56 when only wind speeds larger than 10 m/s are considered, Figure 7e). This correlation was lower for the calibrated data (correlation coefficient of +0.71 when all wind speeds are considered) and in particular 385 basically vanished for wind speeds larger than 10 m/s (correlation coefficient of +0.16, Figure 7f). The SO_2 emission fluxes are of magmatic origin and thus no causal link to the meteorological conditions would be expected.

For March–October 2014, the SO_2 emission fluxes can be calculated alternatively via the triangulation results, i.e. using the triangulated plume height and plume propagation direction instead of the parametrised plume height and the wind direction from ECMWF. We calculated the SO_2 emission fluxes accordingly, while using only data with triangulated plume altitudes 390 below 1200 m a.s.l. in order to be consistent with the above explained parametrisation approach (and again in order to avoid the influence of the artificial “wings”). For these alternative SO_2 emission flux estimates, the correlation between the SO_2 emission fluxes and the wind speeds were significantly lower and completely vanished for wind speeds larger than 10 m/s (correlation coefficient of +0.05 and +0.02 for the two NOVAC stations, see Figure D1).

We conclude that the observed correlation between the SO_2 emission fluxes and the wind speed is rather not a real observation 395 but is more likely caused by inaccurate SO_2 emission fluxes and in particular due to neglecting the variations in the plume height. For better readability, we postponed a more detailed discussion of this observation to Section 5 “Discussion of the SO_2

emission flux retrieval”.

On the one hand, our proposed calibrations were able to correct this spurious correlation for wind speeds larger than 10 m/s (Figure 7f). On the other hand, we were not able to explain or correct for that correlation for wind speeds smaller than 10 m/s.

400 Accordingly, it could be appropriate to reject all data with wind speeds smaller than 10 m/s but this would massively reduce our dataset (this would reject 72% and 78% of the remaining scans for Caracol and Nancital station, respectively). As a compromise between data reliability and temporal resolution, we thus applied a more conservative filter and reject only those data with wind speeds smaller than 5 m/s. This subsequent filter rejected 15% and 22% of the remaining scans for Caracol and Nancital station, respectively.

405 **Retrieval of the BrO/SO₂ molar ratios**

When retrieving BrO column densities in a volcanic gas plume from DOAS measurements, the expected optical depth of BrO absorption bands is at least one order of magnitude smaller than for SO₂. Thus, a better photon statistic is required for sufficiently precise BrO results beyond the detection limit. At manually controlled measurements, this is often realised by averaging over a sufficiently large number of consecutive exposures (and besides, typical state-of-the-art campaign DOAS instruments 410 are much more precise than NOVAC instruments due to better spectrometers and an active temperature stabilisation, see e.g. Kern and Lyons, 2018). For NOVAC data optimised with respect to the SO₂ retrieval requirements, the required larger number of exposures per spectrum can be realised by a subsequent co-adding of multiple spectra which are recorded in temporal proximity and in the same or at least similar viewing direction.

415 For this purpose, the retrieved SO₂ dSCD distribution was used to identify all spectra which were predominantly part of the volcanic plume and then these spectra were added in order to get one “added-plume-spectrum” per scan. Analogously, the spectra which were associated with the 10 lowest SO₂ dSCDs were added in order to get one “added-reference-spectrum”. The drawback of this approach is the loss of spatial information because the retrieval derives only one averaged value for the BrO dSCDs and thus for the BrO/SO₂ molar ratios. Accordingly, this approach does not allow to investigate possible variations of the BrO/SO₂ molar ratio as a function of, e.g., the distance to the plume centre.

420 As mentioned above, a volcanic gas plume can be expected to have an approximately Gaussian shaped angular gas distribution embedded in a flat, gas-free reference region. Therefore we fitted a Gaussian distribution to the SO₂ dSCD distribution as a function of the zenith angles. The standard deviation range of the Gaussian distribution ($\alpha_{\text{peak}} \pm \sigma_{\text{Gauss}}$) was then defined as the plume region. The applied filters of the BrO/SO₂ retrieval were less strict than for the SO₂ emission flux retrieval: A scan was rejected from the further analysis only if the Gaussian fit failed to converge or if $\sigma_{\text{Gauss}} < 5^\circ$. Furthermore, if σ_{Gauss} was 425 rather large the such defined plume region may have overlapped with the reference region. To avoid this inconsistency, we implemented the following procedure: if the derived (Gaussian) plume region included more than 10 spectra, the plume region was instead defined as the angle range with the highest running mean value over 10 spectra for the SO₂ dSCD. The spectra associated to the plume region were spectroscopically added to a single “added-plume-spectrum”.

430 We highlight that it would be more consistent to fit the Gaussian distribution to the SO₂ VCD distribution as a function of the tangent of the zenith angles (instead of a fit to the SO₂ dSCD distribution as a function of the zenith angles). Nevertheless, the

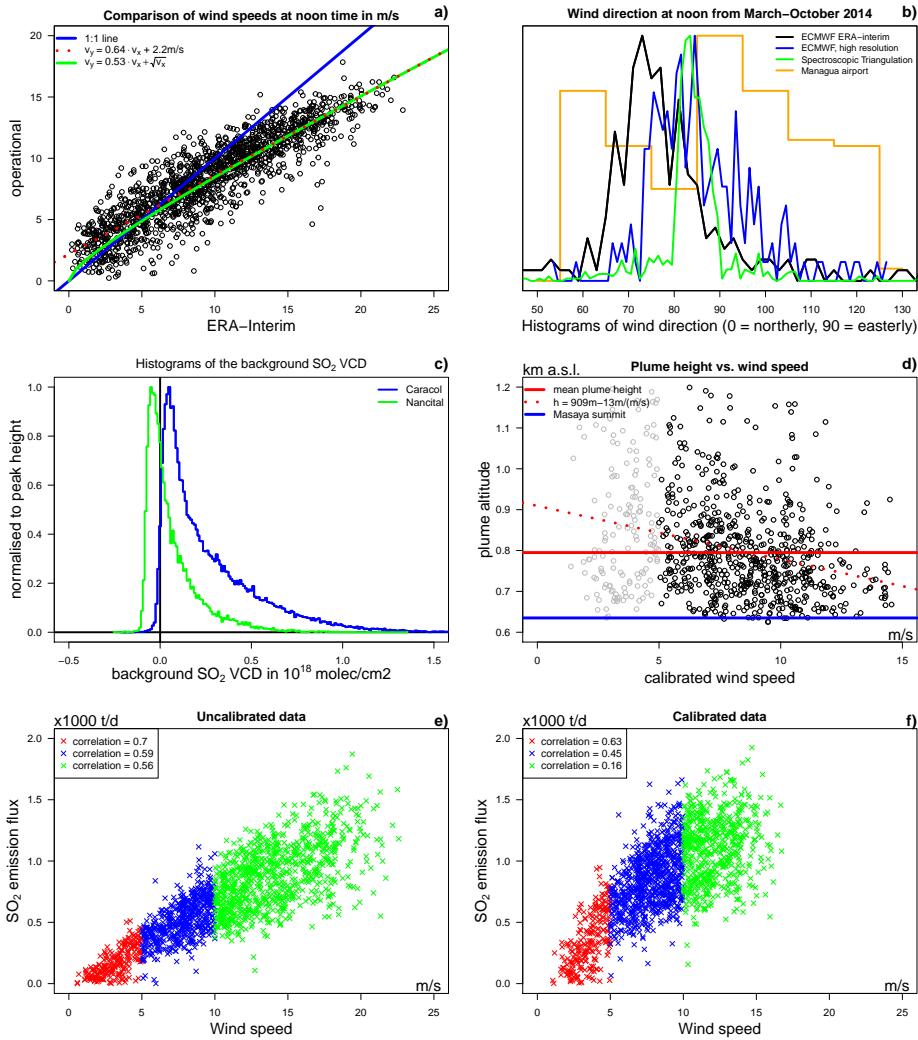

Figure 7. Summary of several empirical observations used for filtering and estimations. **a)** Comparison of the wind speeds from the ECMWF ERA-Interim data and the operational ECMWF reanalysis data. **b)** Comparison of the distribution of the wind directions estimated by four different methods. **c)** Histograms of the absolute SO_2 SCD of the background spectrum for both instruments for their respective total time series. **d)** Scatter plot of the triangulated plume height and the calibrated wind speed. The red dotted line indicates the relationship between wind speed and plume height (fit based on the black circles). **e+f)** Correlation between the retrieved SO_2 emission fluxes and the wind speed. The plots compare daily SO_2 means and the means of the wind speed at the respective measurement times. **e)** Original ERA-Interim wind speeds versus the non-calibrated SO_2 emission fluxes calculated with original ERA-Interim wind conditions and a fixed plume altitude of 635 m a.s.l. **f)** Calibrated wind speeds versus the SO_2 emission fluxes calculated with the calibrated wind conditions and a dynamic plume altitude as a function of the wind speed.

maximum possible effect would be that ± 1 spectrum is included to the plume region. We used the fit in the dSCD–angle space for practical and historical reasons but, in the future, would encourage fitting in the VCD–tangent space instead for maximum consistency with the SO_2 flux retrieval.

The added-plume-spectra and added-reference-spectra per scan were used for a second iteration of the spectroscopic retrieval
435 in order to retrieve SO_2 and BrO dSCDs representative to the plume centre. From this set of scans, all scans with sufficiently reliable BrO fits (here: scans with a fit quality of $\chi^2_{\text{BrO}} < 2 \cdot 10^{-3}$) were used for a third iteration: the added-plume-spectra and added-reference-spectra of 4 consecutive scans were added and again SO_2 and BrO DOAS fits were applied. An I_0 -correction was applied to these final data (Platt and Stutz, 2008), which had not been done beforehand in order to save evaluation time.

The SO_2 and BrO dSCDs and the BrO/SO_2 molar ratios discussed in this manuscript refer to the results of the third spectroscopic iteration (Figure 8). We highlight that these dSCDs are not absolutely calibrated for a background contamination (see above) because no reliable method for an absolute calibration of a background contamination with BrO has been developed (in contrast to the SO_2 retrieval). The interpretation of the BrO/SO_2 molar ratios thus tacitly assumes that a possible background contamination has the same BrO/SO_2 molar ratio as the main plume. For first investigations of this assumption and possible advances towards a correction of a BrO contamination see Wilken (2018).

445 We highlight that the retrieval of the BrO/SO_2 molar ratios is hardly affected by the numerous potential sources of systematic effects as it is the case for the SO_2 emission fluxes. For instance, the BrO/SO_2 molar ratio is not affected by assumptions on the air mass factor and on the plume height. In addition, when BrO and SO_2 are retrieved from similar wavelength regions, the BrO/SO_2 molar ratio appears to be hardly susceptible to systematic effects in the radiative transport, because then the quantitative effects are similar for BrO and SO_2 and thus cancel in good approximation (Lübcke et al., 2014).

450 4 SO_2 and BrO time series at Masaya

In this section, we present the SO_2 and BrO time series retrieved from the NOVAC data. There were two major data gaps in the NOVAC time series from September 9 to November 16 2015 and from March 21 to June 23 2018. The statistical analysis results discussed in the following, therefore, refer to the time intervals (1) March 2014 – September 2015, (2) November 2015 – March 2018, (3) June 2018 – March 2020.

455 This separation in three time series is also in good agreement with the three episodes of general volcanological observations of the lava lake activity: (1) “prior to the lava lake appearance (until November 2015)”, (2) “period of high lava lake activity” (from November 2015 to October 2018, where the thermal activity started at latest on November 15 and the lava lake visualised on December 15 INETER, 2015a, b; Aiuppa et al., 2018), and (3) “period of low lava lake activity (from October 2018 on)” (Smithsonian Institution, 2018). It has been reported that Masaya was already relatively calm before May 2018 (Smithsonian Institution, 2018), indicating that the major transition from high to low activity may have happened somewhat during the data gap from March–June 2018. The minor discrepancy in separation with respect to the time span from June–October 2018 was not elaborated in our study.

