Revised: January 12, 2021

Abstract. Pre-activation of freezing nucleation (PFN) with mercuric iodide was first reported by Edwards, Evans and Zipper (1970). They found that freezing, followed by melting just a few degrees Celsius above the melting point, leads to subsequent freezing of the sample more than 10°C above the temperature of the initial nucleation temperature. Results presented in this paper are from laboratory experiments that followed the procedure designed by Edwards, Evans and Zipper (1970) but employed multiple sample drops and many repetitions of the pre-activation cycle. The results obtained confirm the basic findings of the earlier work and refine it. It is shown that the pre-activation effect is lost gradually as the sample is heated above the melting point and that some effect is still seen with heating above +5°C. Instrumental limitation in these experiments precluded detection of pre-activated freezing above -2°C but that possibility is not excluded. Some PFN was noted to at least -6°C. By also drawing on the results of Seeley and Seidler (2001), PFN is analyzed in search of constraints that help define the process responsible for it. No firm conclusions are reached, but the accumulated evidence points quite clearly to the role of definite structures, surface sites, in leading to PFN. Thus, sites are seen to play the same role as they do in heterogeneous freezing nucleation in general. PFN differs from pore condensation and freezing described by Marcolli (2020) and David et al. (2020) in that PFN is observed in liquid water while that process takes place in the vapor phase. Further explorations of the process leading to PFN can help understanding ice nucleation at the basic level and in its practical manifestations. The results call attention to an ice nucleation pathway hitherto barely explored and which can be expected to have consequences in how ice nucleation occurs in atmospheric clouds and in other systems. PFN is also a potential tool for deliberate initiation of freezing in clouds and other systems.

1 Introduction

The phenomenon that is to be examined here consists of observations of freezing nucleation by suspended particles just a few degrees below the melting point that follows prior freezing of the sample and heating to just a few degrees above the melting point. This specific cycle was first reported by Edwards, Evans and Zipper (1970; EEZ70 in the following) The phenomenon is referred to in the following as "pre-activated freezing nucleation", PFN¹.

¹A clearer definition of PFN will be given in the following section and its meaning refined in Section 5.2.

Other manifestations of nucleation depending on the prior history of the sample are known, variously named in the literature as enhancement or as memory effect. PFN is perhaps the most neutral expression to use, in that it does not imply a specific process. "Enhancement" seems to imply that a given INP or nucleating site is responsible for nucleation both in the normal mode and in previously exposed cases. In contrast, "memory effect" puts emphasis on the fact that prior freezing is a precondition for the observed high freezing temperatures. To retain some flexibility of description, and as a reminder that different interpretations of the results are possible, while PFN will be used most frequently in this paper, other terms will also be occasionally employed .

Because ice nucleation is so inaccessible to direct observation, concepts of the process rely on empirical evidence bounding the conditions for it. PFN is of interest from the point of view of broadening or restricting those concepts. PFN provides additional evidence to be incorporated into the known set of constraints about how to view the process of freezing nucleation. Much recent work focused on pore condensation and freezing (PCF) which takes place in the vapor phase. Both processes are relevant to atmospheric conditions, with the difference that pore condensation is expected to play a role in the upper troposphere while PFN is more likely to have a role in low and mid-tropospheric clouds.

2 Previous results

EEZ70 reported experiments with mercuric iodide, HgI_2 , and other substances. HgI_2 is a moderately effective ice nucleating substance. Observed activity is comparable to what was seen with some minerals in similar experiments: nucleation temperatures of -8°C and lower. However, HgI_2 is one of a very few substances for which pre-activation is known to be possible.

In the EEZ70 experiments, a single drop of water containing some HgI_2 was suspended in a pressure cell and surrounded by an inert fluid. The cell was then subjected to a prescribed sequence of temperatures. The principal finding of EEZ70 is that ice nucleation at some T_f followed by continued cooling to $T < T_C$, and further followed by warming to a temperature T_w such that $0^\circ\text{C} < T_w < T_D$ leads to nucleation on subsequent cooling at T_f^* barely below the melting point of ice². If warmed to above T_D , subsequent nucleation takes place at $T_f \ll T_f^*$. In addition to HgI_2 , EEZ70 report on similar experiments with other substances, at different pressures and with salt solutions. The results are interpreted, following the results of Evans (1967), in terms of the formation of a two-dimensional ice-like monolayer on the substrate which facilitates nucleation of bulk ice unless destroyed by heating above T_D . Prior cooling below T_C is necessary for the monolayer to change from disordered to ordered form. Fig. 1 is a schematic representation of this process. Two cooling and freezing cycles are shown. The first one with $T_w < T_D$ leads to PFN at T_f^* , while the second one with $T_w > T_D$ does not.

The basic features of the pre-activation described above were shown by Seeley and Seidler (2001a; abbreviated as SS01) to be also exhibited with aliphatic alcohols as ice nucleators. Their experiments were performed at 1 bar using a single drop coated with the nucleating Langmuir film of the aliphatic alcohol and placed on a cooling stage. Many hundreds of cycles of cooling and heating were performed varying the warm limit T_w in stepwise fashion. Three different alcohols were used giving different T_D values but all leading to similar values of T_f^* between -6 and -10°C . In SS01, there is some gradual lowering

²A list of symbols is given in Table 5

Figure 1. Schematic representation of the findings of EEZ70 and defining the notation used in this paper. The blue lines represent ice and the blue squares points of nucleation.

of the freezing temperature as T_w is raised and there is an abrupt shift to lower values at T_D . There is no further lowering of the freezing temperatures beyond that. No results are given regarding T_C ; apparently cooling below a given limit was not a necessary condition for pre-activation in their experiments. An important aspect of the results in SS01 is that for any given T_w , the freezing temperatures vary over a range of approximately 4°C in random fashion over the many cycles of the experiments.

60 They showed the same variations of nucleation temperatures for the aliphatic alcohols without pre-activation. In all cases, the frequency of freezing as a function of temperature, $R(T)$ in their notation, is interpreted in SS01 in terms of CNT.

SS01 considered their results to be in accord with the monolayer explanation of EEZ70. A strong dependence of $R(T)$ on the exponential factor of the CNT equation is claimed to be consistent with a monolayer being responsible for the pre-activation and not any "dimensional" change such as a rare defect in the Langmuir layer. This, in effect, reduces emphasis on
 65 the nucleating substrate, or nucleating sites on it, and focuses attention on changes in the water structure near the substrate. SS01 point to the findings of Majewski et al. (1994) for evidence on the ordering of a monolayer on the aliphatic alcohols and suggest experiments to examine how the changes in the monolayer relate to the dependence of pre-activation on T_D .

The findings of EEZ70 and of SS01 are about pre-activation of freezing nucleation. Pre-activation was shown to also exist for deposition nucleation by Fournier d'Albe (1949), Mason and Maybank (1958), Higuchi and Fukuta (1966) and Roberts and
 70 Hallett (1968). In addition to the potential for an ice layer to be retained on the surface, the possibility that liquid water or ice in cavities, pores or crevices of a substrate can exist outside the normal boundaries of phase changes for the bulk phases has also been proposed for explaining pre-activation. More recently, pore condensation and freezing received strong empirical evidence and theoretical support (Marcolli, 2014, 2020; Wagner et al. 2016; David et al., 2019, 2020); this process, if coupled with

nucleation sites within the pore, lead to ice formation at low supersaturations. The process has not been linked to pre-activation
75 in the liquid.

The current work confirms the main findings of EEZ70, and has some parallels with the results of SS01. A detailed compar-
ison with these works will be given in Section 5 after the presentation of the experimental method for this work in Section 3
and the data obtained in Section 4. The experiments were performed in the early 1970s with much simpler equipment than
now available at many research institutions. Yet, the paucity of information on PFN gives relevance to the data then obtained.
80 A preliminary summary of this work was given in Vali (1992).

3 Experimental technique

3.1 Sample preparation

All experiments here described were performed with the same batch of the mercuric iodide, HgI_2 , supplied by Mollinckrodt
Chemicals (St. Louis, MI, USA; Lot WYLS, 99% purity). It is described as a soft material. Mercuric iodide is only slightly
85 soluble in water (6×10^{-5} g/mL); the solute effect on the depression of the melting point is ignored in this work. Weighed
amounts of the red HgI_2 powder, as received, were added to 100 mL of distilled water to reach concentrations of 0.02 and 0.04
g mL^{-1} . Supernatant was drawn into a sterile syringe for dispensing drops of 0.01 cm^{-3} volume onto the cold stage. In most
experiments, 121 drops were tested simultaneously.

Mercuric iodide is listed as being light-sensitive. The suspended particles were illuminated during the freezing tests. This
90 may account for some of the variations that were observed over the durations of the experiments. No attempt was made to
quantitate this.

The goal of these experiments was to examine the memory effect, with no emphasis on characterizing the activity of HgI_2
per se. This meant that no special effort was made to achieve close control of the sample preparation. No rigid protocol was
set, partly because control of many aspects of the sample preparation was unachievable with the available means. As a result,
95 no data are available on particle size distributions in the drops. Variations in sample preparation and handling, and the spread
of the experiments over a period of a year, led to variations in the activity observed in the samples. Perhaps most importantly,
the time that lapsed between mixing the powder into water and the freezing tests was not held to a constant. However, the data
of interest here derived from repeated cycles of freezing with given sets of drops and those observations are independent of the
sample-to-sample variations. Additionally, even a given set of drops cannot be taken to be perfectly identical, due to possible
100 settling of particles and the need to refill the syringe various times for the production of a set of drops for a run. These factors
add to the random distribution of INPs in the powder to give the appearance of overall randomness in the observed freezing
events. Separation of the various factors of importance is attempted in this paper but is only possible to a limited extent.

In spite of the practical difficulties referred to above, the number of particles of HgI_2 was undoubtedly high enough to make
variations relatively unimportant. Assuming a mean particle diameter of $0.1 \mu\text{m}$, the number of particles per drop was on the
105 order of 10^{11} , an ample number to consider each drop to have the same chance to contain an INP. The experiments detected
the INP with the highest freezing temperature in a drop, making that event unique.

3.2 Freezing experiments

The experiments were carried out in the same manner as those described by Vali (2008). They were performed intermittently over a period of about a year (1972-73) when the drop-freezing apparatus was available. Briefly, the apparatus consisted of a cold stage of a 1 cm thick copper block of 10×10 cm dimensions. The block was covered with aluminum foil using a heat-conducting cream under it to reduce temperature variations. A thin silicone varnish was applied on the foil to provide a hydrophobic surface. Cooling of the cold stage was via Peltier elements and a circulating liquid heat exchanger, controlled to be at $-1^{\circ}\text{C min}^{-1}$. Temperature measurement was obtained with a calibrated thermocouple. A digital temperature display and the drop array were photographed at intervals of 15 s. Illumination was optimized to have the cold stage nearly completely dark, thus enabling freezing to be detected by reflection by the ice within the drops. After all drops were frozen the stage was heated at roughly $1^{\circ}\text{C min}^{-1}$ to a maximum preset value of T_w . Temperature overshoot at T_w was held to $<0.2^{\circ}\text{C}$.

The photographic records were evaluated by experienced technicians. The images were projected on a table one frame at a time, stepping from frame to frame on a manual command (push button) by the technician after a thorough visual scan of the image. It was possible to move backward and forward to compare adjacent images. When a change in opacity was discerned for a drop, the temperature reading from that frame was written over the image of the drop. These records were subsequently entered into spreadsheets for computer analysis. Detection of freezing from the change in drop opacity was rather critical in these experiments because many of the freezing events were at just a few degrees below the 0°C . The processing of the photographic film (16 mm) was tailored to achieve good but not excessive contrast and to be reproducible. To control for the unavoidable uncertainty in the detection of freezing events due to human subjectivity, some of the readings of the film records were repeated by two individuals. Differences were $<0.5^{\circ}\text{C}$ for the majority of cases at few degrees below 0°C and less than that at lower temperatures. In all, freezing events were reliably detected at $T_f < -2^{\circ}\text{C}$ and colder and for this work that is viewed as the detection limit.

Measurement errors of the stage temperature, as well as non-uniformities across the stage were smaller than the uncertainty resulting from determination of the moment of freezing. Therefore, the overall accuracy of data here reported is taken as 0.5°C , but occasional larger errors can't be ruled out.

3.3 Types of experiments

In order to explore different aspects of the memory effect, experiments of various types were performed, falling into two major groups. One group was aimed at determining the limits of heating above 0°C that still produces some enhanced nucleation. In this group are the following experiments: (i) Gradual increase of the warm limit T_w from one run to the next (Exp. A, B) (ii) Gradual decrease of the warm limit (Exp. C), (iii) Alternating high and low warm limits (Exp. G, H). The other group of experiments was performed to examine the reproducibility of the memory effect and the influence of time: (iv) Varying lengths of time at the warm limit (Exp. D), and (v) Repeats of the same warm limit (Exp. I).

In all experiments, the initial run was performed right after placing the drops on the cold stage. These runs started at room temperature which was not controlled but was $20\pm 2^{\circ}\text{C}$. Cooling was continued until all drops were frozen.

140 With warming of the drops to only a few degrees above 0°C, and only over a short time, a valid concern arises about the possibility of some ice being retained in the drops. All evidence points to this not having been the case. In general terms, some supercooling was required for all drops to freeze as indicated by sudden changes in opacity at the moment of nucleation. Gradual freezing that started at 0°C would have led to gradual darkening of the drop images. Results to be presented in a later section with varying length of time above 0°C provides further proof for the absence of bulk ice when repeat freezing cycles are started.

The number of sample drops varied from experiment to experiment because in most cases two or more different dilutions of the suspension were tested simultaneously. Results are reported only for the dilutions exhibiting clear PFN. One or two rows of drops of distilled water were also included for control.

4 Results

150 4.1 Nucleus spectra

The HgI₂ suspensions used in these experiments (after initial tests to arrive at a particle concentration in the working range of the experiments) exhibited moderate activity. The differential concentration of INPs is shown in Fig. 2 for the various experiments to be described in this paper. Data here displayed are from the initial run of each experimental series when the drop array was first cooled from room temperatures. The differential INP concentration plotted in Fig. 2 is defined in Vali (1971, 2014) and is computed as

$$k(T) = \frac{1}{V \cdot n_{uf}(T)} \cdot \frac{\Delta n_{uf}}{\Delta T} \quad (1)$$

where $V = 0.01 \text{ cm}^{-3}$ is the volume of the drops, T is the temperature in °C, $n_{uf}(T)$ is the number of drops remaining unfrozen at T , and Δn_{uf} is the number freezing upon cooling from T to $(T + \Delta T)$.

160 There is considerable variation among the experiments due to variations in the degree of dispersion of the HgI₂ powder and the degree of settling that took place before the supernatant was withdrawn for producing the sample drops. This variation was not of particular concern for this work and no special effort was made to reduce the variability. The main concern was to have, in each experiment, freezing temperatures spread over the range -5°C to -20°C.

4.2 Determining the "warm limit" above 0°C for PFN to occur

165 Three series of experiments were performed to define the upper limit of temperature which allows PFN to occur. In two experiments the warm limit T_w was increased gradually from one run to the next with the same set of drops. In one series the warm limit was gradually decreased. In all experiments the stage was held at T_w for 5 minutes between runs.