The long-term averages of these time intervals were retrieved for intervals spanning exact multiples of a year in order to avoid

Table 5. Main statistical properties of the spectroscopic results for Caracol station. Early BrO/SO₂ NOVAC observations between 2007–2009 are listed for completeness. The daily variations are based on the standard deviations of the single days. The given errors are standard deviations, except for the annual trend and the amplitude of the annual cycle for the BrO/SO₂ molar ratios were the errors refer to the standard regression error.

time interval	SO ₂ emission fluxes (in 1000 t d ⁻¹)			BrO/SO ₂ molar ratios (in 10 ⁻⁵)			“BrO emission fluxes” (in kg d ⁻¹)
	daily means	daily variation	daily maxima	daily means	annual trend (in 10 ⁻⁵ a ⁻¹)	amplitude of annual cycle

SO₂ and BrO dSCDs

The data from Caracol station and Nancital station were in general in good agreement (correlation coefficients of $+0.82$ and $+0.77$ for daily averages of SO₂ and BrO dSCDs). The Caracol station observed in average higher dSCDs with a relative factor of 1.18 ± 0.21 for SO₂ and 1.06 ± 0.24 for BrO (when neglecting data with BrO dSCDs below $5 \cdot 10^{13} \frac{\text{molec}}{\text{cm}^2}$ as these were

470 deemed too close to the instrument detection limit). Analogously, relative factors of 1.12 ± 0.20 and 0.99 ± 0.19 were observed for the daily averages of the SO₂ emission fluxes (see Section 5 and Figure 9) and of the BrO/SO₂ molar ratios, respectively.

In the following, we discuss the typical variations observed by Caracol station. From March 2014 to September 2015, the SO₂ dSCDs varied between $1\text{--}3 \cdot 10^{18} \frac{\text{molec}}{\text{cm}^2}$ and the BrO dSCDs had daily maxima of about $1.5 \cdot 10^{14} \frac{\text{molec}}{\text{cm}^2}$ but with peaks of up to $3 \cdot 10^{14} \frac{\text{molec}}{\text{cm}^2}$. From November 2015 to March 2018, the SO₂ dSCDs varied predominantly between $1\text{--}4 \cdot 10^{18} \frac{\text{molec}}{\text{cm}^2}$ but with

475 9% of the data varying between $4\text{--}8 \cdot 10^{18} \frac{\text{molec}}{\text{cm}^2}$ and the BrO dSCDs had doubled with daily maxima of about $3 \cdot 10^{14} \frac{\text{molec}}{\text{cm}^2}$ with peaks of up to $6 \cdot 10^{14} \frac{\text{molec}}{\text{cm}^2}$. From June 2018 to March 2020, the SO₂ dSCDs were lower again and varied between $1\text{--}2 \cdot 10^{18} \frac{\text{molec}}{\text{cm}^2}$ and the BrO dSCDs had daily maxima of about $1.5 \cdot 10^{14} \frac{\text{molec}}{\text{cm}^2}$. In summary, for the second time interval the SO₂ and BrO dSCDs time series showed enhanced long-term averages but also a significantly larger variability.

Furthermore a Lomb-Scargle periodicity analysis indicated that the SO₂ dSCDs followed an annual cycle with pronounced 480 minima during January of each year (false alarm probability of $3 \cdot 10^{-211}$) and that the BrO dSCDs followed an annual cycle ($3 \cdot 10^{-213}$) with an additional semi-annual modulation ($2 \cdot 10^{-110}$).

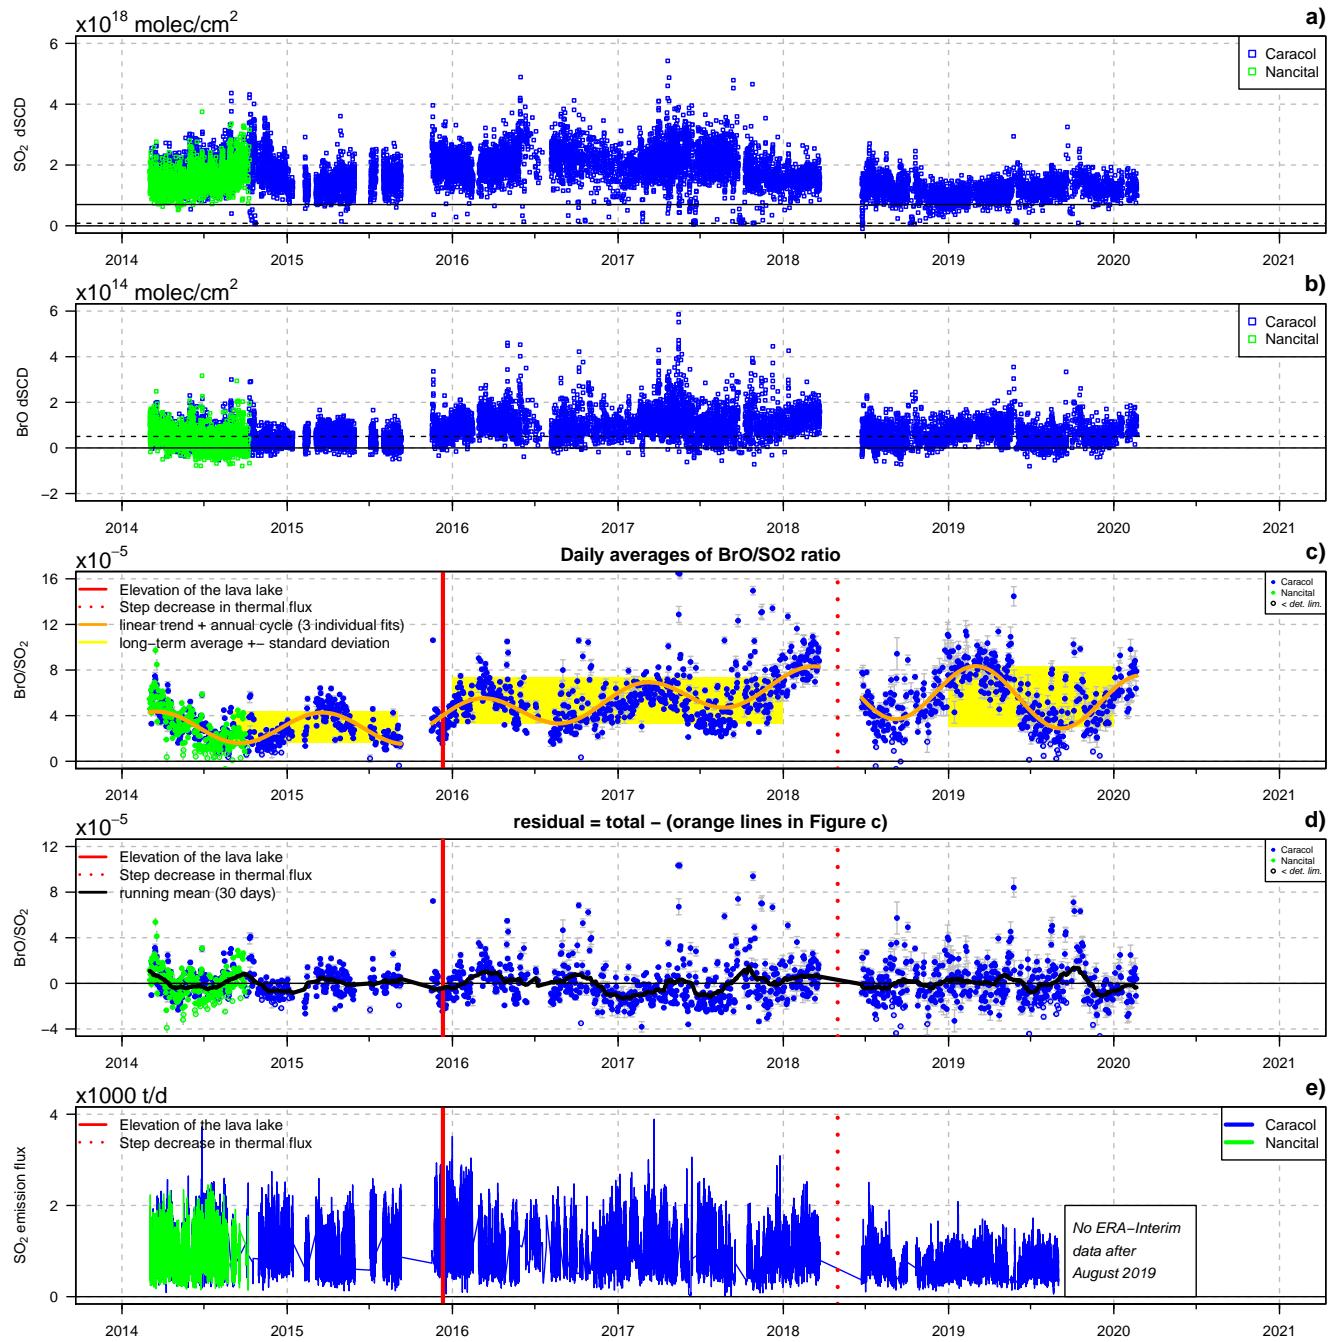

Figure 8. a-c) Time series of the differential slant column densities of SO_2 and BrO and calculated daily means of the BrO/SO_2 molar ratios in the gas plume emitted from Masaya (long/short tick marks indicate first of January/July). The two NOVAC stations are indicated by the different colours. **c)** Best fits of the long-term pattern are given for three individual time intervals (orange lines). The yellow bands indicate the long-term averages and the standard deviations. **d)** Residual BrO/SO_2 time series when subtracting the best fits from the three individual parts of the BrO/SO_2 time series. **e)** Daily means of the SO_2 emission fluxes.

Patterns in the BrO/SO₂ time series

Considering the whole time series from 2014–2020, the average BrO/SO₂ molar ratios were $(4.4 \pm 2.3) \cdot 10^{-5}$ and subject to characteristic variations between $1\text{--}10 \cdot 10^{-5}$. The BrO/SO₂ molar ratios strongly differed between the three periods of volcanic activity with average BrO/SO₂ molar ratios of $(2.9 \pm 1.5) \cdot 10^{-5}$, $(4.8 \pm 1.9) \cdot 10^{-5}$, and $(5.5 \pm 2.6) \cdot 10^{-5}$ (see yellow bars in Figure 8c).

In addition to the variations described in the previous section, the BrO/SO₂ time series indicated an annual cycle with maxima in early March accompanied by a semi-annual modulation (indicated by a Lomb-Scargle analysis, false alarm probability of $9 \cdot 10^{-74}$) as well as a varying long-term trend. These patterns were investigated for each of the three time intervals separately by fitting linear trends plus a sinusoidal variation with a period of one year to the respective BrO/SO₂ time series. All fits were significant with p-values $< 2.2 \cdot 10^{-16}$ and the same holds for all individual regressors if not stated differently. For all three time intervals the phase of the annual cycle remained basically the same but the average amplitude of the cycle varied between the three time intervals being $(1.36 \pm 0.08) \cdot 10^{-5}$, $(1.40 \pm 0.10) \cdot 10^{-5}$, $(2.52 \pm 0.12) \cdot 10^{-5}$, respectively. The accompanying linear trends in the BrO/SO₂ time series were $(-0.08 \pm 0.12) \cdot 10^{-5}$ (p-value = 0.48), $(1.44 \pm 0.10) \cdot 10^{-5}$, $(-0.81 \pm 0.18) \cdot 10^{-5}$ per year for the three time intervals (see Table 5). An extrapolation of the trends of the two earlier time intervals to December 11 2015, that is the date of the lava lake appearance, implied an apparent step increase by $0.7 \cdot 10^{-5}$ in the average BrO/SO₂ molar ratios.

The residual patterns were investigated by subtracting the fitted variations (annual cycle and trend) from the respective time series for the three time intervals. Most residual variations spanned between $\pm 2 \cdot 10^{-5}$ subject to a standard deviation of $1.3 \cdot 10^{-5}$ and some outliers of up to $9 \cdot 10^{-5}$ (Figure 8d). A Lomb-Scargle periodicity analysis indicated a weak semi-annual modulation with an amplitude of $0.5 \cdot 10^{-5}$ of the dominant annual periodicity with maxima in each March and September (false alarm probability of $9 \cdot 10^{-16}$).