In experiment A, after the initial run, ten more runs were performed with values of $T_w = 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 6.0$ and 10°C. In Exp. B a shorter series was performed with $T_w = 10.0, 1.5, 2.0, 3.0, 4.0,$ and 5.0°C. A series of runs with

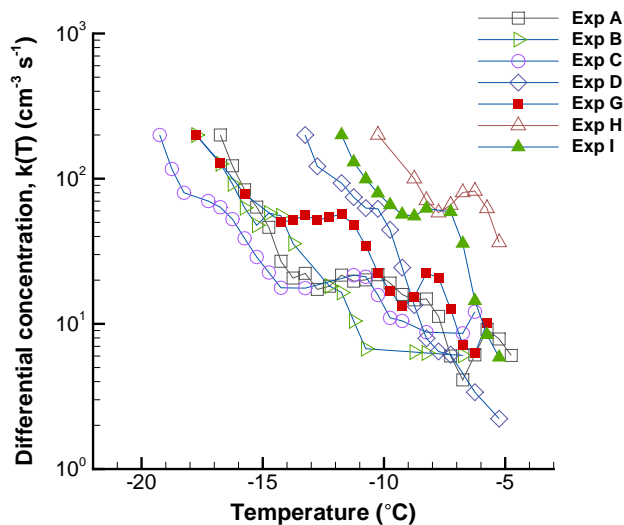

Figure 2. Differential nucleus spectra, $K(T)$ for the HgI_2 suspensions used in the various experiments.

gradually decreasing warm limits was executed in Experiment C, with $T_w = 10.0, 8.0, 8.0, 5.0, 4.0$ and 3.0°C . The number of
 170 drops tested simultaneously was 77 for Exp. A and 33 for Exp. B and Exp. C.

A summary of the results for these series of runs is given in Table 1 and in Figures 3, 4 and 5. All three series indicate a pronounced change between $T_w = 3^\circ\text{C}$ and $T_w = 4^\circ\text{C}$ independently of the direction of the change from increasing or decreasing warm limits. This is the main finding, bracketing the value of T_D . The detection limit for freezing of the sample drops is another factor limiting a fully clear delineation of the magnitude of the PFN effect observed. When taking into account
 175 the range of freezing temperatures indicated by the vertical bars in the figures it may be noted that there is some overlap between the events on either side of the major jump.

Another way to illustrate the impact of raising the warm limit past T_D is to look at the fraction of drops showing significantly elevated freezing temperatures, given as the fraction of drops freezing above some 'cutoff' value. The cutoff values used to generate the table varied somewhat in order to have adequate sample sizes. The results are shown in Table 2. A large jump near
 180 $T_w = +3.5^\circ\text{C}$ in the percentage of drops freezing above the cutoff is evident in all three experiments. However, it is important to note that some PFN can be seen even at $T_w = +5^\circ\text{C}$ and $T_w = +6^\circ\text{C}$. That these are not artifacts is reinforced by the 0 values for the initial run and for runs with $T_w = +10^\circ\text{C}$.

The description given above in terms of ensemble parameters can be put into better perspective by elaborating on the variations encountered when examining individual sample drops. To this end, the temperature histories of individual drops
 185 are displayed for Exp. A in Fig.6. Apart from the steady T_f values in runs 2-4 where the detection limit restricts variations, a number of different patterns can be distinguished. For example, drops 2, 35, 56 and many others retained $T_f \approx -4^\circ\text{C}$ even

Table 1. Average freezing temperatures, \overline{T}_f ($^{\circ}\text{C}$), observed in the three series of experiments with gradually increasing and gradually decreasing warm limits, T_w ($^{\circ}\text{C}$).

	Run	0	1	2	3	4	5	6	7	8	9	10
Exp. A	T_w		1.5	2.0	2.5	3.0	3.5	4.0	4.5	5.0	6.0	10.0

to run 8 that followed $T_w = -5^{\circ}\text{C}$. On the other hand, drops 1, 21, 39, 80 and others exhibit sharp decreases in T_f after run 6 following $T_w = -3.5^{\circ}\text{C}$. There are other patterns as well: gradual shifts, sudden changes up or down, or no systematic changes. These variations complicate the definition of T_D and have to be born in mind when discussing the significance of that

Figure 4. Freezing temperatures in a sequence of runs (Exp. B) with increasing warm limit, T_w , after run 1 with $T_w = +10^\circ\text{C}$. Run 0 was started at room temperature. The 50% value is indicated by the square symbols and the vertical lines show the 5 and 95 percentile values.

Table 2. Percentage of drops with $T_f > -4.0^\circ\text{C}$ in Exp A, and $T_f > -5.5^\circ\text{C}$ in Exps. B and C after melting at different warm limits. There are large decreases in the percentages frozen for $T_w > -3.5^\circ\text{C}$ but non-zero values extend to warm limits well above that value.

Warm limit, $T_w =$	10.0°C	1.5°C	2.0°C	2.5°C	3.0°C	3.5°C	4.0°C	4.5°C	5.0°C	6.0°C	8.0°C	10.0°C

4.3 The effect of time duration samples are held at the warm limit

Data in the preceding section was produced with a 5-min holding period at the warm limit. Clearly it was of interest to test how shorter or longer exposures to temperatures above the melting point would effect the degree of PFN. This factor was tested, although only in one experiment (Exp. D), with the time at $+1.5^\circ\text{C}$ altered between 1 and 5 minutes. Two sequences were tested with an overnight gap between them.

In a sense, the 1-min holding time was also a test of whether incomplete melting may have led to subsequent freezing right at 0°C . Because of that, extra care was taken in the data reduction in this experiment to detect freezing of the drops as early

Figure 5. Freezing temperatures in a sequence of runs (Exp. C) with decreasing warm limit, T_w . The 50% is indicated by the square symbols and the vertical lines show the 10 and 90 percentile values.

as possible. Events were recorded starting at -2°C . No difference was found in that threshold between the 1 and 5 minute holding times. Results for the sequence of runs are shown in Fig. 7. The two repetitions are shown as one series.

200 Mean temperatures for the 6 runs were: -10.2 , -2.3 , -2.8 , -11.1 , -3.3 , -4.4°C . The large changes from room temperature to $T_w = +1.5^\circ\text{C}$ (runs 0 to 1 and runs 3 to 4) show a strong PFN effect. The difference between runs with 1 or 5 min at the warm limit is 0.5°C for the first pair and 1.1°C for the second pair. Small as these differences are, a test of the difference of means (Blank 1980; Section 20.4) show that they are statistically significant to better than 0.01%. This result shows that longer time in the liquid state, at T_w , tends to lower T_f^* , but, within the small range of times tested, PFN is exhibited nearly equally.

205 A better appreciation of the change with time exposure can be gained from looking at the frequency distributions of the changes in T_f , as shown in Fig. 8. Most of the changes are small in the first pair of runs (1 to 2) but are larger for the second set (4 to 5). There are positive as well as negative changes, the positive ones indicating a higher T_f after 5 minutes than after 1 minute at the warm limit. The 90% ranges were 0.6 to -2.5°C in the first pair and $+1.45$ to -6.0°C for the second pair. This type of scatter in the way T_f changes for individual drops is seen in all runs and will be examined further in the next section.

210 4.4 Variability and repeatability of nucleation temperatures with HgI_2

It has already been noted that there is considerable variation among drops in how they respond to the various sequences of PFN tests. Since that variability is a potential indication of what the underlying process is for the PFN phenomenon, some of

Figure 6. Freezing temperatures in Exp. A for run 0 and runs 1 to 10 for individual drops. Run 0 is the initial run, 1 to 10 are runs with controlled T_w values as shown in Table 1.

the manifestations of that variability are illustrated in the following, with focus on the sequences of T_f^* for individual drops. As detailed in Section 3.1, each drop was certain to contain a large number of particles of HgI_2 assuring good statistical equivalence from that point of view. Even so, there are considerable differences in freezing temperatures among drops. This makes it clear that the nucleation events in each drop are linked to rare particles or parts thereof.

In all of the following, repeatability refers to multiple nucleation events of a drop within a range of ≈ 1 to 2°C . Such repeatability is, of course, significant only when it is in contrast with a much larger range of freezing temperatures for the full sample set of drops.

220 4.4.1 Run to run correlations

In the current experiments, run-to-run correlations of freezing temperatures can not be meaningfully evaluated for experiments with strong PFN, and hence a small range of T_f^* values, since the range of freezing temperatures in these runs is only about twice the precision of the temperature data. Only for runs with higher warm limits or with reasonably large spreads in freezing temperatures is this analysis possible. For selected pairs of runs, correlation coefficients are given in Table 3. These correlation coefficients are generally weak. Highest values are for Exp. C, probably because of the relatively flat spectrum for this experiment (cf.

Figure 7. Freezing temperatures in a sequence of runs with 1 and 5 minute holding times at $T_w = +1.5^\circ\text{C}$. The 50 percentile is indicated by symbols and the vertical lines show the 5 and 95 percentile values.

Figure 8. Histograms of the changes in the freezing temperatures of drops between runs with 1 and 5 minutes at $T_w = +1.5^\circ\text{C}$.

Fig. 2). Exp. I (to be described in Section 4.4.2) is included in this table for completeness; runs 0 to 5 were with $T_w = 10^\circ\text{C}$ and runs 6 to 10 with $T_w = 1.5^\circ\text{C}$.

In addition to the correlations, individual drop histories are a revealing way to examine the variability, or repeatability, of freezing temperatures. The "spiderweb" diagram in Fig. 9 shows sequences of freezing temperatures for individual drops in

Table 3. Correlation coefficients for selected pairs of runs. Values with an asterisk are for runs involving PFN.

Runs	0-1	1-2	2-3	3-4	4-5	5-6	6-7	7-8	8-9	9-10
Exp A							0.45*	0.45*	0.18*	0.52
Exp B	0.49					0.59				
Exp C	0.74	0.85	0.93	0.92	0.70					
Exp I	0.39	0.48	0.65	0.58	0.66		0.62*	0.69*	0.61*	0.44*

230 Exp. A. The spread of T_f values in the initial run is also represented in the spectra shown in Fig. 2. The rise in T_f^* after $T_w = +1.5^\circ\text{C}$ brings all drops to a narrow range. That range starts to spread, with smaller and larger excursions, in subsequent runs. Beyond $T_w = +3^\circ\text{C}$ large positive and large negative changes are evident. In the region between $T_w = +3.5$ and $+6^\circ\text{C}$, some drops retain freezing temperatures near the highest values while others drop to lower values. Some of these latter ones return to high T_f in subsequent runs.

235 To illustrate the degree of variation in the changes in freezing temperatures, frequency distributions of these changes are shown in Fig. 10 for the four runs where the relaxation of PFN begins. Changes of the mean temperatures were -0.42 , -0.27 , -3.9 and -0.13°C . Gradually increasing spread is seen as well as a shift to negative values for the pair $T_w = +3.5$ to $+4.0^\circ\text{C}$. This histogram reflects the significant losses in pre-activation for the increase in T_w . Changes remain centered on 0 for the last pair, $T_w = +4.0$ to $+4.5^\circ\text{C}$, but with changes of up to $\pm 10^\circ\text{C}$ in magnitude.

Figure 11. "Spiderweb" diagram of individual drop histories for the sequence of runs with increasing warm limits in Exp. B. A statistical representation of these observations is given in Fig. 4.

240 Spiderweb diagrams are shown in Fig. 11 and Fig. 12 for Exp. B and Exp. C. The overall pattern of high PFN is evident for $T_w \leq +3^\circ\text{C}$ in both cases. The large variability in freezing temperatures from run to run for given drops is also evident in both cases. An extreme example is seen in Fig. 11 (Exp. B) with one drop falling to a low T_f for $T_w = +2$ and $+3^\circ\text{C}$. There is a similar, smaller magnitude event for two drops at $T_w = +3^\circ\text{C}$ in Fig. 9 but with the high PFN regained after a low freezing temperature. The evidence points to the possibility that PFN may be regained after a new cycle of freezing and heating to above
 245 0°C even after a previous cycle in which there was less, or no enhancement.

Figure 12. "Spiderweb" diagram of individual drop histories for the sequence of runs with decreasing warm limits in Exp. C. A statistical representation of these observations is given in Fig. 5.

4.4.2 Sequence of runs with high and low values of the warm limit

Perhaps the best data set for examining the repeatability of the nucleation events is the series of runs (Exp. I) in which a warm limit well above the transition value, $T_{w,1...5} = +10^{\circ}\text{C}$ was repeated for 5 runs, followed by 5 runs with $T_{w,6...10} = +1.5^{\circ}\text{C}$. The observed ranges of freezing temperatures are shown in Fig. 13 in the format used for other experiments.

250 The difference between the two halves of the experiment stands out quite clearly. The difference for the two different warm limits is $\overline{T_{f,6...10}^*} - \overline{T_{f,1...5}^*} = (-4.6) - (-8.9) = 4.3^{\circ}\text{C}$. This increase with PFN is less than the corresponding change of 10.5°C in Exp. A (Section 4.2), probably because the initial activity was already higher than in that experiment (cf. Fig. 2).

Gradual decreases with time are evident in the mean freezing temperatures. For the first 5 runs this is -0.3°C per run; for the last 5 runs it is -0.08°C per run. Decreases for individual drops have considerable spreads: the 10 to 90-percentile
 255 values for the run-to-run changes are -2.3 and $+1.7^{\circ}\text{C}$ for the runs with $T_w = +10^{\circ}\text{C}$, and -2.0 and $+1.9$ for the runs following $T_w = +1.5^{\circ}\text{C}$.

Data from this experiment lends itself well to examining the correlation between pairs of runs because there is a reasonably large spread in T_f^* for the $T_w = +1.5^{\circ}\text{C}$ runs. Correlation coefficients for successive pairs of these runs are 0.62, 0.69, 0.61 and 0.44. The values for $T_w = +10^{\circ}\text{C}$ are 0.48, 0.65, 0.58 and 0.66. These latter values are comparable to those observed in
 260 Exp. A and B, but are lower than those seen in Exp. C (cf. Table 3).

A full appreciation of the great variety in the way freezing temperatures of different drops change from run to run is best gained from a display of freezing temperatures for each drop in Fig. 14. As a first observation, it can be noted that in spite of the large difference in $\overline{T_f^*}$ between the two halves of the sequence, some drops show very little discernible PFN. Examples of this are

Figure 13. Range of freezing temperatures in Exp. I consisting of a sequence of runs with high and low warm limits. The 50 percentile is indicated by symbols and the vertical lines show the 10 and 90 percentile values.

265 drops 1, 36, 43, and 66. On the other hand, 36 out of the 68 drops have $\overline{T}_f > -4^\circ\text{C}$ for $T_w = +1.5^\circ\text{C}$ while there are none for the runs with the higher T_w .

270 A considerable variety of patterns can be discerned in the sequences. Many sequences contain irregular jumps, but in many more some regular patterns can be seen. Monotonic increases and decreases exist over three or four runs, perhaps with gaps. Some sequences appear to be arcs. The lack of a uniform response for all drops poses a major quandary for explaining the results. Quantitating these patterns and distinguishing between random variations and perceived patterns are evidently not easy and, due to the small number of runs, one can expect the strength of any test be limited. Nonetheless, these signatures, and similar ones seen in all other experiments, are the only available indicators of the stability, or lack of, of nucleating sites. The following analyses are directed to this aim.