SO₂ and minimum bromine emission fluxes

For Caracol station separated for the three time intervals (a) the mean daily averages of the SO₂ emission fluxes, (b) the average daily variability, and (c) the averages of the daily maximum SO₂ emission fluxes are listed in Table 5. From March 2014 – March 2018, the daily means of the SO₂ emission fluxes were in general constant at $(1.0 \pm 0.3) \cdot 10^3 \text{ t d}^{-1}$ with the exception of December 2015 – February 2016 (i.e. in the three months after lava lake appearance) when they were enhanced at $(1.3 \pm 0.3) \cdot 10^3 \text{ t d}^{-1}$. Furthermore, a Lomb-Scargle analysis indicated a weak semi-annual cyclicity in the SO₂ emission fluxes (false alarm probability of $1 \cdot 10^{-22}$). The product of the SO₂ emission fluxes and the BrO/SO₂ molar ratios $R_{\text{BrO/SO}_2}$ allowed the calculation of the apparent BrO emission fluxes $F_{\text{BrO}} = F_{\text{SO}_2} \cdot R_{\text{BrO/SO}_2} \cdot \frac{M_{\text{BrO}}}{M_{\text{SO}_2}}$ (with the molar masses M_i). The according apparent BrO emission fluxes would be 44, 72, and 56 kg d⁻¹ for the three time intervals. The apparent BrO emission fluxes multiplied with $\frac{M_{\text{Br}}}{M_{\text{BrO}}} = 0.83$ can be considered as lower limits for the total bromine emission fluxes, because not all emitted bromine would have been transformed into BrO. According to model studies, the total bromine emissions would likely have been at least a factor of 2 larger than the derived apparent BrO emission fluxes (von Glasow, 2010; Roberts et al., 2014).

Intrinsic uncertainty in the SO₂ emission fluxes

The simultaneous observation of basically the same volcanic gas plumes by two close NOVAC stations was a rare opportunity to retrieve empirically the lower limit of the uncertainty of the SO₂ emission fluxes. For ideal measurements, both stations would observe identical SO₂ emission fluxes, but under real measurement conditions systematic as well as statistical deviations can be expected.

520 It is important to remark that the two stations usually did not record the exactly same plume but their telescopes pointed at different times to the volcanic plume, with time differences of several minutes between their “simultaneous” observations. Pering et al. (2019) reported for SO₂ camera measurements at the crater rim, however, that the SO₂ emission fluxes frequently vary by more than 100% within minutes. We observed a similar variability when we analysed the SO₂ emission fluxes retrieved 525 by the two stations with only several minutes between their observations. Accordingly, the higher the temporal resolution of the compared data, the larger is the expected scatter of the comparison.

We calculated the ratios (called “relative factors” in the following) of the SO₂ emission fluxes retrieved by Caracol station divided by the SO₂ emission fluxes retrieved by Nancital station using several temporal bin sizes. The relative factor and standard deviation of the scatter were 1.22 ± 0.55 for a 10-min binning, 1.19 ± 0.40 for a 1-hour binning, 1.13 ± 0.21 for daily means, 530 and 1.11 ± 0.15 for weekly means (the 1-hourly data and the daily means are shown in Figure 9). Our observations confirmed the significant reduction in the scatter with increasing bin size. In contrast to that, we observed a rather persistent relative factor of 1.1–1.2 for all bin sizes, with nevertheless a weakly decreasing trend as a function of the bin size.

The observed relative factor of 1.13 for daily means is relatively small in view of the uncertainties in the estimates of the 535 meteorological conditions but also other measurement uncertainties. There are four obvious candidates for effects which may have contributed to the deviation of that factor from unity: (i) wrong geometric parameters of the NOVAC stations, (ii) misestimations of the wind direction or the plume height, (iii) systematic deviations in a possible underestimation of the SO₂ dSCD, and (iv) radiative transport effects.

(i) The most mundane cause for the observed offset would be wrong information on the viewing directions of the telescopes of the NOVAC instruments. For instance, with respect to a wind direction of 84° a variation of the scan plane orientation β by 540 $\pm 15^\circ$ would result in a systematic miscalculation of the SO₂ emission fluxes by a factor of 0.92–1.01 for the Caracol station or 0.92–1.02 for the Nancital station, i.e. up to a relative factor of 1.11. Analogously, a misalignment of the zenith angle by as little as $\pm 5^\circ$ can cause a systematic miscalculation of the VCDs (and thus the SO₂ emission fluxes) by a factor of 0.9–1.1 when the volcanic plume is observed at $\pm 50^\circ$. If both stations are affected, such apparently negligible misalignments of the zenith angle can cause a relative factor of about 1.2 between both stations.

545 (ii) A misestimation of the plume altitude can not only result in an absolute misestimation of the SO₂ emission fluxes but can also contribute to the observed relative factor because the stations are installed at different altitudes. For instance and for the particular conditions at Masaya, using a mean plume altitude of 1000 m a.s.l. instead of 635 m a.s.l. would cause a relative factor of 1.09.

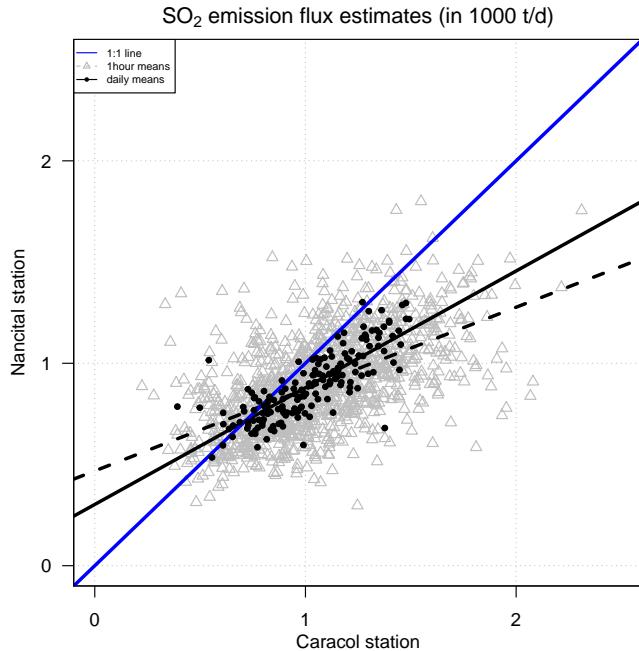

Figure 9. Comparison of the SO₂ emission flux estimates when both NOVAC stations observed volcanic plumes within the same time bin of hourly means (grey triangles) and daily means (black circles). The plot compares the bin averages and only data for wind speeds larger than 5 m/s were considered.

- (iii) A more subtle source for the observed relative factor and scatter could be the relation between an underestimation of the 550 SO₂ VCD and the absolute zenith angle: given a fixed SO₂ VCD, the larger the absolute zenith angle, the larger is the observed SO₂ dSCD, and thus the larger is the probability of a significant underestimation of the SO₂ VCD. Accordingly, if one of the instruments records shallow plumes systematically more often than the other instrument, this instrument would thus retrieve systematically lower SO₂ emission fluxes. Both instruments, nevertheless, observed the volcanic plumes in average at the same (absolute) zenith angles and thus this possible candidate appears to be irrelevant here.
- (iv) There could be significant deviations in the SO₂ emission fluxes recorded by the two stations due to different radiative 565 transport effects. For Masaya, the radiative transport effects associated to the relative position of the sun were, however, presumably rather similar for both NOVAC stations because for March–October the sun was for most of the day close to the zenith. Relative differences in the radiative transport caused, e.g. when there were systematically more clouds either to the North or the South of the NOVAC stations, could be nevertheless not ruled out as a source for the relative factor deviating from unity.

560 Correlation of SO₂ emission fluxes and wind speeds

We observed a strong correlation between the SO₂ emission fluxes and the wind speeds when none of our correction approaches for the wind speed, the wind direction, or the plume height were applied (correlation coefficient of +0.84 when all wind speeds

are considered and of +0.56 when only wind speeds larger than 10 m/s are considered, Figure 7e). This correlation was lower for the calibrated data (correlation coefficient of +0.71 when all wind speeds are considered) and in particular basically vanished
565 for wind speeds larger than 10 m/s (correlation coefficient of +0.16, Figure 7f).

The SO₂ emission fluxes are of magmatic origin and thus no causal link to the meteorological conditions would be expected. There are three groups of possible causes for this observation: (1) a chance coincidence of shared long-term patterns (e.g. an annual cyclicity), (2) causal links between the wind speed and the “volcanic” (in contrast to “magmatic”) gas emission flux, and (3) a systematically wrong calculation of the SO₂ emission fluxes. In the following the plausibility of these options is
570 discussed.

(1) The wind speed followed a semi-annual cyclicity with strong maxima in January/February and weaker maxima in July. If the observed correlation was caused by a chance coincidence this would imply an annual cyclicity in the volcanic degassing behaviour with maxima in January/February. Such an annual cycle could e.g. be caused by an astronomical forcing. The both best candidates, the solar irradiance and the Earth tidal potential, are indeed at Masaya minimum in December/January and
575 June/July. Nevertheless, it is still far from obvious that these forcings can cause such a strong annual modulation of the SO₂ emission flux.

(2) There is indeed a plausible mechanism which links the wind speed and the SO₂ emission flux: Volcanic gas emissions often accumulate in the crater of Masaya. The larger the wind speed, the higher is the atmospheric turbulence and thus the lower is the accumulation. Accordingly and if the wind speed is subject to significant short-term fluctuations, over-proportionally much
580 volcanic gas gets effectively released from the volcanic edifice to the atmosphere during high wind speed peaks. However, the observed correlation is based on long-term variations in the wind speeds but not on short-term fluctuations. While the temporal variability of our SO₂ time series could be partially caused by this mechanism, our wind data (with a temporal resolution of 6 hours) is insensitive for short-term effects and that causal link can be ruled out as a cause for the observed correlation. We highlight that this mechanism may partially explain the high variability in the SO₂ emission fluxes as observed by Pering et al.
585 (2019).

(3) There are a number of possibilities how the observed correlation could be caused by systematic effects in the retrieval of the SO₂ emission fluxes: the plume height estimate could systematically depend (a) on the wind speed or (b) on the SO₂ emission flux, (c) the retrieval of the background SO₂ SCD, or (d) an observational bias caused by the applied filters.

(a) As discussed above, we expected and indeed observed a weak anti-correlation between the plume height and the wind
590 speeds (Figure 7d) which can explain the observed correlation for wind speeds larger than 10 m/s (Figure 7f). We therefore conclude that this mechanism is one of the predominant causes of the observed correlation.

(b) The stronger the absolute volcanic gas emission fluxes (i.e. in particular of H₂O), the slower is the cooling of the volcanic plume due to in-mixing of air, and thus the higher is the effective plume height of the buoyant gas plume. Combined with the general expectation that the wind speed is larger with increasing height above ground, we conclude that the higher the SO₂
595 emission flux (when assuming that it is proportional to the absolute gas emission flux), the higher is the wind speed at plume propagation altitude. Using only wind speeds for a fixed altitude level to calculate the SO₂ emission fluxes, we can then expect an anti-correlation between the SO₂ emission flux estimates and the applied wind speed.

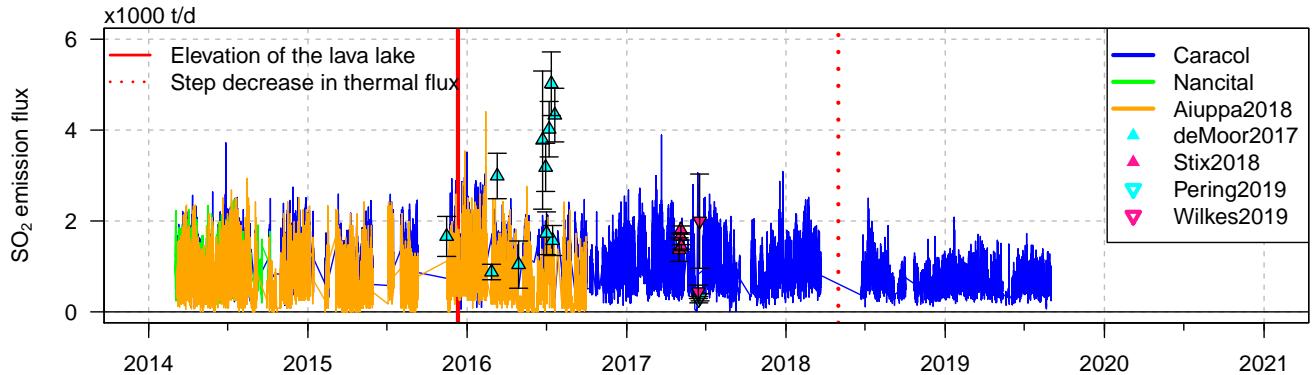

Figure 10. Comparison of the SO₂ emission fluxes reported in this and other studies.

(c) Lübcke et al. (2016) reported for Nevado del Ruiz and Tungaragua that the probability of the clear-sky reference spectrum being contaminated with SO₂ is higher for low wind speeds. Thus, at low wind speeds the SO₂ SCD (and hence the SO₂ emission flux) is more likely to be underestimated than at high wind speeds. Nevertheless, applying our method for removing SO₂ contaminated references had practically no effect on the correlation of emission rate and wind speed, thus indicating that background contamination was not a major cause of the observed correlation.

(d) The stronger the observed plume shape deviates from an ideal Gaussian shape, the larger is the probability that the scan gets rejected from the applied data filters. The plume shape is arguably better confined for larger wind speeds because then the relatively short time interval prior to the observation implies a smaller horizontal plume dispersion. Nevertheless, we would neither expect nor did some data checks support the assumption that such observational biases could have caused the observed correlation.

Comparison with reported SO₂ emission fluxes

For 2014–2017, Aiuppa et al. (2018) retrieved from the same NOVAC data and ERA-Interim data mean SO₂ emission fluxes of $(700 \pm 400) \text{ t d}^{-1}$ subject to variations between $0\text{--}2600 \text{ t d}^{-1}$ (Figure 10). Our and their SO₂ time series show a good agreement in relative variability but we observed considerably higher values with average relative factors of 1.42 ± 0.46 (Figure 11). This relative factor can be explained by the combination of the deviations in (1) the SO₂ dSCD retrieval, (2) the plume height estimates, and (3) the wind speeds estimates, as detailed in the following.

(1) Aiuppa et al. (2018) used the standard NOVAC SO₂ dSCD retrieval whose fit range starts as low as 310 nm. As motivated in Appendix B, we argue that they therefore may have underestimated the SO₂ dSCDs at Masaya by up to a factor of 1.25 (or to be more precise: their underestimation relative to our underestimation was up to a factor of 1.25, see Figure B1).

(2) The different estimates in the plume height explain another relative factor of $\frac{374\text{m}}{253\text{m}} = 1.48$ (we applied in average a plume altitude of 756 m a.s.l. implying an average plume height of 374 m above Caracol station while Aiuppa et al. (2018) applied a constant plume altitude of 635 m a.s.l. implying a plume height of 253 m above Caracol station).

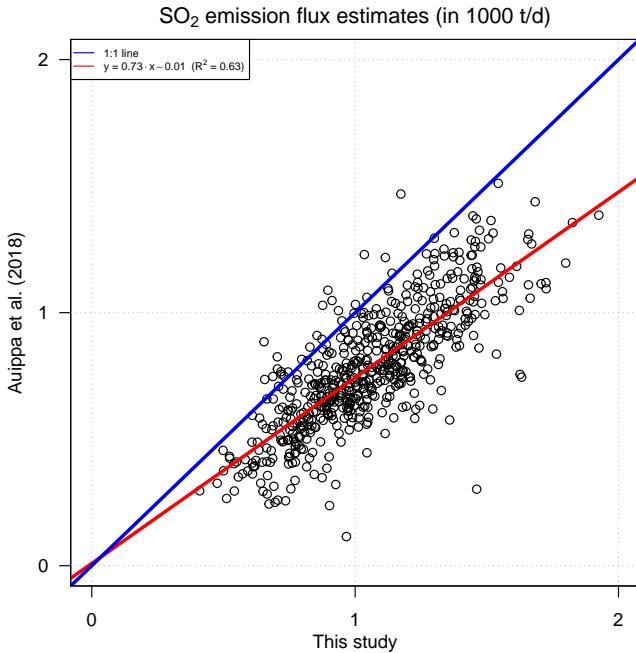

Figure 11. Comparison of the SO₂ emission fluxes from Caracol station reported in this study and by Aiuppa et al. (2018).

620 (3) Aiuppa et al. (2018) provided their wind data as an upload what allowed a direct comparison with our wind data. They interpolated the ERA-Interim data to the location of the volcano and used only data where the plume propagated in the proximity of the Caracol station (pers. comm. Santiago Arellano, Chalmers University of Technology). The seasonality in their wind speed data is in good agreement with our data. The long-term ratio (from March 2014 to October 2016) between their wind speed data (interpolated to 635 m a.s.l.) and our ERA-Interim data or our operational ECMWF reanalysis data (both interpolated to 625 700 m a.s.l.) was 1.02 and 1.28, respectively (see also Figure 7a). We remark that in contrast to that actually a factor of less than 1 would be expected because of their lower retrieval altitude of 635 m a.s.l. instead of our 700 m a.s.l.

For a complete record, there are further deviations between both retrievals which manifest predominantly in the extended filtering for unstable measurement conditions in our retrieval (see Section 3).

630 We highlight nevertheless that the conditions at Masaya are rather an exception than the rule. Most NOVAC stations are usually more than 4 km away from the volcanic edifice and their altitudes are usually more than 1 km below the altitude of the volcanic summit. In consequence, a given absolute uncertainty in the plume height of, e.g. 100 m, results usually in relative uncertainties in the plume height of less than 10%. Accordingly, for other volcanoes the uncertainty in the SO₂ emission fluxes may be dominated by other sources of uncertainty. Similar considerations hold for the proposed weak anti-correlation of the plume height and the wind speed.

635 Besides the NOVAC long-term time series, the SO₂ emission fluxes of Masaya were also determined episodically by short-term (at most several weeks) measurement campaigns. From 1976–2010, reported SO₂ emission fluxes varied between (300 ± 100)

and $(2100 \pm 900) \text{ t d}^{-1}$ with all-time averages of roughly 800 t d^{-1} (Nadeau and Williams-Jones, 2009; Martin et al., 2010; de Moor et al., 2013). Since 2014, SO_2 emission fluxes spanning between $1000\text{--}5000 \text{ t d}^{-1}$ were reported, determined via DOAS traverse measurements (de Moor et al., 2017) or via SO_2 camera measurements (Stix et al., 2018; Pering et al., 2019; Wilkes et al., 2019). Those campaign data match in general well with our observed range of SO_2 emission fluxes, with the exception of most of the June 2016 data from de Moor et al. (2017) (see Figure 10).

Critical assessment of our SO_2 emission flux retrieval

This paragraph summarises the extensions implemented in our retrieval as well as a set of possible future advances which have not yet been investigated. Furthermore, the justifications for some retrieval steps introduced in Section 2 of this manuscript are 645 motivated. The main findings are summarised in Table 6.

1. *Spectroscopic retrieval*: We documented the possibility for an underestimation of the SO_2 dSCDs when the SO_2 DOAS fit range is not chosen appropriately (see Appendix B). For strongly degassing volcanoes, we recommend to use a fit ranges which starts at least at 314 nm (see Table 3). Furthermore, we encourage to investigate the possibility of a hybrid retrieval using an interpolation of the dSCDs retrieved from two or more fit ranges. Another source of possible errors can be a missing I_0 - 650 correction of the absorption cross section of a strongly absorbing gas species. We highlight that, nevertheless, the I_0 -correction appears to be relevant to reduce the fit errors but usually of negligible importance for the accuracy of the retrieved SO_2 dSCD. For instance, even for SO_2 dSCDs of about $4 \cdot 10^{18} \frac{\text{molec}}{\text{cm}^2}$ the difference in the retrieved dSCDs was usually less than 1% but the peak-to-peak range of the residual structures were reduced by about 10–15%. Because precision is quite relevant for the BrO retrieval but not for the SO_2 retrieval, we applied the I_0 -correction routinely to the final data of the BrO/ SO_2 retrieval but 655 not to the final data of the SO_2 flux retrieval. The reason for this was the pragmatic decision to save run time: the effective number of spectra was more than two orders of magnitude lower for the BrO/ SO_2 retrieval than for the SO_2 flux retrieval—and so was the run time required for the I_0 -correction. Nevertheless, we encourage to use the I_0 -correction when aiming for a spectroscopically optimal retrieval.

2. *Filter unstable conditions*: We documented unstable measurement conditions for a significant fraction of the scans. We 660 recommend to filter for unstable conditions but our filters should be understood as first proposals. A logical advance would be for instance the additional check via a two-modal Gaussian fit or to apply filter thresholds which more dynamically adjust to the conditions of the investigated NOVAC station. Another filter whose potential is clearly not yet exhausted is the absolute SO_2 background calibration—neither with respect to its spectroscopically optimisation nor in the use of its results. Here, we need to highlight that these filters for unstable conditions were applied only in the SO_2 flux retrieval but not transferred to the 665 BrO/ SO_2 retrieval. The investigation of such a filtering in the BrO/ SO_2 retrieval is a logical extension of the current retrieval.

3. *Wind conditions*: Lacking measurement data for the wind conditions, the best proxy for wind data are usually weather model data. We compared the wind conditions proposed by the ECMWF ERA-Interim data ($1^\circ \times 1^\circ$ resolution) with operational 670 ECMWF reanalysis data (up to $0.125^\circ \times 0.125^\circ$ resolution). We documented that the ERA-Interim data proposed for Masaya were in average systematically larger wind speeds with deviations of up to 30% for wind speeds of 20 m/s (or respectively 15 m/s) and wind directions which were 11° further to east-northeasterly (in contrast to easterly) than both, the operational

Table 6. Applied and possible future advances in the SO₂ and BrO analysis. See text for details.

Status	Description
Spectroscopic retrieval	
done	$\lambda_{\text{lower limit}} > 314 \text{ nm}$ required for strong emissions
to do	always apply I_0 -correction?!
Filter unstable conditions	
done	SO ₂ fluxes: 5 filters summarised in Table 2
	BrO/SO ₂ : 2 filters see Section 3
to do	further optimise the filter conditions
	apply more filters on BrO/SO ₂ retrieval
Wind conditions	
done	ERA-Interim data ($1^\circ \times 1^\circ$) as consistent long-term data base but calibrated with operational data ($0.14^\circ \times 0.14^\circ$)
to do	investigate a direct use of operational data
Plume height estimate	
done	plume height retrieved via triangulation
	plume height as function of wind speed
to do	optimise the triangulation algorithm
SO₂ emission flux versus wind speed	
<i>strong correlation observed for un-calibrated data, not expected!</i>	
done	no more correlation for $> 10 \text{ m/s}$ with our calibrations
to do	improve calibration for $< 10 \text{ m/s}$
	establish such checks as benchmark for good estimates
Instrument line function (only a side note)	
done	provide empirical evidence for long-term stability
to do	direct retrieval from the recorded spectra

ECMWF reanalysis data and the triangulation results. We hesitated, however, to exclusively use the operational ECMWF reanalysis data due to the frequent jumps in the model set-up. As a cautious compromise, we calibrated the ERA-Interim data such that they matched the operational ECMWF reanalysis data in the long-term average and used these calibrated ERA-Interim data in all further evaluation steps (see Figure 7a+b). We encourage, nevertheless, a comprehensive investigation of the jumps in the operational data set-up with the possible finding that an exclusive use of the operational data is the best available proxy for the wind data.

4. *Plume height estimate*: The triangulation results documented a standard deviation of about 100 m which corresponds to a relative error of the plume height estimate of 30–40% (see Figure 7). As long as no temporally resolved information on the plume height is available, this has to be seen as a fundamental lowest limit for the uncertainty of the retrieved SO₂ emission fluxes at Masaya. Furthermore, the retrieved mean plume height deviated just 100 m from the plausible best guess used by Aiuppa et al. (2018) but this deviation in the applied plume height resulted directly in a deviation by a factor of 1.5. While these numbers are extreme for Masaya and presumably less drastic for most other NOVAC volcanoes, this highlights that the estimate of the plume height can be an important source of uncertainty in the SO₂ emission flux retrieval. Furthermore, we observed a weak anti-correlation between the wind speed and the plume height, which is also expected because of the buoyancy of the initially hot gas plume. Ignoring this relationship could cause a spurious correlation of the SO₂ emission fluxes with the wind speed (see below). We highlight that the applied triangulation algorithm is rather simple and several advances are desired, e.g. a filter when both instruments simultaneously see different plumes (see “wings” in Figure 6).