275 The meaning of run-to-run correlations (cf. Table 3) with r values near 0.6 for this experiment is somewhat ambiguous in itself. A stronger signal emerges in comparison with randomized freezing temperatures. Randomization tests were performed by re-ordering the observed freezing temperatures of drops according to a sequence created by placing random numbers in an increasing order. For Exp I. the T_f values were scrambled for runs 2, 3, 4, 5 from the first group and for runs 7,8,9, and 10 from the second group (cf. Fig. 13), for comparisons with runs 1 and 6 respectively. The correlation coefficients using these scrambled runs dropped to between -0.2 and +0.1 for both the +10 and +1.5°C runs. On this basis, the actual correlation coefficients near $r = 0.6$ acquire significance as indications of repeatability. This seems to hold for freezing with or without PFN.

280

Figure 14. Freezing temperatures of 68 drops in Exp. I. The first 5 points (square symbols) in each panel are for runs 1...5 with $T_w = +10^\circ\text{C}$ and the last 5 points (diamond symbols) for runs 6...10 with $T_w = +1.5^\circ\text{C}$.

Another characterization of the individual drop sequences was made by fitting linear equations to the 5 points corresponding to each of the two warm limits. The means of the slopes of these lines are -0.33 and -0.13 for the two groups but with considerable scatter about the mean; standard deviations are 0.64 and 0.65 for the two groups. As a measure of the degree of scatter in T_f , the mean of the absolute deviations ("absdev" for short) from the fitted lines was determined for each warm limit and each drop. The mean values of these parameters are $\overline{absdev}_{10} = 0.74^\circ\text{C}$ and $\overline{absdev}_{1.5} = 0.68^\circ\text{C}$. The values for $T_w = +1.5^\circ\text{C}$ have clear temperature dependence ranging from 0.35 for drops with $\overline{T_f} > -4^\circ\text{C}$ to 1.4 for drops with $\overline{T_f} < -6^\circ\text{C}$.

The means and standard deviations of *absdev* for the two groups are $0.74/0.39$ and $0.68/0.61$. After randomization these values became $1.13/0.56$ and $1.14/0.6$. Lesser scatter for the actual data than in the randomized runs reinforce the indication of non-random patterns in T_f .

290 **4.4.3 Alternately high and low warm limits**

Data in the preceding section provide some evidence that freezing temperatures of some drops remain fairly constant in repeated cycles with $T_w = +1.5^\circ\text{C}$. Also, some drops showed a return to high T_f^* after a much lower one in an intermediate run (cf. Section 4.2). To further examine this, two experiments (Exp. G and H) were carried out with alternate cycles of $T_w = +1.5^\circ\text{C}$ and $T_w = +10^\circ\text{C}$. Observed ranges of freezing temperatures for four repetitions of the cycle are shown for Exp. H in Fig. 15.

295 The results for Exp. G were similar.

Figure 15. Freezing temperatures in a sequence of runs (Exp. H) with alternating high and low warm limits, T_w . The 50 percentile is indicated by the symbols and the vertical lines show the 5 and 95 percentile values.

The average difference for all four pairs of +10 and +1.5 runs in Exp. H is only 1.4°C . The difference is statistically meaningful to better than 1% significance level according to a test of differences of means (Blank 1980; Section 20.4). The largest difference of means is 2.0°C for the second pair of runs. These are clear, but smaller signatures of PFN than seen in other experiments. For individual drops, the 90% range of changes is -0.40 to $+3.15^\circ\text{C}$; 90% of the drops showed positive changes. Changes in T_f^* between one run and the next with the same $T_w = +1.5^\circ\text{C}$ are spread over a range of $\pm 7.3^\circ\text{C}$. This large variability is different from the comparable value of $\pm 2^\circ\text{C}$ for Exp. I (Section 4.4.2).

The large variability notwithstanding, even this series has some examples of patterns of repetition for individual drops as shown for 6 cases in Fig. 16. There are indications for freezing temperatures to repeat or to change in systematic ways. It is noteworthy that the patterns of changes for the two sets of T_w appear to be independent of one another. A set of traces for drops from Exp. G are shown in Fig. 17. Similar patterns of changes are seen here again showing persistence in T_f^* in spite of intermediate cycles with a T_w above the value for retaining PFN.

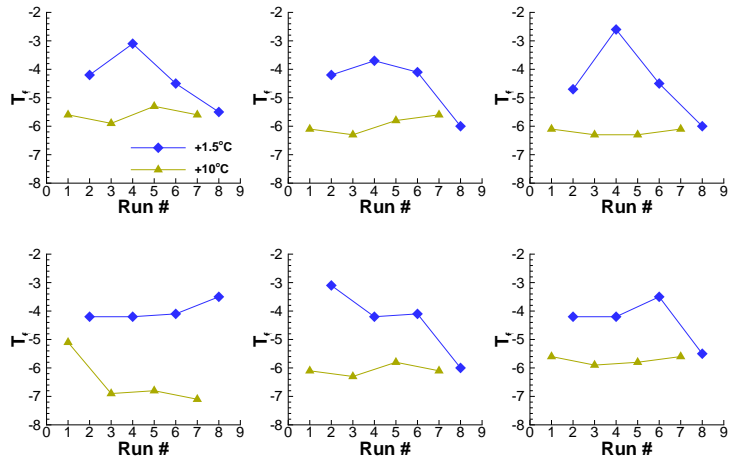

Figure 16. Sequences of freezing temperatures for drop numbers 67, 68, 73, 77, 90 and 96 in Exp. H.

Figure 17. Sequences of freezing temperatures for drop numbers 44, 48, 53, 55, 58, 65, 66, 69 and 81 in Exp. G.

Table 4. Comparison of the average freezing temperatures \overline{T}_f^* in runs $i + 1$, $i + 2$ $i + 3$ for the n_f drops frozen with $T_f^* > -4^\circ\text{C}$ in run i , against the n_{uf} drops that froze below that limit. The comparison is given for four different values of T_w . Bold font indicates differences exceeding 2°C .

T_w in run i		$i + 1$	$i + 2$	$i + 3$
$T_w=+3.0$	$n_f=66$	-3.8	-7.4	-7.6
	$n_{uf}=11$	-3.8	-9.6	-9.7
$T_w=+3.5$	$n_f=62$	-7.2	-7.3	-9.6
	$n_{uf}=15$	-9.9	-10.4	-11.6
$T_w=+4.0$	$n_f=14$	-7.3	-8.4	-12.8
	$n_{uf}=63$	-8.0	-10.3	-12.5
$T_w=+4.5$	$n_f=19$	-7.7	-11.6	-12.6
	$n_{uf}=58$	-10.7	-12.9	-13.9

4.4.4 Other tests of repeatability

In the search for evidence of repeatability, a test was developed that provided a measure of how subsequent T_f values for drops with $T_f^* > -4^\circ\text{C}$ in a given run compared to those with $T_f^* \leq -4^\circ\text{C}$. The results, for Exp. A (gradually increasing warm limits), are shown in Table 4. It is seen that, drops frozen with $T_f^* > -4^\circ\text{C}$ in any of the runs had higher freezing temperatures in subsequent runs. This holds for all but one of the pairs of runs. Examples of the more pronounced differences are shown in bold font in the table. With this test having sufficiently large numbers of drops in each category, the test results are good indications of real differences. The level of significance of the differences was not evaluated because the differences are quite emphatic and point in the same direction as the other tests of repeatability. The pattern holds even as T_w is raised. Furthermore, the difference persists at least for two subsequent runs.

As mentioned in Section 4.4.3, there appears to be no clear relationship between the nucleation temperature with or without pre-activation. This finding is further examined for runs 5 to 6 in Exp. I (Section 4.4.2) and for averages of the two groups of runs in the same experiment. For both of these, the correlation coefficient is 0.3 and the corresponding scattergrams reveal that a few outliers have a strong effect. Random mixing of the values of the second of the pairs of runs leads to smaller r values. It takes about 50 re-randomizations of the second run to get one of them to yield an r value near the observed one. These tests confirm the lack of correspondence between T_f and T_f^* for any given drop.