5. *Correlation of SO₂ emission flux and wind speed*? We observed a strong correlation between the original ERA-Interim wind data and the SO₂ emission fluxes when these were calculated without our proposed retrieval advances (+0.84 when all wind speeds are considered, Figure 7e). This correlation is weaker when our retrieval advances are applied (+0.71 when all wind speeds are considered) and basically vanishes for wind speeds larger than 10 m/s (then only +0.16, Figure 7f). As mentioned above, this apparent correlation was most likely caused by systematics in the SO₂ emission flux calculation and namely the ignorance of the variations in the plume height. Correlation checks like this should be used to validate under which measurement conditions the applied assumptions are justified. Considering Figure 7f, we highlight that our proposed retrieval advances were able to correct this spurious correlation only for high wind speeds larger than 10 m/s.

6. *Instrument line function*: We retrieved the instrument line function (ILF) from a mercury emission spectrum recorded prior to the installation of the instrument in the field (this is the standard approach for NOVAC data). The ILF varies, however, in general with temperature and due to ageing and such variations of the ILF could be another important limitation of the accuracy of gas data from NOVAC (and presumably of most automated measurement platforms). A frequent recording of the ILF could reduce ILF-related uncertainties, but this is not always feasible at each location. Another approach would be the retrieval of the ILF directly from the recorded spectra. Such retrievals have been developed, e.g. for satellite data (Sun et al., 2017), and are for example available in the QDOAS software package (<http://uv-vis.aeronomie.be/software/QDOAS/>). However, as today none of those retrievals has been optimised for the specifications of NOVAC instruments (i.e. rather low quality of recorded spectra and no active temperature stabilisation). First steps in this direction have been made by Kleinbek (2020) using the HeiDOAS software package (currently under development by Udo Frieß, University of Heidelberg). Nevertheless, we highlight that both

instruments enjoyed a surprisingly good long-term stability in their wavelength-to-pixel calibration which may indicate that also their ILFs were rather stable (see variations of their wavelength-to-pixel calibration in Figure D2). Furthermore, Dinger (2019) investigated the effect of the variations in the ILF for a NOVAC instrument installed at Nevado del Ruiz. That exemplary study concluded that for the BrO/SO₂ molar ratios the ILF-related uncertainties are an order of magnitude smaller than the 710 typical measurement error. While such exemplary findings can not be adopted directly for other instruments, this has been another hint that the ILF-related effects may be in reality contribute only insignificantly to the total measurement error.

7. *Network design:* NOVAC has been conceptualised such that the available NOVAC stations may be distributed as a good compromise between covering most of the relevant plume propagation directions but also to allow for a retrieval of the wind direction and plume height directly via triangulation. The here presented triangulation results gave a rare opportunity to validate 715 the use of weather model data as a proxy for the meteorological conditions at a volcano. While similar results could be retrieved also by a single NOVAC station using the optional “flux measurement mode” (Galle et al., 2010), this mode has hardly been used in the past indicating that maintaining two rather autarkic stations is apparently more likely to happen than actively scheduling the NOVAC measurements. While there are of course financial and maintenance limitations in adding another 720 station, we highlight that there is a significant number of NOVAC volcanoes with at least three NOVAC stations where a re-positioning of one of the stations may be beneficial in the long run. As an even further advance, McGonigle et al. (2005) demonstrated that installing three instruments in the main plume direction would also allow a direct retrieval of the wind speed.

6 Discussion of SO₂ and BrO time series

Correlations between gas data and meteorology

We investigated the NOVAC data and ERA-Interim data for correlations. For this purpose the daily means of the SO₂ dSCDs, 725 of the BrO dSCDs, of the BrO/SO₂ molar ratios, and of the SO₂ emissions fluxes and the noon-time ERA-Interim data were compared (Figure 12).

A correlation analysis of the ERA-Interim parameters with each other indicated: (1) The barometric pressure was not correlated to any of the other parameters. (2) All remaining ERA-Interim parameters (except the wind direction) were correlated with the total cloud cover (absolute correlation coefficients between 0.36–0.56). This was presumably mainly a manifestation of 730 the shared general seasonality of the weather conditions with extrema roughly in March and in October where the total cloud cover represents the seasonality apparently most clearly. (3) As expected, the three water related parameters (water vapour concentration, relative humidity, total cloud cover) were strongly correlated and the atmospheric water vapour concentration correlated with the temperature. (4) The ozone mixing ratio was anti-correlated with the water vapour concentration (−0.55), however, this was presumably first of all the shared seasonality. (5) The wind speed and the wind direction were correlated 735 (−0.44).

A correlation of the NOVAC parameters with each other indicated: (1) The variability in the BrO/SO₂ time series originated almost exclusively from the variability in the BrO dSCDs (+0.81) and not at all from the variability in the SO₂ dSCDs (−0.15). (2) The correlation between the SO₂ and BrO dSCDs was far from proportional (+0.40) indicating that these two parameters

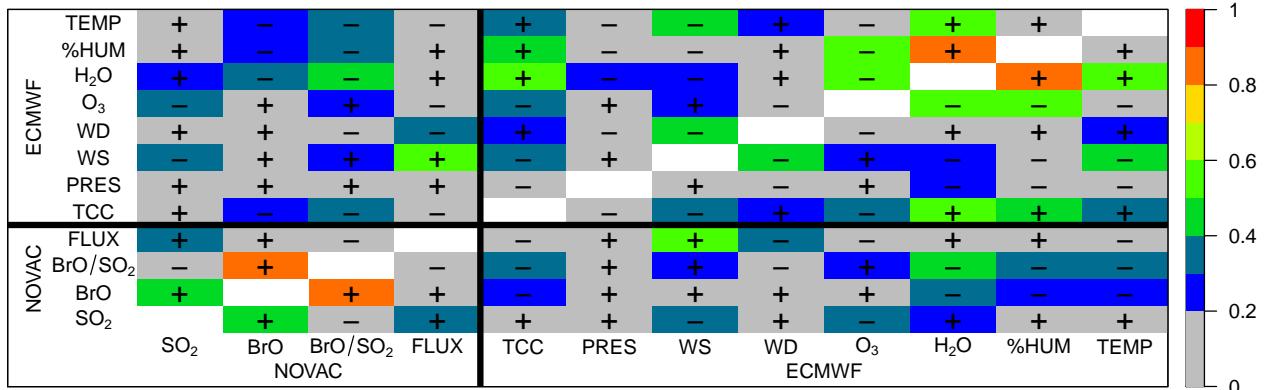

Figure 12. Correlation matrix between the different NOVAC parameters and the original ECMWF ERA-Interim parameters. The colour bar indicates the absolute value of the correlation coefficient and the plus and minus signs indicate the sign of the correlation coefficient. The abbreviated parameters are from left to right: daily means of SO_2 dSCDs, BrO dSCDs, BrO/SO_2 molar ratios, and SO_2 emission fluxes, and noon-time time series of total cloud cover, pressure, wind speed, wind direction, ozone mixing ratio, water vapour concentration, relative humidity, and ambient temperature. The auto-correlation pixels are removed for better readability.

were sufficiently independent from each other (i.e. the BrO data is an independent proxy for magmatic or atmospheric processes).

740 (3) The SO_2 emission fluxes were only relatively weakly correlated with the daily average of the SO_2 dSCDs (+0.35). This can be explained by the two processes which presumably predominantly control the variability in the SO_2 dSCDs: On the one hand, strong long-term variations in the SO_2 emission flux should manifest proportionally in the long-term means of the SO_2 dSCDs, but on the other hand, the variability of the SO_2 dSCDs in the plume centre is also significantly controlled by the horizontal plume dispersion and thus the wind speed (see also Figure 12). Given that the SO_2 emission fluxes of Masaya have 745 been basically constant for several years, the observed absence of such a correlation hints towards the latter reasoning.

A cross correlation between the NOVAC data and the ERA-Interim data indicated two strong correlations: (1) A correlation between the SO_2 emission fluxes and the wind speed (+0.57) and (2) an anti-correlation of the BrO/SO_2 molar ratios with the water vapour concentration (-0.47). As explained above, this correlation between the SO_2 emission fluxes and the wind speed was most likely predominantly an artefact because in this correlation analysis the original ERA-Interim data were used 750 for consistency within the comparison of the meteorological data. The correlation became insignificant (+0.16) when the wind speeds are calibrated and only wind speeds larger than 10 m/s are considered (see Figure 7e+f).

We highlight that the BrO/SO_2 molar ratios were at most weakly correlated with the other meteorological parameters (except the water vapour concentration). In particular, the correlation coefficient with respect to the wind speed (+0.26) and the ozone mixing ratio (+0.22) were remarkably small. The correlations between the BrO/SO_2 molar ratios and the three highlighted 755 meteorological parameters are discussed in the next three paragraphs.

BrO/SO₂ and atmospheric humidity

The oxidation of bromide ions (Br⁻) to BrO in a volcanic gas plume is an autocatalytic process, thus it is plausible that the HBr → Br⁻ ⇌ BrO formation rate in a volcanic gas plume could be positively correlated with the Br⁻ concentration in the aerosol phase. A slower BrO formation rate also implies a lower BrO equilibrium level because the equilibrium level of BrO/Br_{total} is reached once the BrO formation rate is equalled by the rate of the BrO destruction mechanisms.

A higher humidity level could cause a smaller Br⁻ concentration and thus a slower BrO formation rate, as supported by model simulations and experimental results (Rüdiger et al., 2018, and pers. comm. with Stefan Schmitt). As a remark, H⁺ concentration in the aerosol phase (i.e. its pH-value) should be affected similarly, however, it can be expected that the H⁺ concentration far exceeds the Br⁻ concentration and thus this effect on the pH-value is presumably negligible.

The observed anti-correlation between the BrO/SO₂ molar ratios and the humidity supports this hypothesis for the rather humid conditions at Masaya. Accordingly, the BrO conversion at Masaya is humidity-limited in summer and autumn when the atmospheric humidity is rather high while this mechanism is much weaker in spring when the atmospheric humidity is in its annual minimum.

BrO/SO₂ and wind conditions

The NOVAC stations at Masaya were located in close proximity to the volcanic edifice, thus they almost exclusively observed volcanic gas plumes with an atmospheric plume age between 2–8 min (see Figure 13 where the calibrated wind data were used). Furthermore, almost all outliers in the BrO/SO₂ time series were associated with plume ages larger than 10 min or with measurements when the plume had allegedly not transacted the scan planes at all.

The BrO/SO₂ molar ratio apparently reached a maximum within the first 2 min after the release from the volcanic edifice, decreased to a slightly lower value within the 3rd minute, and remained on this long-term equilibrium level for at least the first 20 min. We highlight that the very young plumes, whose observation indicated the early peak in the BrO/SO₂ molar ratio, were observed almost exclusively in spring when by coincidence also the atmospheric humidity is minimum and the wind speeds are maximum (Figure 13b). This early peak may thus not necessarily imply a “fundamental overshoot” in the BrO formation but could be explained as a manifestation of higher BrO equilibrium level at times of relatively low atmospheric humidity or enhanced ozone in-mixing.

We may highlight that the lack of significant correlation between BrO/SO₂ molar ratios and the plume age could be in principle also a chance result caused by two opposing wind speed dependent processes: On the one hand, in-mixing of ambient air (and in particular ambient ozone) would be more efficient at high wind speeds. This speeds up the chemistry, but also reduces the time that elapses before the plume is measured by the NOVAC instrument. On the other hand, in-mixing is less efficient at low wind speed, but more time elapses before the BrO/SO₂ ratio is measured.

As a remark for completeness: the BrO/SO₂ molar ratios were not correlated with the plume altitude for March–October 2014.

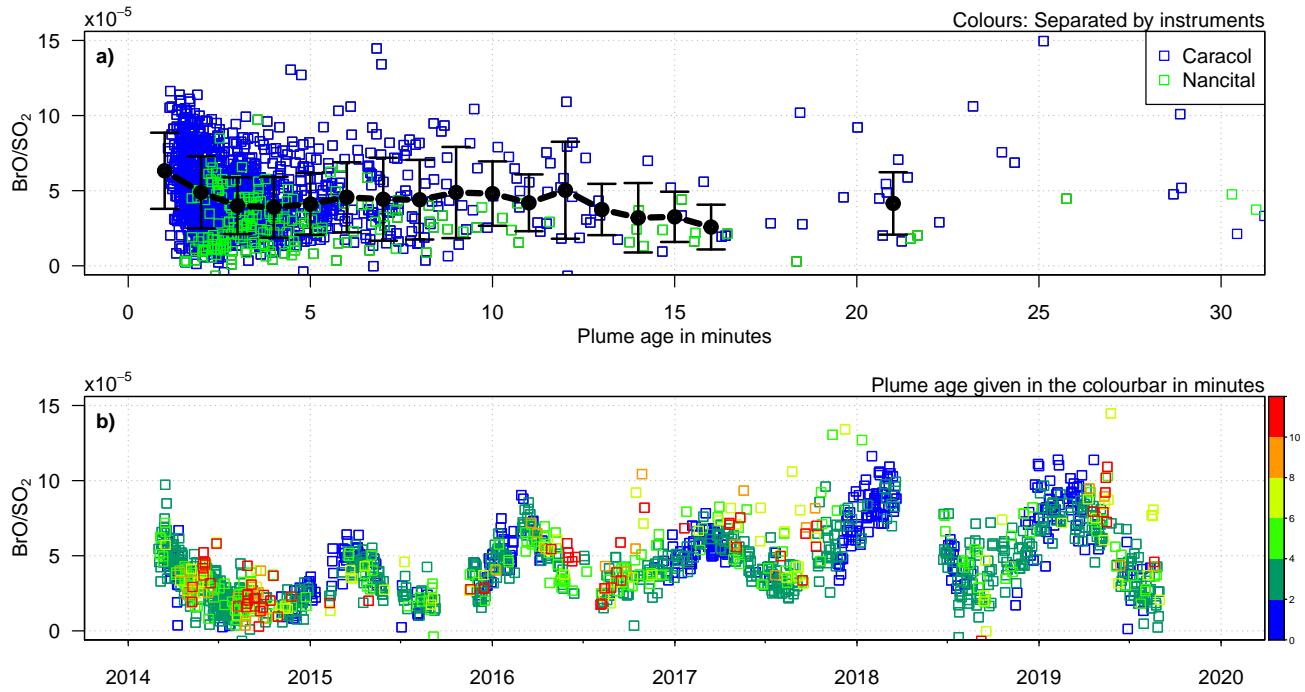

Figure 13. BrO/SO_2 molar ratios in the gas plume of Masaya depending on the plume age. The wind data imply for some data that the plumes did not transacted the scan planes; these data are excluded from the plot. **a)** The black dots refer to the averages of the respective 1min bins. **b)** The red-coloured data span plume age between 10–20 min.

BrO/SO₂ and ozone mixing ratio

The bromide to BrO conversion requires ozone, whose destruction is catalysed by BrO. If insufficient atmospheric ozone is mixed into the volcanic plume, the BrO formation stops. The amount of ozone mixed into the plume depends on the ambient ozone background concentration and on the degree of turbulent mixing. A comparison of the BrO/SO_2 data with the ERA-Interim ozone time series (Figure 2) does not allow a detailed investigation of the chemical processes in the volcanic gas plume. Nevertheless, the ERA-Interim data allows an investigation of the Br^- to BrO conversion in the context the temporal variations in the general ozone availability.

On the one hand, the observed correlation coefficients between the BrO/SO_2 molar ratios and the atmospheric ozone mixing ratio and the wind speeds were both rather small, indicating that the BrO conversion is not predominantly controlled by the background ozone mixing ratio or the air in-mixing rate. On the other hand, the maxima in the BrO/SO_2 molar ratios coincide with the observed maxima in the wind speeds as well as in the ozone mixing ratio. Accordingly and despite of the low general correlation coefficient, strong Br^- to BrO conversion rates may be possible nevertheless only for relatively large wind speeds and/or ozone background concentrations.

Aiuppa et al. (2018) suggested a model, based on their data and past studies, that the (re)appearance of the lava lake on the surface was most likely caused by the enhanced magma convection supplying CO₂-rich gas bubbles from minimum equivalent depths of 0.36–1.4 km. They proposed that this elevated gas bubble supply destabilised Masaya's shallow magma reservoir (<1 km depth). The model is not completely new, already Rymer et al. (1998) and Williams-Jones et al. (2003) proposed that Masaya's cyclic degassing crises are caused by convective replacement of dense, degassed magma by gas-rich vesicular magma in the shallow plumbing system (<1 km depth). Their ideas were based on results of periodic gravity surveys and they also argued such convective overturning is not necessarily triggered by intrusion of fresh (gas-rich) magma but may simply be initiated by degassing/crystallisation (and consequent sinking) of shallow resident magma. The data from Aiuppa et al. (2018) seem to confirm this model.

810 Our BrO/SO₂ data are characterised by a pronounced annual cycling but in addition we observed further changes in our gas data, which might be linked to the magma dynamics connected to the lava lake. As stated already in Aiuppa et al. (2018) and confirmed with the data presented here, no significant long-term changes in the SO₂ emissions fluxes were observed when the lava lake became visible at the surface. But a step increase in the BrO/SO₂ molar ratios can be noted after September 815 2015 (happening somewhat between September–November 2015, covered by a data gap). This change in the gas composition was thus caused by variations in the volcanic bromine emissions rather than in the sulphur emissions, similar to the change in CO₂/SO₂ molar ratios noted by Aiuppa et al. (2018), which respectively was caused mainly by the variation of the CO₂ emission flux. Those authors interpret these observations as evidence for supply of CO₂-rich gas bubbles, sourced by enhanced magma transport and degassing at a depth >(0.36–1.4) km. Following their interpretation and assuming that BrO is somehow 820 an indicator for bromine emissions, that would mean that either also bromine is degassing below that depth or that there is another process which leads to an enhanced transformation of HBr into BrO.

By ignoring the latter possibility, the increasing BrO/SO₂ molar ratios would thus indicate that bromine degasses together with or is enhanced/driven by CO₂ degassing. Unfortunately, there are to our knowledge no studies (apart from conceptual models) to prove or disprove the counter-intuitive early degassing of halogens, specifically bromine. However, also Bobrowski et al. (2017) described a similar behaviour between CO₂/SO₂ and BrO/SO₂ in connection with a lava lake level change.

825 Aiuppa et al. (2018) further observed an increase in the SO₂ degassing after the appearance of the lava lake at the surface, which is a further argument on their hypothesis for a faster shallow magma convection. Our data confirms an enhancement of the mean SO₂ emission fluxes by 30 % for the period from December 2015 to February 2016 when compared with the previous and subsequent degassing behaviour. The described observation of Aiuppa et al. (2018) ends with March 2017. The decrease in the lava lake activity in mid 2018 is therefore not described by those authors. We here report a significant decrease in the SO₂ 830 emission fluxes after June 2018 (happening somewhat between March–June 2018, covered by a data gap), while the BrO/SO₂ molar ratios hardly changed. This decrease of the SO₂ emission fluxes in time in connection with the decrease in the lava lake activity is consistent to the interpretation that the convection of the magma inside the conduit below the upper reservoir has slowed down again after 2018 and an important further indicator to sustain this hypothesis could be additional CO₂/SO₂ molar

ratios. Unfortunately no CO₂/SO₂ molar ratios are available to the authors by the time of writing of the manuscript.

835 An unchanged BrO/SO₂ ratio and a lower SO₂ emission flux would lead to lower bromine emission as well, if we assume a correlation of bromine emissions and amount of BrO. We might further speculate that the bromine emission and carbon emission are characterised again by a similar pattern, which would mean that we also see a decrease in the CO₂ emission flux.

7 Conclusions

840 This study contributes to three independent fields of research: (1) a comprehensive discussion of a reliable retrieval of SO₂ emission fluxes from ground-based remote sensing data, (2) a dataset for the bromine chemistry in volcanic gas plumes with extraordinary temporal coverage and resolution, and (3) an investigation of the BrO/SO₂ molar ratio as a proxy for magmatic processes.

SO₂ emission flux retrieval

845 An important conclusion of our study is the reminder that calculating reliable SO₂ emission fluxes requires a careful investigation of the local conditions. This holds true not only for their accuracy but also for the patterns in the data.

We reported suggestions for the retrieval of SO₂ emission fluxes from ground-based remote sensing data and retrieved SO₂ emission fluxes which are in average a factor of 1.4 larger than those retrieved by Aiuppa et al. (2018) from the same spectroscopic data. This factor is an accumulation of three major differences between the two retrieval approaches: the SO₂ fit range, the wind speed estimate, and the plume height estimate. (1) The different choices of the SO₂ fit ranges (our range starts at 850 314 nm, theirs starts at 310 nm) causes a relative factor of 1.25, indicating their systematic underestimation of the rather strong SO₂ SCDs in Masaya's gas plume. (2) Both studies estimated the wind speeds based on ERA-Interim data but we calibrated those wind speeds to the local conditions by using the higher resolved operational ECMWF reanalysis data. In consequence, our estimates for the wind speeds are in average a factor of 0.8 smaller than theirs. (3) Aiuppa et al. (2018) assumed a plume height fixed at Masaya's summit altitude while we used a dynamic estimate of the plume height based on our triangulation 855 results and the observed weak dependency on the wind speed. In consequence, our estimates for the plume height were in average a factor of 1.5 larger than theirs.

When it comes to spurious patterns, we observed a strong correlation between the SO₂ emission fluxes and the wind speeds when several of our retrieval extensions are not applied (correlation coefficient of +0.84 when all wind speeds are considered and of +0.56 for wind speeds larger than 10 m/s). We discussed that no such correlation is expected and that it is most likely 860 an artefact, e.g., due to the assumed fixed plume height. In consequence, the SO₂ emission fluxes would then falsely inherit patterns from the variability of the wind speeds and thus conclusions drawn from the variability of the SO₂ emissions fluxes would be only of limited reliability. The correlation was significantly reduced (+0.71) after retrieval extensions were applied and in particular basically vanished for wind speeds larger than 10 m/s (+0.16). Another conclusion is thus that low wind speeds can result in rather unreliable results (at least at Masaya).

865 We encourage for future publications on SO₂ emission fluxes to state detailed information on the used SO₂ emission retrieval

algorithm. The investigation strategy presented in this study may provide a framework for that task. We nevertheless highlight the large set of further possible advances which can be still applied and highlight that the choice and setting of the filters may vary significantly for different volcanoes.

Atmospheric bromine chemistry

870 We observed an annual cyclicity in the BrO/SO₂ time series. This annual cyclicity was most likely a manifestation of the meteorological seasonality. In particular, an anti-correlation (coefficient of -0.47) was observed between the BrO/SO₂ molar ratios and the atmospheric water vapour concentration. In contrast to that, no clear correlation was observed between the BrO/SO₂ molar ratios and the atmospheric ozone mixing ratio (coefficient of +0.21) or the wind speed (coefficient of +0.25). A comparison of the BrO/SO₂ molar ratio and the atmospheric age of the volcanic plume suggested that the BrO/SO₂ reached 875 in the long-term average maximum values within the first 2 min after the release from the volcanic edifice, dropped to a slightly lower level within the 3rd minute, and remained at this level for at least the next 20 min. The enhancement prior to the 3rd minute may be real but could also be explained by an observational bias. We conclude that the BrO formation rate at Masaya may be partly controlled by the rather high ambient humidity with higher humidity leading to dilution of the bromide concentration in the aerosol phase, and thus a lower BrO conversion rate.