The same point can be made by looking at the magnitude of the $(T_f - T_f^*)$ difference drop by drop. While the mean value of the change from $T_w = +10^\circ\text{C}$ to $T_w = +1.5^\circ\text{C}$ is 4.6°C the 90% range for individual drops is $(\overline{T}_f)_{+10} - (\overline{T}_f^*)_{+1.5} = -0.4 \rightarrow 7.3^\circ\text{C}$. The change from the last $+10^\circ\text{C}$ run to the first $+1.5^\circ\text{C}$ run ranges from 0.1 to 9.3°C . In this case, the large variation isn't entirely due to the bunching of freezing temperatures at the lower warm limit, as seen in Fig. 13 with the vertical bars.

5 Discussion and conclusions

To reiterate the title of the paper, it is emphasized that the data presented is exploratory, not firm. Two reasons contribute to this. One relates to the methodology of the experiments: lack of knowledge of the amount of HgI_2 remaining in suspension, no information of the size distribution of the particles in the sample drops, and the absence of a fixed time frame between sample preparation and testing. The other is the surprising complexity of the results obtained. It may be that the latter is a consequence of the former, but the evidence points to that not being the main reason. Bearing these points in mind, the discussion to follow, as the experiments themselves, is focused on two aspects: defining basic characteristics of the PFN phenomenon, and providing some constraints for potential explanations. The experimental evidence is first compared with the results of EEZ70, then the results obtained with the multiplicity of samples and diverse set of experiments are summarized. Finally, the implications of the results are explored in view of various theories.

5.1 INP derived from HgI_2

In the current experiments, the HgI_2 suspensions were tested in identical fashion to other materials in previous work (e.g. Vali, 2008), thus the initial runs in each series is directly comparable to what has been found for other INPs. Similarly to other materials, the activity of INPs exhibits a spread over a range of temperatures with the number of INPs generally increasing with decreasing temperature. This is expressed quantitatively with the nucleus spectra shown in Fig. 2. The HgI_2 concentration of 20 or 40 g L^{-1} was selected to yield freezing events at temperatures $> -20^\circ\text{C}$. The spectra exhibit some minor peaks but are not consistent for all the experiments. The general trend of the spectra, as expressed by the slope of the logarithm of the cumulative concentration is in the range $\omega = 0.3\dots 0.5$. This is comparable with the range of values in Fig. 2(b) and Table 1 of Vali (2014). From this perspective there is nothing unusual regarding the INP activity of HgI_2 . Somewhat unexpectedly, the magnitude of the variation in INP concentration seen in this graph exceeds what would result from the factor 2 variation in the amount of HgI_2 added. It is unknown to what extent this was due to alterations of the stored powder or variations in sample preparation. Light sensitivity, different degrees of clumping and different degrees of settling in the water are potential factors. Since the samples proved to be stable on the time scale of the tests (after the suspension was dispersed as drops), and since the main focus was on the sequences of runs not on comparisons among runs, the sample variability was not very important. The only evidence contrary to stability of INP activity in the sample drops is the gradual loss over the first 6 runs in Fig. 13.

It is likely that the variability of HgI_2 as INP is related in some way to the relatively low run-to-run correlations (Section 4.4.1) and to drop to drop variations in PFN. No hints were found in this work as to what the underlying cause might be.

5.2 Limiting conditions for PFN.

Our findings regarding the upper temperature limit that PFN can survive are close to those of EEZ70³ but indicate that the notion can be broadened. EEZ70 concluded that there is a definite upper limit at $T_D = +3^\circ\text{C}$ (shown in Fig. 1). Data here

³EEZ70 contains results with HgI_2 and various other substances. In this work only HgI_2 was tested.

presented show that the maximum temperature above the melting point permitting PFN to remain possible is not sharp. As described in Section 4.2, a major loss of PFN is found near $T_w \approx +3.5^\circ\text{C}$ but some PFN can be found even after heating to $T_w \approx +5^\circ\text{C}$. This change from a fixed value to a gradual limit indicates that the upper temperature limit is not like a melting point, as argued in EEZ70, but is dependent on specific configurations of critical factors in either the substrate or in bound molecular clusters.

The fraction of sample drops exhibiting PFN as the warm limit is increased is given in Table 2. The transition from 100% to 10% for Exp. A extends from $T_w = +2$ to near $+5^\circ\text{C}$. An important distinction regarding what to consider the limit for PFN is that variations within a temperature range of several degrees are not limited to drop-to-drop differences which might be associated with the variations in the size or number of HgI_2 particles in different drops. Some fluctuations are also exhibited on repeated freezing cycles by single drops with fixed INP content. This is quite clearly seen in the many lines crossing back and forth in the transition region in Figs. 9, 11, and 12 and in Fig. 6.

The second point demonstrated by the data is that the duration of exposure to T_w has an impact. Longer times reduce the degree of PFN observed. This finding can't be compared with the EEZ70 results as no time scale was specified in their paper.

The third point to emphasize concerns the dependence of PFN on the degree of prior cooling necessary. EEZ70 quotes a minimum of $T_C = -20^\circ\text{C}$ for PFN to occur. The experiments here described did not specifically test this assertion, but a contradiction is evidenced in that the lowest temperature reached in some tests was considerably higher. In Exp. D (Fig. 7), Exp. I (Fig. 13) and Exp. H (Fig. 15) cooling proceeded to only about -16°C and PFN was nonetheless observed. Also, many drops were already frozen at much higher temperature than the final values in a run, so that later changes in water structure near the INP surface were precluded. This observation rules out the formation of a 2-D ice layer at some specific temperature as hypothesized in EEZ70.

Finally, how close to 0°C PFN will take place was not well defined in this work, because the detection limit for freezing events was near -2°C . However, the data presented here contradict EEZ70 in that PFN doesn't always occur close to 0°C . In these data, there is a large range of temperatures over which PFN is exhibited. If we take the temperature at which $<5\%$ of the samples were frozen in the initial run and at which 95% was frozen after activation to define the lower limit for PFN, the values obtained are -5°C in Exp. A (Fig. 3), near -8°C for Exp. B. (Fig. 4) and near -7°C for Exp. I (Fig. 13). It is clear from these graphs that as T_w increases greater degree of supercooling is required for subsequent T_f^* . Based on this, it is fair to consider $T_f^* \approx -6^\circ\text{C}$ as a lower limit for PFN on HgI_2 INPs in these experiments. This lower limit for what to consider PFN is not a measure of the general range of effectiveness of PFN, but is due to the presence of nucleating sites effective below that temperature even without pre-activation.

Based on the foregoing, the approximate boundaries for PFN in these experiments fell between -2°C and -6°C . However, the variability of the upper boundary is clearly seen in the bar diagrams of Figs. 3, 4, and 5. Also, the lower boundary, the separation between what is PFN and what is due to unaffected INPs, is somewhat arbitrary as described in the preceding paragraph.

The experiments of SS01 with aliphatic alcohol layers as ice nucleators can't be directly compared with those for HgI_2 . However, there are qualitative agreements on all aspects of pre-activation. Their results confirm the existence of a warm

temperature limit for PFN to occur: they give the warm limit $T_D = +27.5 \pm 2.5^\circ\text{C}$ and for pentacosanol (C25) $T_D = +35 \pm 2.5^\circ\text{C}$. The tolerances attached to the values reflect the fact that the loss of PFN is gradual near T_D . This is in accord with the findings presented. There is no mention in SS01 of the need to reach T_C and they also show a large spread in T_f^* . Results in
395 SS01 show an even stronger difference from the EEZ70 claim for freezing near 0°C after pre-activation. For the most active aliphatic alcohol nucleant, SS01 report no freezing events with $T_f^* > -5^\circ\text{C}$ and mean values near $\overline{T_f^*} > -8^\circ\text{C}$.