880 Volcanological findings

We observed a complementary sensitivity of the SO₂ emission fluxes and the BrO/SO₂ molar ratios on magmatic processes. The long-term trend of the SO₂ emission fluxes was hardly affected by the initial lava lake appearance but dropped in mid 2018, when the lava lake activity ceased, to significantly lower SO₂ emissions fluxes. In contrast to that, the BrO/SO₂ molar ratios doubled due to the lava lake appearance but showed only a weak response to the reduced lava lake activity since mid 2018. 885 Accordingly, the combination of SO₂ emission fluxes and BrO/SO₂ molar ratios — the latter one showing a similar behaviour like the CO₂/SO₂ molar ratios for the period both data sets are available — might give new possibilities for monitoring. When corrected for the annual cyclicity, we observed an approximately linearly increasing trend in the BrO/SO₂ molar ratios during the period for high lava lake activity (November 2015 until March 2018) and an approximately linearly decreasing trend in the BrO/SO₂ molar ratios since May 2018. The isolated interpretation of these observations did not provide clear information 890 on, e.g., the degassing order of sulphur and bromine of the juvenile magma at Masaya. However, the provided data may help to double-check and enhance models on the magmatic processes at Masaya.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We express our thanks to Santiago Arellano for critically reading our manuscript and for helpful discussions. FD wants to thank Stefan Schmitt (IUP Heidelberg) for fruitful discussions on the bromine chemistry in volcanic gas plumes. We would like to thank

895 Tom Pering and Christopher Kern for their comments on the paper. We thank the Deutsche Forschungsgemeinschaft for supporting this work
within the project DFG PL193/14-1.

Appendix A: Ground-based data from Managua airport

The ground-based data from Managua airport are recorded at an altitude of 59 m a.s.l. and thus their quantitative values are expected to differ from the meteorological data modelled for 700 m a.s.l. Nevertheless, the ground base data agree with the 900 ERA-Interim data in the general patterns and relative variations, with variations in the ambient temperature between 302–307 K, variations in the relative humidity between 40–70%, variations in the wind speeds between $2\text{--}8 \frac{\text{m}}{\text{s}}$, and a mean wind direction of $(86 \pm 31)^\circ$ (Figure A1). The wind directions differ significantly with $(102 \pm 29)^\circ$ when considering all times of the day.

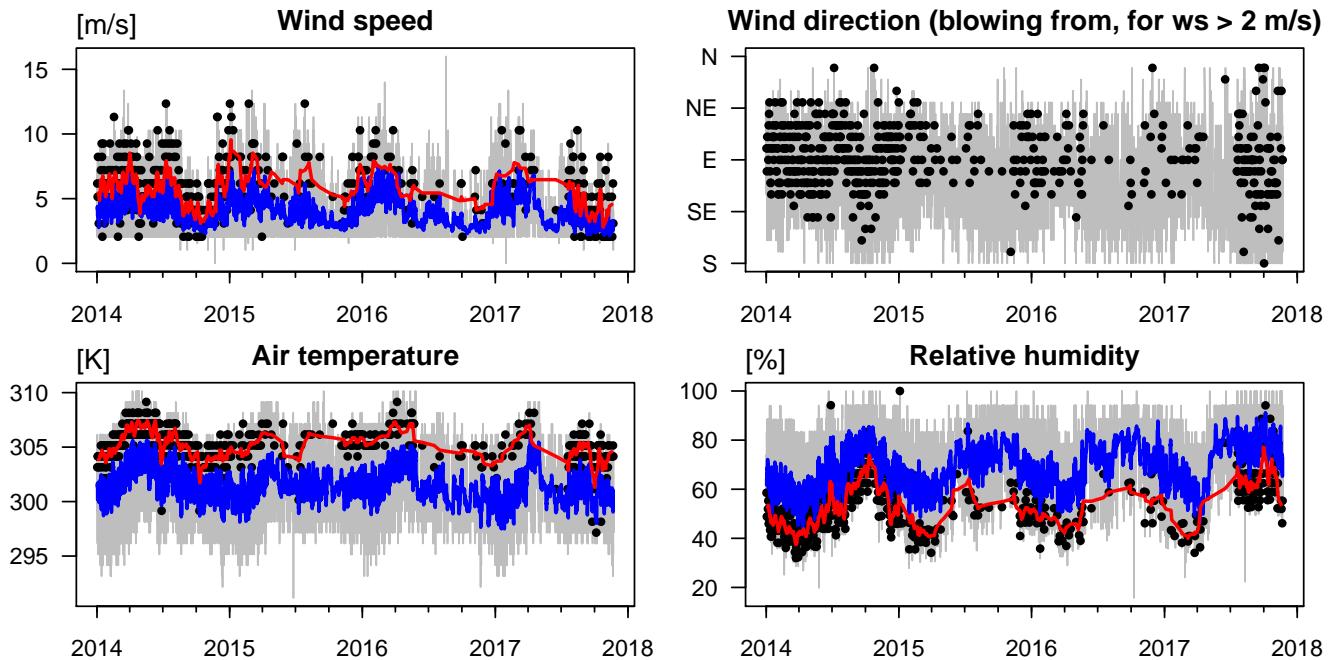

Figure A1. Meteorological conditions measured by a ground-based station at Managua airport (15 km north of Masaya volcano). The data were provided by Iowa State University (<https://mesonet.agron.iastate.edu>). **Grey lines:** hourly data. **Blue lines:** sliding average over the horly data (± 2 weeks window). **Black dots:** noon-time (18:00 UTC) data. **Red lines:** same sliding average but over the around noon data.

Appendix B: Choice of the wavelength range in the SO_2 DOAS fit

The choice of the wavelength range (and in particular its lower limit) used in the SO_2 DOAS fit can cause major deviations in 905 the spectroscopic results. The standard NOVAC evaluation routine uses 310 nm for the lower limit because this value is optimal for detecting low SO_2 dSCDs of several $10^{17} \frac{\text{molec}}{\text{cm}^2}$ (which is the case for volcanoes with a low to moderate degassing strength or considerable distances of the DOAS instrument to the emission source). As a drawback, such a short wavelength for the lower limit makes the SO_2 DOAS fit susceptible to saturation effects and spectrometer stray light, resulting in underestimations of SO_2 dSCDs larger than $1 \cdot 10^{18} \frac{\text{molec}}{\text{cm}^2}$ (see Figure B1a and e.g. Bobrowski et al., 2010; Fickel and Delgado Granados, 2017).

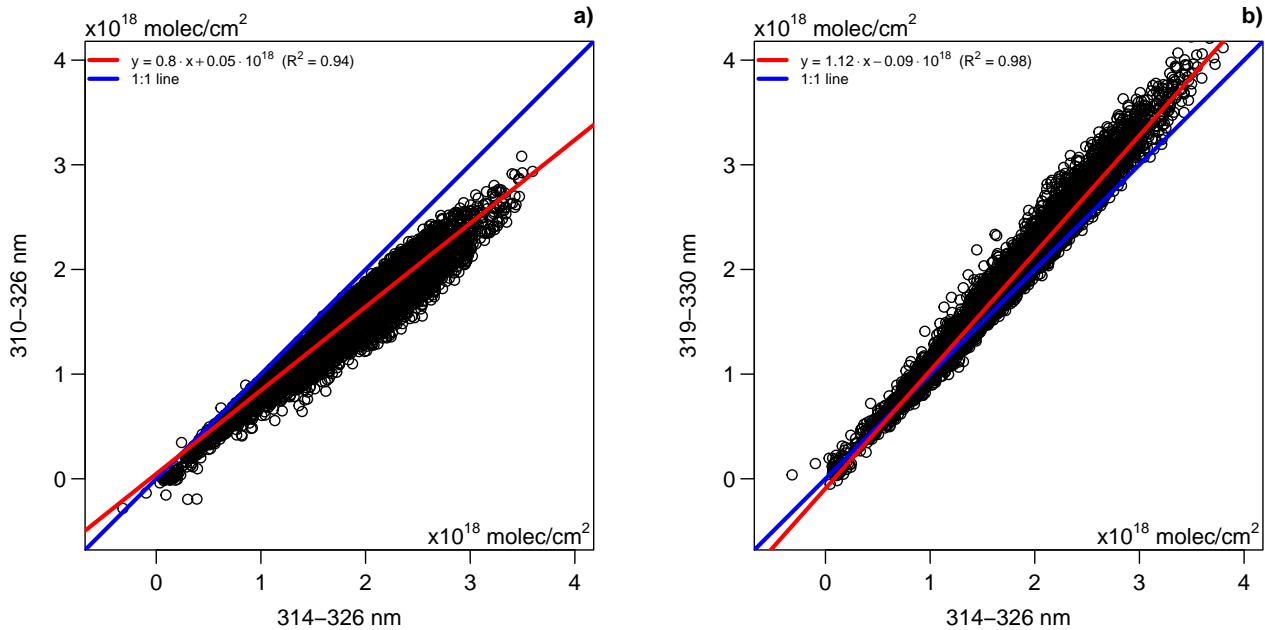

Figure B1. SO₂ dSCDs retrieved in the chosen wavelength range compared with those retrieved in other wavelength ranges, as retrieved for Caracol station from 2014–2020. For statistical interpretation of the 314–326 nm data: 9% of the SO₂ dSCDs were lower than $1 \cdot 10^{18}$ molec/cm², 63% were between $1\text{--}2 \cdot 10^{18}$ molec/cm², 26% were between $2\text{--}3 \cdot 10^{18}$ molec/cm², 2% were larger than $3 \cdot 10^{18}$ molec/cm².

910 In contrast to that, our choice of 314.9–326.8 nm can be considered to be hardly affected by saturation effects up to SO₂ SCDs of $1 \cdot 10^{18}$ molec/cm² (3% underestimation, see Figure B1b) and still of acceptable accuracy at SO₂ SCDs of $3 \cdot 10^{18}$ molec/cm² (9% underestimation). We observed at Masaya, nevertheless, a significant amount of data with SO₂ SCDs above $3 \cdot 10^{18}$ molec/cm² which were underestimated also by our retrieval (Figure B1b and 8). A separated retrieval of those data with an alternative fit range starting, e.g., at 319 nm would in general result in more accurate estimates for these particularly large SO₂ SCDs. Fickel and 915 Delgado Granados (2017) proposed such an approach for Popocatépetl volcano using even three wavelength ranges at 310–322 nm, 314.7–326.7 nm, and 322–334 nm. The risk of such a compound retrieval would be, however, artificial jumps along the chosen thresholds. We therefore hesitated to use such an approach but encourage further investigations, e.g., whether an interpolation between the results retrieved by several fit ranges could avoid this risk while enhancing the accuracy of large SO₂ SCDs (see e.g. Theys et al., 2017; Elias et al., 2018, for the implementation of such an approach in satellite and ground-based 920 observations, respectively).

Appendix C: Absolute calibration of background SCD

We checked for an SO₂ contamination of the background by applying the absolute calibration algorithm described by Lübcke et al. (2016). This algorithm performs SO₂ DOAS fits where the recorded added-reference-spectrum is used as the measure-

ment spectrum and the solar atlas provided by Chance and Kurucz (2010)—convoluted with the instrument line function—is used as the reference spectrum. Such a fit results in large residual spectroscopic structures because the solar atlas does not contain information on the instrument characteristics. These characteristics can, nevertheless, be determined from the fit residual structures via a principal component analysis applied on a time series of the residual structures. Hereby, it is important that the principal components do not contain structures caused by an interference with the major absorbers in the investigated wavelength range. Accordingly, we used only those residual structures for the principal component analysis (1) where the retrieved SO_2 SCD was smaller than two times the (individual) SO_2 fit error, (2) where the solar elevation angle was $> 30^\circ$ to avoid large tropospheric ozone columns, and (3) where the SO_2 fit had a fit quality of $\chi^2 < 0.1$ to avoid potentially problematic spectra. We retrieved a unique fixed first principal component for the total 6 years time series and added it as a pseudo-absorbers to the DOAS fit. This second iteration of the DOAS retrieval gave the absolute SO_2 SCD of the added-reference-spectrum (see histograms of these results in Figure 7c). We highlight that the second principal component for the total 6 years time series explain only 1% of the residual structures and thus adding also this component to the fit scenario would not have improved the spectroscopic retrieval.