5.3 Repeatability of PFN

Repeatability, or stability, of observed freezing temperatures under various conditions is a useful means for considering what are the possible mechanisms responsible for the PFN and to examine the potential roles of nucleation sites.

400 One reasonably firm result from these experiments is that, for single drops, there is no relationship between the freezing temperature T_f on first freezing, or with $T_w > +8^\circ\text{C}$, and T_f^* with pre-activation. This suggests that the pre-activation observed in these experiments is not an enhancement of the ability of a given site to nucleate ice, but that different sites are responsible for the nucleation with or without pre-activation.

The correlation coefficients shown in Table 3 provide one measure of the stability of sites. The majority of the correlation
405 coefficients are in the range $r = 0.5 \dots 0.9$. These values are lower than the values reported in Vali (2008) for soil suspensions and for distilled water. However, the randomization tests in Section 4.4 showed that the observed r values are significantly larger than would be expected for random rearrangement of the INPs among the drops.

A more focussed discussion about repeatability relies on examinations of the sequences of freezing temperatures of individual drops taken from the same sample and exposed to the same temperature histories. As mentioned in Section 3.1 there was
410 no control over the number of HgI_2 particles per drop, but that number was almost certainly large enough ($\approx 10^{11}$) to consider any observed freezing event to be unique, beyond particle number effects, and the repeatability of freezing events in subsequent cycles to be indicative of the stability of the INP responsible for the event.

Figs. 14, 16, 17 and in the "spiderweb" diagrams in Figs. 9, 11 and 12 are graphic representation of the drop histories. These diagrams show complex patterns. The presence of horizontal segments in the figures, limited as they are, can be taken as an
415 indication for repeatability. These steady segments fall within ranges of 1 to 2°C . The presence of sudden changes or drifts can be interpreted as variations superimposed on permanence. The sample sizes here available demonstrate how varied drop histories can be, but much larger sample sizes would be needed to make statistical analyses of the various patterns.

Results shown in SS01 for many repetitions of the freeze cycle for a single drop indicate an approximately 4°C random spread of T_f^* over 140 repetitions. Roughly the same spread was associated with each T_w and even for $T_w > T_D$. The spread
420 was also about the same for the three different aliphatic alcohols.

The question of repeatability and stability of nucleation sites is a question beyond the pre-activation phenomenon. The relative frequency of near-constant freezing temperatures versus variable ones, pre-determined versus random events, lies at the heart of the debate about nucleating sites. A thorough discussion of the matter is beyond the scope of this paper. Just two comments follow.

425 To put the current data in perspective, a "spiderweb" is included for a soil sample in Fig. 18. Other data for this sample has been given in Vali (2008). The prevalence of roughly horizontal trend lines in this diagram is an indication of a fair degree of repeatability, greater than is seen for HgI_2 with or without PFN. The median correlation coefficient for pairs taken from these 20 runs is 0.92; the 90% range is $r = 0.6 \rightarrow 0.96$. Sudden changes as well as minor ups and downs are also evident in this spiderweb

430 Kaufmann et al. (2017) performed refreeze experiments with single drops in a differential scanning calorimeter. The observed sequences of freezing temperatures show a mixture of steady values, sudden changes and gradual drifts, overall appearing similar to those found in this work and in Vali (2008). They focused on interpretations of the relatively steady repetitions in terms of CNT implicitly acknowledging that these segments evidence a degree of stability of sites. Interpretation as random sites on uniform surfaces is discarded. Alterations of the sites are seen as the cause of the non-steady segments of the sequences.

435 Form these comparisons, it seems warranted to focus on the role of sites in PFN much the same way as for freezing nucleation in general. Sites may be thought of in a general sense as specific features on the substrate surface, with more or less permanence depending on their particular configuration.

Figure 18. "Spiderweb" diagram of freezing temperatures of 20 drops of a soil suspension in 20 runs from a subset of data in Vali (2008).

5.4 Explanations of PFN

A summary of the empirical evidence for PFN and other pre-activation effects, and some of the explanations offered for them, has been given in Section 2. Explanations, in general and for PFN in particular, center on two broad alternatives: special surface features, or ice-like layers at the particle/water interface. For PFN, special features on the substrate such as cavities, cracks, etc. are considered to retain some of the solid phase past the bulk melting point (Turnbull, 1950). Arguments supporting the role of cavities are based on examinations of the thermodynamic conditions for phase stability of confined water or ice. This notion has been considerably elaborated for pore condensation and freezing, PCF, by Marcolli, 2020. Alternatively, PFN is considered to arise via the formation of an adsorbed ice-like layer enabling PFN to take place past a greatly reduced energy barrier (e.g.

Mason 1950, 1956, Mason and Maybank 1958). A solid 2-D ice layer was suggested by EEZ70. Support for the role of ice-like layers was found by EEZ70 in the independence of T_D on pressure or on the presence of dissolved salts. SS01 found support for the ice-like layer explanation in the shift to lower freezing temperatures with increasing chain length of the alcohol layer without much change in the range of values.

450 The results here presented offer some input for weighing possible theoretical explanations. The 2-D phase transformation explanation of EEZ70 is discounted by the arguments given in Section 5.2. To reconcile the repeatability here described with the adsorbed ice-like layer explanation, that theory would have to be altered to include the possibility of variations of some characteristic of the layer from one INP to the other. In an abstract sense, this could be occurring via variations in the thickness, size, or completeness of the ice-like layer. For example, it could be assumed that the layer is more like a patch than an extended
455 layer. The size of the patch then can be assumed to be influenced by some underlying feature of the substrate. In this way, the patch becomes an extension of a site thus melding the points of view. Furthermore, the explanation has to be confronted with the evidence that there is no relationship between the initial nucleation temperature of a site and the pre-activated nucleation temperature, as shown in Section 5.3. In answer to that, it is not difficult to imagine that ice-like patches would form on different surface features than the ones leading to nucleation without pre-activation. The difference between temperatures T_f and T_f^* is
460 in itself an indication that different sizes of ice-binding locations are involved. The spread in observed upper limits T_D could also be a consequence of different size patches melting at different temperatures. This is clearly a heuristic solution and is given here as an example of the type of model that would have to be developed to account for the known characteristics of PFN with ice-like layers playing a role.

While finding support for the ice-like layer model, SS01 also raise the possibility of pre-activation arising via changes in the
465 Langmuir layer of the aliphatic alcohol. They describe this as "... a metastable conformation of the alcohol layer itself ... the freezing process induces a phase transition of the alcohol film". Furthermore, "... based on the known chain length dependence of two-dimensional melting temperatures for fatty acid monolayers, it is not unreasonable that the increase which we observe in T_D with chain length could in fact be related to a structural change of the Langmuir film". However, as argued in the preceding paragraph, the modification of the alcohol film would also have to be thought of as having different "patch sizes" or other
470 characteristics differing from drop to drop and having some degree of stability.

The idea expressed in the foregoing paragraph can perhaps be extended to thinking about PFN on HgI_2 too as some modification of the substrate surface. The fact that HgI_2 is said to be a soft substance helps such thinking. More directly, the weaker correlations found for HgI_2 for runs without pre-activation, in comparison with mineral nucleants, also indicate some "softness" or malleability of the substrate on the scale of ice embryos. The large changes observed from one cycle to the next,
475 both with and without pre-activation, further encourage thinking about changes on the substrate itself between cycles. Most importantly, since PFN follows a prior freezing event, it is quite conceivable that some favorable site is created on the surface by the mechanical and thermal stresses associated with freezing.

In reality, the line is blurred between considering surface sites, or ice-like patches of specific character, to explain PFN. SS01 also came to the conclusion that a "... complete explanation of the pre-activation mechanism will treat the monolayer and

480 the vicinal water as a strongly interacting system.” (Monolayer in this sentence refers to the alcohol covering of the drop that serves as the nucleant.)

It is also important to consider the reverse of repeatability, namely the degree of variability observed in much of the data. First of all, molecular fluctuation of water molecules associated with embryo formation are an inescapable part of nucleation and this leads to some random variability of the nucleation temperature. Additional factors relate to the fragility of the structures making up the sites. For PFN, it is clear that the structure may have undergone some change by the previous formation of ice on it, and this modified structure is likely to be less rigid than what are normally considered potential sites. The fragility of PFN structures on HgI_2 is perhaps pre-conditioned by the relatively weak permanence of sites on the HgI_2 surface in comparison with other materials. The low values of the correlation coefficients given in Table 3 for runs without PFN underscores this possibility.

490 5.5 Broader context

The results presented here will, hopefully be re-examined in future tests. The two conflicting aspects - the evidence for sites and their paucity and fragility - are challenging aspects to study. The range of warm limit conditions which lead to only partial PFN (not all drops freeze at the same temperature) may be a specially fruitful situation to study. Experiments with other materials exhibiting PFN would be useful.

495 The abundance of mercuric iodide in the atmosphere is not known. Atmospheric concentrations of mercury, of its compounds, and the reactions connecting these, as well as the surface sources and removal processes have been subjects of study for decades. Schroeder and Munthe (1998) and Lyman et al. (2020) present overviews of the physical, chemical and toxicological properties of mercury in various forms. No mention is made of mercuric iodide in these papers indicating that it has no known importance in atmospheric processes. Neither have numerous physical and chemical analyses of atmospheric ice nucleating particles (INPs) over the years reveal mercuric iodide to be a significant component.

500 In addition to mercuric iodide, PFN was observed by EEZ for lead iodide, gypsum, cadmium iodide, muscovite, L-asparagine, L-aspartic acid and p-benzyl phenol. The absence of PFN was reported for graphite, chlorite, silica gel and a number of other inorganic materials. Evans (1967) reported PFN on phloroglucinol dihydrate. These findings were not stated to be the results of any exhaustive search for materials that would exhibit PFN, so it is reasonable to assume that further research will reveal PFN associated with yet more substances. The detailed character of PFN for the substances listed above, and for others yet to be identified, will have to be determined in future research. On the basis that the general features identified for PFN on mercuric iodide are in concert with other evidence for ice nucleation in the immersion mode, it is reasonable to think that similar results will eventually be found for most other substances.

510 Since pre-activation is a sequence of exposures to different temperatures, atmospheric impact of the process will also depend on the occurrence of such sequences in clouds. Vertical circulation of parcels in clouds is well known to occur in deep convection and in extended layer clouds. For the PFN activity observed in these tests, circulations would have to extend over a km or more in the vertical. In any event, the initiation of freezing at temperatures slightly below the melting point is of great importance for clouds and for many biological and environmental systems. It is also of great interest for artificial snow

making, tissue preservation and more. In those controlled situations pre-activation may be a method for greatly increasing the efficacy of INPs. Overall, PFN may have to be considered as a potential pathway for natural and induced freezing at minimal supercooling.

From the point of view of nucleation basics, the results presented in this paper underscore the need for more fundamental understanding of what surface structures constitute nucleation sites, how stable they are, and what influences are exerted by time, temperature and other factors. In that sense, PFN is an aspect of ice nucleation that presents further options to characterize the process.

6 Conclusions

As already indicated in the title of this paper, instrumental and procedural limitations cause the work described here to be considered exploratory. While the conclusions given below are consistent with the data presented, and are supported by comparisons with previous work in EEZ70 and SS01, various caveats had to be attached to them.

1. Pre-activated ice nucleation, PFN, on HgI_2 , as reported in EEZ70 and as schematically depicted in Fig.1, was confirmed. PFN leads to freezing at temperatures much higher than would otherwise occur with the same substance.
2. PFN was observed in these experiments at $T_f^* \leq -2^\circ\text{C}$. The possibility of PFN at smaller degrees of supercooling, $0^\circ\text{C} > T_f^* > -2^\circ\text{C}$, is not ruled out. PFN is exhibited over a temperature range extending at least to -6°C ; it became indistinguishable, under the conditions of these experiments, from nucleation without pre-activation .
3. PFN can be detected after a limited degree of warming above the melting point. Raising the degree of heating leads to a gradual lowering of the subsequent nucleation temperatures T_f^* . Significant lowering of T_f^* was found at approximately $+3.5^\circ\text{C}$, but PFN is still clearly evident after heating to $+5^\circ\text{C}$ and above. This gradual loss of PFN effectiveness is contrary to the total loss at a fixed temperature that was reported in EEZ70. Superimposed on the general pattern of loss of PFN activity, considerable variation was found for individual INPs contained in separate drops.
4. There is no support in these experiments for the existence of a minimum temperature to which a sample has to be cooled for PFN to be exhibited. Freezing and limited warming are sufficient conditions.
5. No relationship was found between the initial nucleation temperature T_f of a given drop and its nucleation temperature T_f^* after pre-activation. This raises the possibility that different particles or different parts of particle surfaces are involved in the two cases.
6. Repeatability, as defined at the beginning of Section 4, is supported to a limited degree. Much of the data show a lack of repeatability of PFN, but the cases that do show repeatability are unequivocal in pointing to the role of definite structures (sites) in promoting nucleation. In all, indications are for the role of definable features as sites for nucleation, but that these features are fragile, easily modified, or fully destroyed by the freezing event itself or in the liquid during the subsequent cycle of heating and cooling.

- 545 7. HgI_2 is a relatively poor source of INPs and some unexplained variations were found in INP concentration per unit mass during the course of these experiments. These variations had negligible impact on the results regarding PFN but may be related to the lower degree of stability of sites than is observed for some other materials.
8. Results similar to those here reported have been reported in the literature for a number of other materials. PFN may thus be assumed to be possible with a wider range of materials than hitherto known. PFN may have important – yet unknown
- 550 – contributions to atmospheric and other processes. PFN may have applications in the deliberate initiation of freezing in clouds, in tissue and food preservation and other situations.

Table 5. Nomenclature.

CNT	Classical nucleation theory
INP	Ice nucleating particle, as defined in Vali et al. (2015)
PFN	Pre-activated freezing nucleation
$k(T)$	Differential concentration of INPs; $\text{cm}^{-3} \text{ } ^\circ\text{C}^{-1}$
n_{uf}	Number of unfrozen drops during a cooling cycle
ω	Slope of freezing rate, as defined in equation (7) in Vali (2014): $\omega = -d(\ln R)/dT$
r	Correlation coefficient
T	Temperature; $^\circ\text{C}$
T_f	Observed temperature of freezing of a drop, or as a general reference to nucleation temperature; $^\circ\text{C}$
T_f^*	Observed freezing temperature of a drop with pre-activation; $^\circ\text{C}$
T_w	Temperature to which the sample is heated between runs; the "warm limit"; $^\circ\text{C}$
$T_{w,i}$	Temperature to which the sample is heated before run i ; $^\circ\text{C}$
T_C	Defined in EEZ70 as the temperature to which a sample has to be cooled for PFN to be manifested; $^\circ\text{C}$
T_D	Limiting value for T_w for retaining PFN; $^\circ\text{C}$
V	Drop volume ($=0.01 \text{ cm}^{-3}$ in the experiments here described)

Data availability. Raw data can be made available by the author. It will also be placed in a repository before final publication.

Author contributions. All the work reported here was done by the author.

Competing interests. The author declares that there is no competing interest.

555 *Acknowledgements.* Financial support for the work was provided by the U.S. Bureau of Reclamation via contracts with the University of Wyoming. Thanks are due to Dr. Donald L. Veal (†) for supporting this research in many ways. The contributions of laboratory assistants in carrying out the experiments and in data reduction is much appreciated.