Appendix D: Additional supportive figures

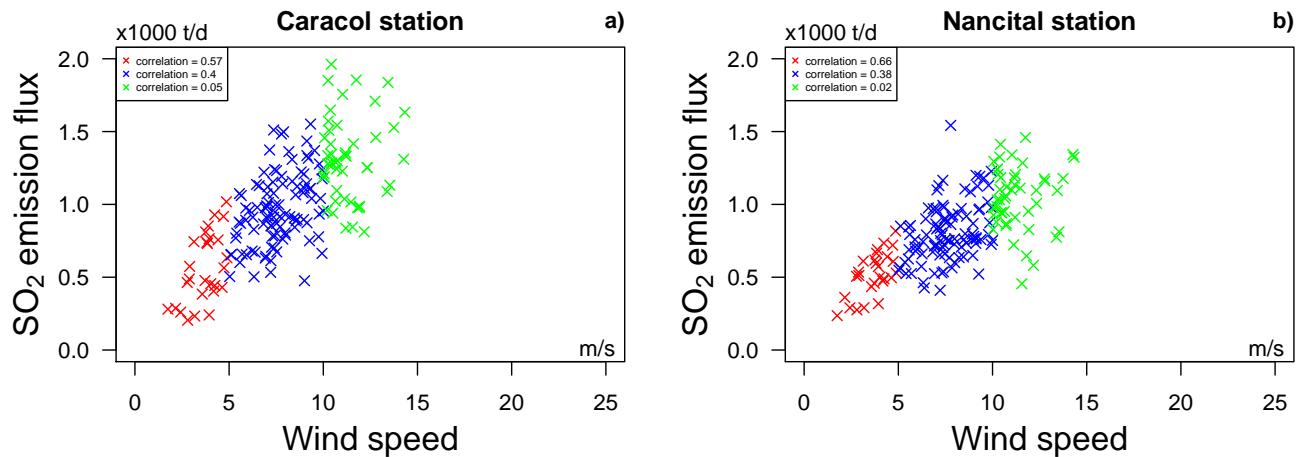

Figure D1. Correlation between the retrieved SO_2 emission fluxes and the wind speed for March 2014 to October 2014 and when the triangulation results are directly used. The plots compare daily SO_2 means and the means of the calibrated wind speed at the respective measurement times. The fluxes were calculated based on the triangulated plume height and plume propagation direction and based on the calibrated wind speeds.

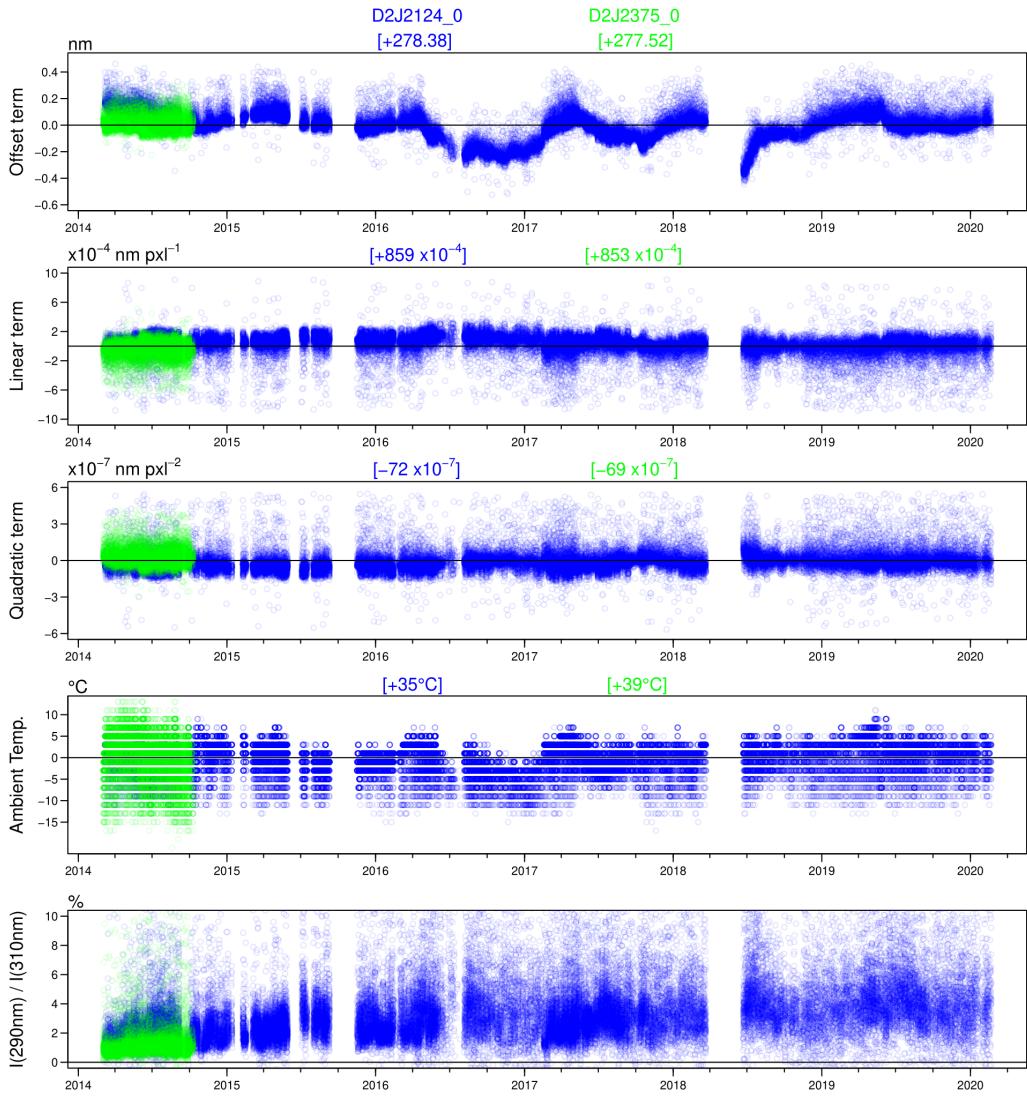

Figure D2. Variation of the instruments' wavelength-to-pixel calibration and stray light, and the ambient temperature. For each parameter, the total values are given by the rough estimate for the mean value (given for each instrument in blue and green above the particular panel) and the variation shown in the plots. The zero lines are chosen arbitrarily and should not be confused with mean values. **a-c)** All spectra were calibrated by matching their Fraunhofer lines with the Fraunhofer lines of a solar-atlas and the wavelength calibration were given by a calibration polynomial of 2nd order (see e.g. Dinger, 2019, for details). The three panels give for each scan the three coefficients of the wavelength calibration polynomial. The variability is already as displayed rather low and but is actually much lower (most of the indicated scatter is predominantly caused by the first scans in the morning when the temperature is significantly lower than for the rest of the day). **d)** Variation of the ambient temperature. **e)** Ratio of the intensity at around 290 nm and 310 nm (each time average over 10 channels) as a proxy for the magnitude and variation of the stray light.

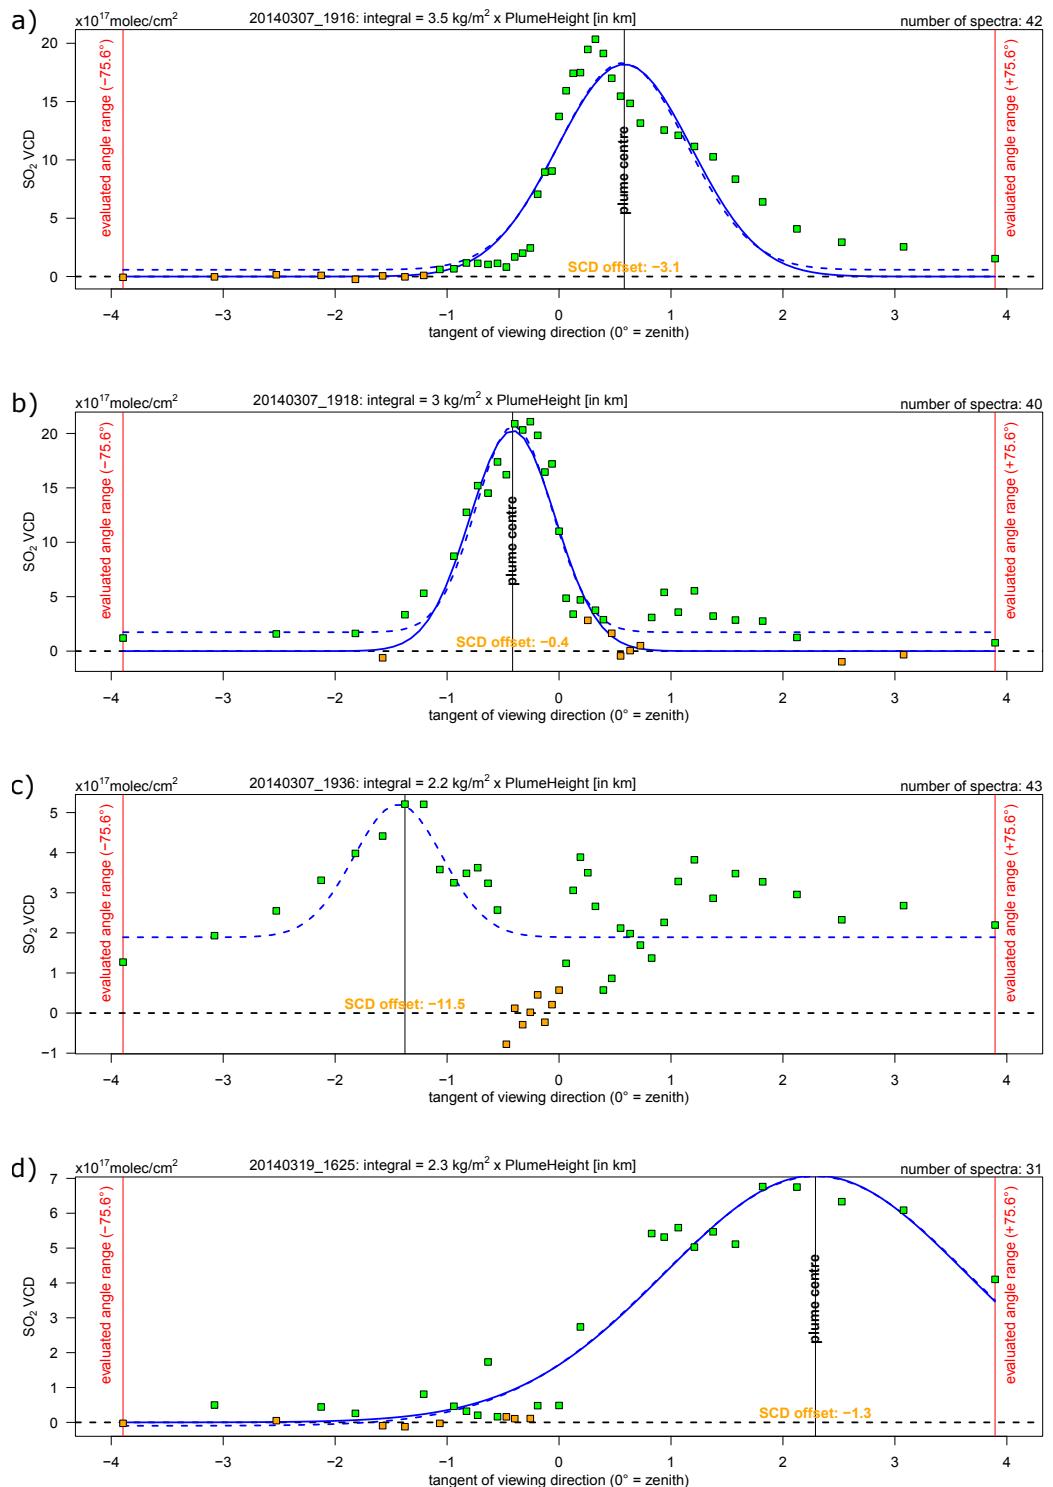

Figure D3. SO₂ distribution retrieved **a)** from the scan starting at 2014-03-07 19:16 UTC recorded at Nancital station and **b-d)** from the scan starting at 2014-03-07 19:18, 2014-03-07 19:36, and 2014-03-19 16:25 UTC recorded at Caracol station.
